The usual practice for armored compression cable is to anchor the joints; however, it was felt that if the armor were eliminated, and the three conductors cabled with a comparatively short lay, the longitudinal movement would be restrained without undue stress on the cable or joints. The following is a brief account of the tests designed to measure the magnitude of such restraining forces.

The three conductors of a 50-foot section of 600,000-circular-mil unarmored compression cable were cabled to a six-foot lay, but not bound together, and then pulled into a six-inch inside diameter iron pipe of the same length. At one end the cable was anchored to the pipe, at the other end means were provided for applying and measuring a restraining force of such magnitude as to prevent any movement of the cable with respect to the pipe end. The cable was heated by circulating current in the conductors. Thermal equilibrium was reached with conductor, sheath, pipe, and ambient air temperatures of 83, 67, 43 and 23 degrees centigrade, respectively. The maximum restraining force required to prevent longitudinal movement during the thermal transition period was 475 pounds, which dropped to 350 pounds when the steady-state temperatures were reached.

In view of the very small forces developed by the cabled conductors, a similar test was made on the same type of cable, in which the conductors were not cabled or bound together in any manner. The final restraining force was 3,000 pounds, with a maximum of 3,500 pounds reached during the transition period, for a final conductor temperature rise of 66 degrees centigrade.

The cable sample above described was then bound by hand with heavy duck tape and tested. The maximum force reached was 4,500 pounds for a final conductor temperature rise of 59 degrees centigrade.

These test results show that when the three conductors of a compression cable are cabled together in a lay of about six feet, but not bound, the longitudinal forces due to restrained thermal expansion are so low that no expansion bends are necessary. This was further verified by the field tests. On the other hand, if the conductors are bound together, either straight or twisted, or kept straight without binding, the forces developed are large enough to endanger joints of usual design.

Outer Coverings

A test was made to determine the ability of duck tape, applied over the outer lead-sheath reinforcing tapes of an unarmored compression cable, to withstand the friction incident to pulling this type of cable into steel pipe. It was observed from laboratory tests that very thin tape was damaged in moving through the pipe even in a short distance of 50 feet. One of the samples used for test was covered with a 20-mil duck tape with salvage. This sample was pulled in and out of the pipe until parts of the sample had been subjected to the same amount of abrasion as would have been received if the cable had been pulled through a 2,000-foot section of pipe. Examination of the sample showed that the heavy duck tape was uninjured.

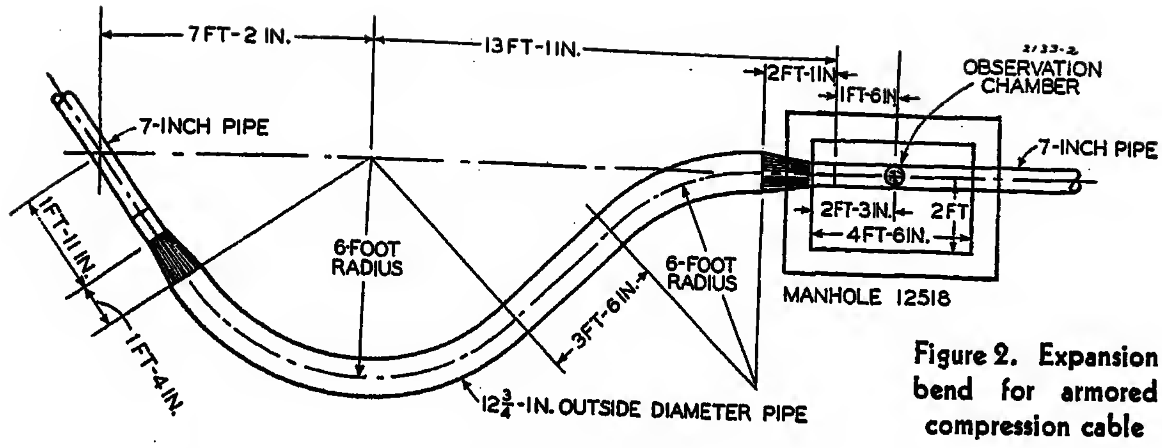

Figure 2. Expansion bend for armored compression cable

sisted of two cable sections each about 700 feet long, one armored and one unarmored, installed in a welded steel pipe. The two sections were connected by means of a joint, and their free ends were provided with terminals for parallel connection with an existing 120-kv overhead line. Suitable equipment was provided for artificially loading the cable by circulating current through the two cable sections with the overhead line providing the return path.

The Pipe Line

Electrically welded steel pipe having an outside diameter of seven inches and shipped in double random lengths was used for this installation. The ends of each length were expanded and beveled for use with chill rings. In the field gas welding was used, and the welds were tested at 500 pounds per square inch air pressure.

The terminal ends were housed in $3^5/_8$-inch outside diameter 0.120-inch wall copper pipes which were fitted and wiped into the trifurcating heads on the ends of the steel pipe line.

The pipe system was provided with nitrogen feeding equipment consisting of a standard cylinder of oil-pumped nitrogen and a gas-pressure regulator with pressure gauges. The line was equipped with a low gas-pressure alarm set for a pressure of 150 pounds per square inch.

The Expansion Bend

An expansion bend was installed near the end of the armored cable in order to protect the joint between the armored and unarmored compression cables from the longitudinal thrust exerted by the armored cable. Figure 2 shows the expansion bend used in this installation, which was made of 12-inch steel pipe with reducers on both ends. The usual practice abroad is to use an expansion bend on each side of the joint.

Corrosion Protection Coverings

The pipe on the unarmored compression cable was given a coating of a material used extensively for pipe covering. This coating, designated as coating *A*, consisted of: a hot application of wax, a spiral wrapping of reinforced asbestos, a hot application of a service coat incorporating natural asphalt, a spiral layer of a single membrane wrapper, and a spiral wrapping of heavy kraft paper. The wax was an adherent coating, chemically and mechanically fortified.

On the armored section concrete was applied around the pipe in the trench to a minimum thickness of three inches.

Cable Design

The armored cable was of conventional design as used abroad. The three 650,000-circular-mil Compack oval conductors were shielded and insulated with 500 mils of impregnated paper. The insulation on each conductor was shielded and covered with 85 mils of lead. There was applied over each sheath three paper tapes, two reinforcing bronze tapes, and two saturated cotton tapes. This assembly was cabled with saturated jute fillers and covered with a heavy saturated duck tape, jute bedding and galvanized steel-wire armor.

The individual legs of the unarmored cable were of the same construction as those in the armored cable, with the addition of two 30-mil presaturated canvas tapes. These legs were cabled without fillers or further finish. Figure 3 shows a sectional view of the unarmored compression cable installed in a steel pipe having an outer protective covering.

Anchoring of the Cables

The armored compression cable was anchored at two points:

1. At the joint with the unarmored cable, to prevent the joint from being moved by the expansion of the cable. Due to proximity of the expansion bend no large forces were involved.

2. At a point approximately 40 feet from the terminal end the armor wires were so anchored as to withstand large longitudinal forces in either direction. The expansion occurring in the 40-foot section was calculated to be negligible and would be taken up by the bend of the cables in the riser pipes. Therefore, at the joint between the terminal ends and the armored cable the armor wires were simply bound in place.

With the above arrangement of anchorage, a longitudinal movement roughly equal to that obtained in a 1,400-foot-long armored compression cable will take place in the direction of the expansion bend and joint between the armored and unarmored compression cables. To observe this movement a removable sight glass with reference mark was installed in the pipe near the end of the expansion bend as well as at other points in the line where such observation would be of use. The cable under each sight glass was equipped with a graduated scale which was fitted in proper position after the cable was placed in its final location.

Normal Joints

Figure 4 shows the normal joint used between the armored and unarmored sections of cable. Figure 5 shows the detailed design for each phase.

The design of the normal joint is of particular interest, because it achieves the connecting of two sections of cable without any appreciable structural change at the point of joining. The design results in a joint that is simple, reliable, and of very small diameter, yet similar in construction to those used on high-voltage single-conductor solid-type cables. Very little schooling is therefore necessary for splicers well-versed in solid-type cable jointing to enable them to construct this joint. Diaphragm action takes place along the joint in a manner similar to that of the cable.

Soldered-type countersunk copper connectors were used with an outside dimension the same as that of the cable conductor. Semiconducting tapes were used to shield the connectors and applied so as to make good contact with the conductor shielding tapes. Long pencils

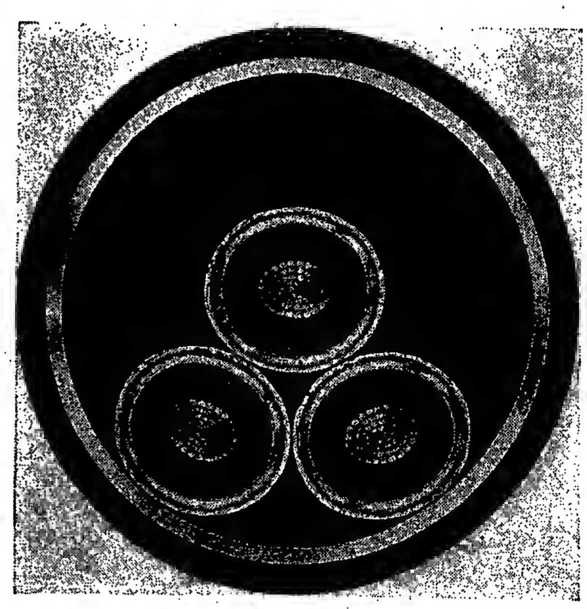

Figure 3. Sectional view of unarmored compression cable installed in steel pipe having an outer protective covering

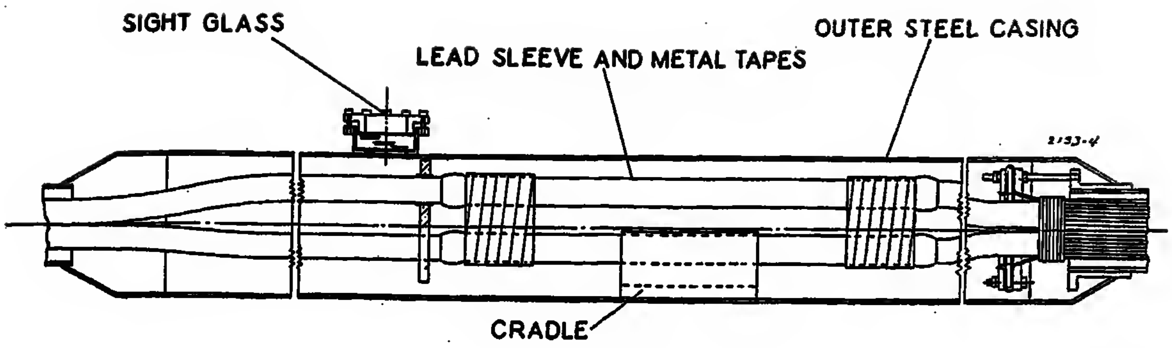

Figure 4. Normal joint between armored and unarmored sections of compression cable

were made on the factory insulation by tearing each tape individually at points one-eighth inch apart. Impregnated-paper tapes were tightly applied, butt-lapped, and wrapped in the same direction, until the thickness of the hand-applied insulation exceeded that of the factory insulation by 20 per cent. Shielding braid was applied over the insulation. The diameter was so made that it required considerable force to draw the oval sleeve over the joint core. The joint core was coated with cable oil before forcing the sleeve in place. This made the sleeve over the joint insulation fit as snugly as the regular sheath over the factory-applied insulation. The sleeve was then beaten down at the ends and wiped to the cable sheath. It was then reinforced with brass tapes similar to the reinforcing on the cable proper. After the individual joints were completed, they were tied together, the steel joint casing pulled over and welded in place.

Laboratory tests had been made previously on two joints of this design. The man making these joints had had no previous experience in making paper-taped joints other than a single similar practice joint. The voltage program as specified in the Association of Edison Illuminating Companies Specification for Oil-Filled Cable was used with the time reduced for the first step to $1^1/_2$ hours, and the 20 per cent increase in voltage every three hours obtained in small steps every ten minutes instead of one large step at three-hour intervals. Breakdown voltages, expressed in volts per mil of cable insulation, of 436 and 445 were obtained. In both joints the breakdown was radial and over the connector; there were no other signs of stressing. These results compared favorably with values obtained on standard normal oil-filled cable joints of this voltage class. These laboratory values are probably very conservative as compared with what might be expected from the field joints where a more nearly circular connector was used, and where the tapes were applied with greater tightness by experienced splicers.

Terminals

Figure 6 shows the design of the terminals used on the experimental line. These terminals have a brass-fitted bakelite stop-tube assembly of sufficient strength to withstand the high internal operating pressure of the cable oil. This stop-tube assembly ends in a stem at the upper end and a flange at the lower end. The porcelain insulator, with a barrier assembly and stress cone, metal rings at top and bottom, and an insulator cap, is placed over the stop tube and bolted to the flange. The space between the stop tube and the porcelain is filled with oil. The terminal is essentially the same design as that used for oil-filled cable with the addition of the stop tube.

Compensators

Compensators were used in order to allow for the expansion and contraction of the impregnating oil contained in the rigid stop tubes of the terminals, and thereby prevent overworking the sheath near the ends of the compression cable. The compensator may be described as a flexible membrane in a housing which is capable of withstanding 200 pounds per square inch pressure. The membrane separates the housing into two chambers; one containing oil is in direct communication with the inside of the stop tube, and the other containing nitrogen is connected to the pipe line. Expansion of the oil in the stop tube and cable due to increasing temperature is accommodated by the movement of the membrane which is spring-loaded to provide a characteristic similar to that of the cable sheath. During cooling the process is reversed, and thus complete impregnation of the terminal at all times without appreciable interchange of oil between the terminal and cable is insured. One compensator is connected to each terminal.

Installation

Methods usually employed for pulling cables into ducts were readily adapted to the installation of the compression cable in the steel pipe. At the start of the installation of the armored compression cable, high pulling stresses (16,000 pounds) were experienced on the pulling line when it passed around the expansion bend located at the pulling end of the section. As soon as the armored cable started to pass through the expansion bend, the pulling stresses on the line became normal.

A maximum pull of 7,800 pounds was experienced during the installation of the unarmored cable. This corresponds to a coefficient of friction of about 0.54. For future installation of unarmored compression cable where an even lower pulling stress is desired, a half-round copper wire wound over the fabric tapes of the individual cables can be employed.

In order to determine the effect on a

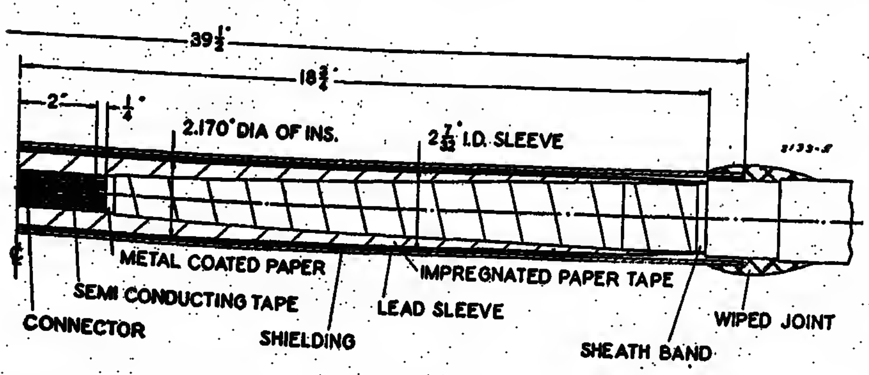

Figure 5. Detail for one conductor of the normal joint

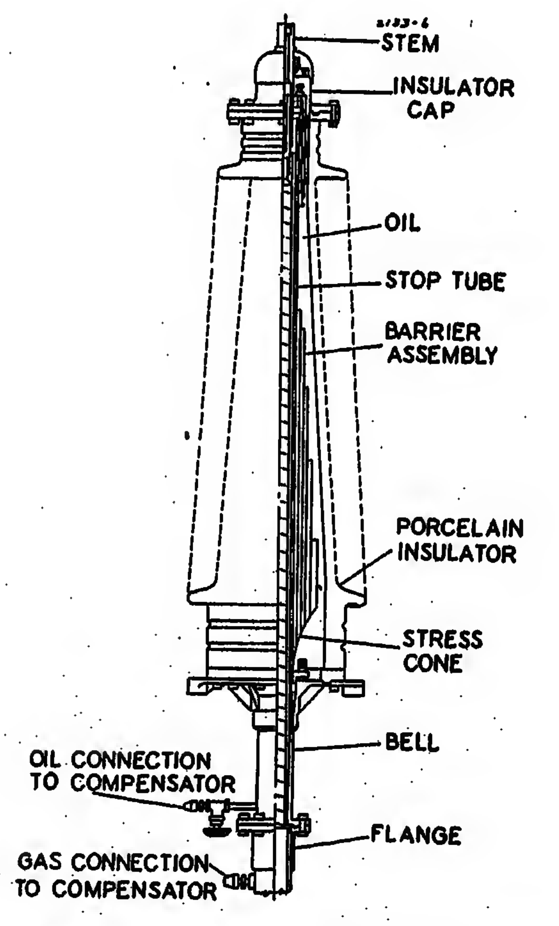

Figure 6. Terminal for 120-kv compression cable

compression cable of nitrogen coming in contact with the insulation, the lead sheath of one phase of the unarmored cable was perforated with holes approximately one-eighth inch in diameter at 25-foot intervals throughout its length.

Before the cables were pulled into their respective pipe sections, the piping was dried with hot air. After the cable was installed the pipe was evacuated and then filled with nitrogen at a low positive pressure. With the help of temporary seals, this nitrogen was kept in the pipes until the cable-splicing operations were completed, at which time the pipe was filled with nitrogen gas at a pressure of approximately 200 pounds per square inch. The nitrogen used was oil-pumped, guaranteed to contain less than 0.3 per cent oxygen and 0.03 per cent water.

Tests on the Cable Before Installation

As the compression cable before installation is essentially a standard solid-type cable, routine factory acceptance tests, usually performed on solid-type cable of similar insulation thickness, were considered adequate for detection of nonuniformities. The impulse strength of compression cables had been determined by previous tests,[2] and calculations showed that this cable would fail at a voltage in the neighborhood of 1,100 kv. A sample of compression cable used in this installation withstood without failure impulse voltages up to 900 kv (the capacity of the generator). This is well above the 138-kv insulation level.

Field Tests

After the installation had been completed the cable was subjected to repeated load cycles, and periodic measurements were made of the power factor and movement of the cable within the pipe.

During the time that the cyclic loading tests were in progress (a little over five months), the cable line was subjected to 54 load cycles with load on for $2^1/_2$ hours and load off for $2^1/_2$ hours, and 249 load cycles with load on for 4 hours and load off for 4 hours. In addition, a number of cycles was used in which the load was applied for durations ranging from approximately 13 hours to 190 hours. During the majority of the load cycles, the current ranged from 500 to 550 amperes (or 10 to 20 per cent above the nominal 95,000-kva rating of the line); during others, particularly those of the longer duration, the currents ranged from 460 to 510 amperes.

The first few heating cycles produced a movement of seven-eighths inch in the armored cable at the entrance to the expansion bend over 613 feet of cable and a slight initial adjustment of position of the unarmored cable. Subsequent heating and cooling cycles produced a cumulative $3^3/_4$-inch movement of the armored cable and no appreciable movement (one-eighth inch) of the unarmored section. This indicated that without armoring, the cables would absorb the longitudinal movement, thus making expansion bends unnecessary. During the recent cold season and without load, the armored cable has returned to its original position.

Power-factor measurements were made on each conductor of the two connected sections at voltages from 20 kv to 100 kv to ground. An initial set of measurements was made before starting the load cycles, and subsequent measurements made at intervals during the period that the cable was under test. It was not practical to obtain the power factor of the test cable at elevated temperatures due to the relatively long time necessary to switch the test cable out of the circuit and connect up the power-factor measuring equipment. The measurements were made after the cable had been de-energized for a period of 15 hours or more.

These power-factor measurements as obtained on one of the conductors are shown in Figure 7. There was no significant difference in the measured values for the different conductors. It will be seen that there is a slight decrease in power factor in the later readings which were at slightly higher temperatures than the initial set.

No noticeable difference in power factor was apparent in the phase with holes in the sheath as compared to the other two phases. However, this cable has not been operating long enough to prove this point definitely.

Summary

1. Methods normally used for pulling cables into ducts can readily be adapted to the installation of compression cable in steel pipe.

2. Conditions in this country make it possible to eliminate the armor which is used on compression cable abroad.

3. By cabling the individual lead-covered and reinforced conductors with a suitable lay, longitudinal expansion becomes of no practical importance, and expansion bends as used abroad can be eliminated.

4. Diaphragm action of the lead sheath when in nitrogen shows indefinite life under simulated operating conditions.

5. Compression cable is well suited for handling loads in the range of 100,000 kva.

6. The experimental installation which has been installed for approximately one year shows no deterioration of the insulation even on the phase with the lead sheath perforated every 25 feet.

120-Kv High-Pressure Gas-Filled Cable

I. T. FAUCETT FELLOW AIEE
L. I. KOMIVES ASSOCIATE AIEE
H. W. COLLINS ASSOCIAEE AIEE
R. W. ATKINSON FELLOW AIEE

THIS paper deals with the theory, manufacture, and testing of high-pressure gas-filled cable and describes an experimental installation by the Detroit Edison Company in co-operation with the General Cable Corporation and a subsequent commercial installation on the Detroit Edison system.

While high-pressure gas-filled cable has been in successful operation in England, these are the first experimental and commercial installations in the world of this type cable in a steel pipe. The installation of such cable in a steel pipe involves the removal of the lead sheath in the field, thus exposing the insulation to the atmosphere and to the possibility of mechanical injury during installation. Since the effect of such conditions is difficult to determine in the laboratory, the experimental installation was made.

The commercial line was subsequently installed on the Detroit Edison System and put in operation on December 31, 1941. This line is seven miles long and designed to transmit 95,000 kva continuously at 120 kv.

Experience Abroad

High-pressure gas-filled cable has been in successful operation in England since 1937 at which time installations of cable of this type were made for operation at 33 kv and 132 kv. Today there are approximately 25 conductor miles in successful operation at voltages ranging from 33 kv to 132 kv and at pressures from 50 to 225 pounds per square inch. These cables[1] are equipped with lead sheaths reinforced so as to withstand the operating gas pressure.

The high-pressure gas-filled cable makes effective use of the well-known fact that the dielectric strength of gas increases very greatly with pressure. The great gain possible by the use of high gas pressure in cable insulation has long been recognized. However, it was not until a more complete knowledge of other facts became available that effective use could be made of this principle.

The low permittivity and dielectric loss of unsaturated paper made the use of this dielectric seem most promising. Many of the expected results were realized in cables made in this way; dielectric losses were very low, and there was no ionization at voltages well above operating voltage. However, the short-time and impulse breakdown voltages were very low. Since there was no measurable ionization at voltages just below failure it seems that complete breakdown in such a cable follows promptly after the smallest amount of ionization.

An entirely satisfactory solution of the problem has been found by combining several features. The use of high-density low-porosity paper presaturated with a high-viscosity compound has eliminated the quickly destructive effect of ionization produced by overvoltage. These features, together with shielding of the conductors as advocated by two of the authors for all very high-voltage cable,[2] and with the use of very thin tapes near the conductors, have resulted in obtaining an insulation entirely free from ionization up to about twice operating voltage and a dielectric strength (short-time or long-time) in the same range as for oil-filled insulation. Perfection of methods of drying and saturation, the use of a saturant of very low loss, and the prevention of moisture absorption during taping have also resulted in extremely low dielectric loss and a high degree of uniformity throughout the thickness of the insulation.

Two different types of saturant have been used abroad. In the earlier ones, the saturant contained a very large percentage of rosin and had a very high viscosity. However, it also had a high power factor and for this reason was not considered entirely satisfactory. In later cables the saturant has been petrolatum. This has a low loss and does not migrate at a temperature below its meltin of 50 or 55 degrees centigrade, b become very fluid at temperati which cables may operate in this try. Thus neither of these saturan entirely satisfactory particularly pipe cable installation. The s used in the Detroit cables has a ve viscosity, possesses extraordinaril stability, and gives a cable of as electric loss as for the best of power cables. The good results o on these cables are attributable small part to the development and this saturant.

The value of the very thin tapes the conductor shielding lies prime the increase of specific dielectric st of gas in very thin films. Because lower dielectric stress farther fro conductor, the thin tapes are re only near the conductor. Thus b ing the paper-tape thickness, the sa electric strength is secured for th as if all the paper were thin; at th time there is secured greater free the penetration of gas and more equalization of the pressure throu insulation wall. Moreover, the re cable withstands without damage t mal bending in manufacture and in tion, as it could not do so fully if m tirely of the thinnest paper.

Nitrogen has been selected as th sure medium, because of its good tric properties, its complete inertne respect to the materials used in the and its commercial availability wi moisture and oxygen content.

The SMD Type Cable

The previous paragraphs dealt w basic principles behind the high-p gas-filled cable and apply to thi cable as manufactured in England the pipe type of cable manufactu this country and hereafter designa *SMD* type. The difference in co tion is in the outer enclosure. Ab reinforced lead sheath is used over sulated conductors to provide th tight enclosure. An additional sheath is usually employed to prote reinforcements. The *SMD* type o pressure gas-filled cable retains the tial insulation of the reinforced sheath type but does away with th manent lead sheaths as used abroa three phases of even the large cables are installed in one common sure chamber. This pressure chan a steel pipe which is in itself gas and which is designed to withstan required pressure. A lead sheath

Paper 42-135, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 11, 1942; made available for printing May 20, 1942.

I. T. FAUCETT is chief engineer, General Cable Corporation, New York, N. Y.; L. I. KOMIVES is engineer, underground lines department, and H. W. COLLINS is assistant to the superintendent of the electrical system, both with Detroit Edison Company, Detroit, Mich.; and R. W. ATKINSON is director of the high-voltage research department, General Cable Corporation, Bayonne, N. J.

The authors wish to acknowledge the contributions of S. M. Dean, Detroit Edison Company, who suggested the use of a steel pipe as the pressure container in this installation, instead of the customary reinforced lead sheath. They are indebted for the valuable assistance given by their other associates in the Detroit Edison Company and the General Cable Corporation, and wish especially to thank W. S. Brown, F. G. Cox, R. C. Fellows, H. G. Hall, E. Johansson, L. Meyerhoff, J. D. Piper, E. Richman, W. D. Sanderson, G. J. Shurts, and J. Sticher.

serves as a protective covering during shipment and storage is removed as the cables are installed.

While the insulation of the *SMD* type cable is the same as for the reinforced sheath type, the removal of the lead sheath requires that a covering be placed over the insulation for protection during installation. In the cable used in the experimental line this was accomplished by the application of a strong canvas tape over the insulation shielding tapes. The cable for the commercial line was manufactured with a half-round copper wire over the canvas tape to increase the mechanical protection and reduce the coefficient of friction between the cable and pipe.

Since the installation of this type of cable requires the removal of the lead sheath in the field, the exposure of the insulation to the atmosphere, and the possibility of mechanical injury during installation, it was felt that an experimental installation was essential to demonstrate the practicability of installing this type of cable in a commercial line.

While the superiority of insulation made with graded tapes of five mils and less was recognized, the question of whether or not an insulation built from papers of standard thickness, five mils or over, would be satisfactory was raised. To obtain an answer to this question, it was decided to employ all five-mil tapes in the *SMD* type cable used in the experimental line. The five-mil thickness was used to facilitate taping and to depart as little as possible from the standard practice used in the manufacture of power cables. In the cables built subsequently for the commercial *SMD* line, grading of paper thickness was employed, thus conforming to the practice abroad.

Manufacture

The cable in the commercial installation was of the following construction: single conductor 600,000 circular mils concentric round strand, 600 mils preimpregnated wood-pulp paper of graded thickness from $2^1/_2$ to 5 mils, two metal-faced paper tapes applied next to the conductor, and two metal-faced tapes over the insulation (all metal-faced tapes included in the 600-mil wall thickness), bronze shielding tape intercalated with a saturated muslin tape, one 20-mil paraffin saturated tape, one half-round 200- by 100-mil copper wire applied in open spiral, and a 94-mil temporary lead sheath. Figure 1 shows a sectional view of this cable installed in the steel pipe having an outer protective covering.

Before being applied to the cable, the paper tapes were dried and saturated with an oil having a viscosity of 3,000 seconds Saybolt Universal (50 centipoises) at 100 degrees centigrade. The preimpregnated-paper tapes were wrapped on the conductor in a standard taping machine and in the usual manner, except that the entire machine was enclosed in a room where in the relative humidity was maintained below 20 per cent regardless of outside atmospheric conditions. This humidity control, together with precautions taken during impregnating, handling, and storing, greatly reduced the moisture content in the finished cable.

The cable for the experimental installation differed from the above only in the omission of the half-round copper wire, the use of five-mil paper tapes throughout, and the application of paper tapes without humidity control.

Specification

SMD type cable may be tested in accordance with the Association of Edison Illuminating Companies Specification for Oil-Filled Cable, provided that during the electrical tests an internal nitrogen pressure of 30 pounds per square inch is maintained on commercial lengths and 225 pounds per square inch on samples. The temporary lead sheath on the commercial lengths should, of course, be of sufficient strength to withstand this pressure.

Experimental Installation

The experimental circuit of *SMD* type cable consisted of one section of cable of approximately 700 feet in length with normal joints at each end connecting to the terminal end cables. Terminals were provided at each end for connection with an existing 120-kv overhead line. The cable was installed in a seven-inch-outside-diameter welded steel pipe having a wall of 0.231 inch and filled with nitrogen gas at a pressure of approximately 200 pounds per square inch. The pipe section housing the cable was provided with manholes at each end at which points sight boxes were provided for observing cable movement.

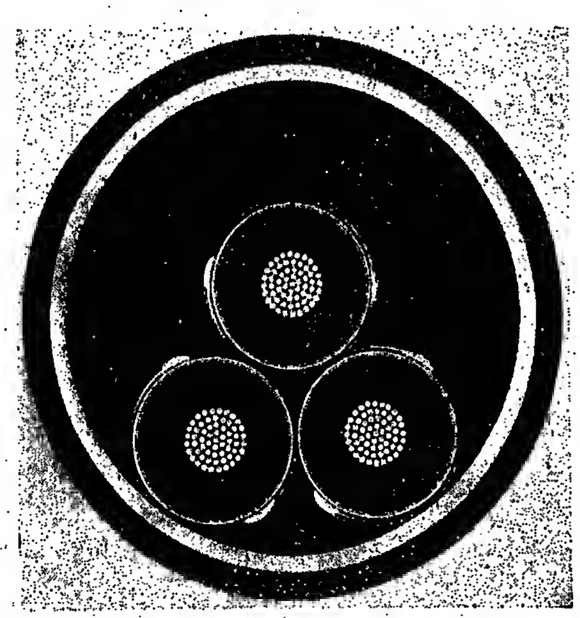

Figure 1. Sectional view of *SMD* type cable installed in a protective-coated steel pipe

Two different types of protective coverings were applied to the pipe. About half of this 700-foot section was covered with a coating of plasticized coal-tar enamel. Joints in the pipe were hand-coated with the same material. The balance of this section of pipe was covered with Somastic. This material consists of a primer coat over which was extruded, hot, a half inch of asphalt mastic material.

The joints and terminals were of the same general design as used on the commercial line and are described hereafter.

Since it was desirable not to expose the insulation to the atmosphere any longer than necessary, a mechanical stripping device was designed which folded the lead sheath back as the cable was pulled into the pipe. V-shaped grooves were made in the lead sheath during the lead covering process in order to facilitate stripping. It was found, however, that scoring of the lead sheath by hand in the field was still necessary, and that mechanical stripping increased the pulling stresses considerably. It was thus unnecessary to score the lead at the factory, as scoring in the field was all that was required to facilitate this operation.

Field Tests

Measurements were made after the installation had been completed in order to determine what effect cyclic loading of the cable would have on the power factor of the insulation and what movement of the conductors would take place.

The cable which was connected to the 120-kv overhead line was subjected to load cycles by the circulation of current through the conductor with the overhead line acting as the return path. During the first 54 cycles the load was on for $2^1/_2$ hours and off for $2^1/_2$ hours. This was followed by 249 cycles of longer duration with the load on for 4 hours and off for 4 hours. In addition there were a number of cycles in which the load was applied for durations ranging from 13 to 190 hours. For the majority of the load cycles the current ranged from 500 to 550 amperes (or 10 to 20 per cent above the nominal 95,000-kva rating of the line). The maximum change in copper temperature

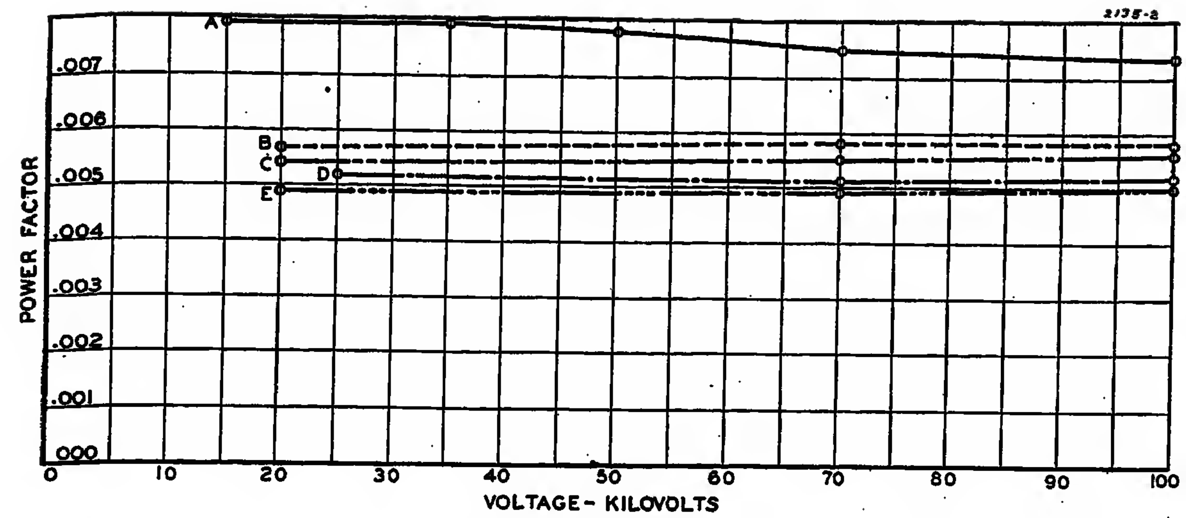

Figure 2. Curves of power factor versus voltage for experimental installation

Curve	Date (1941)	Cable Temperature (Degrees Centigrade)
A	March 29	2.6
B	May 17	19.6
C	May 27	22.3
D	July 2	25.8
E	August 6	27.7

that occurred during this period of loading was 58 degrees centigrade.

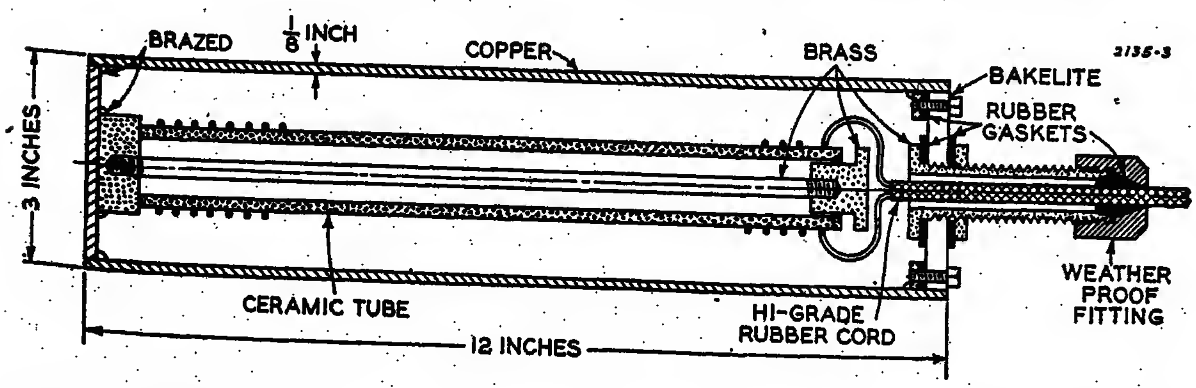
The above load cycles produced only a slight initial adjustment in the position of the cable, and no further movement of the cable occurred thereafter. This indicates that there is sufficient space in the pipe to absorb the longitudinal thermal expansion.

Power-factor measurements were made on each of the three conductors at voltages from 20 kv to 100 kv to ground. An initial set of measurements was made before loading and repeated at intervals during the period that the cable was being subjected to the loading cycles. The measurements were made after the load had been removed from the cable for a period of 15 hours or more. It was not feasible to obtain power-factor measurements at elevated temperatures, since it required a relatively long time to switch the experimental cable out of the circuit and connect up the power-factor measuring equipment.

The power-factor data as obtained on one of the conductors are shown in Figure 2. There was no significant difference in the measured values for the different conductors. It will be noted that the later power-factor values are noticeably lower than the earlier ones. The first tests were made at 2.6 degrees centigrade, and the last one at 27.7 degrees centigrade. This is entirely consistent with laboratory data, which show that in the lower range of temperatures the power factor of the insulation decreases as the temperature increases. These measurements show no evidence of deterioration of the insulation.

Figure 3. Cell for measuring thermal resistivity of soil

Ceramic tube wound with Chromel wire to dissipate 200 watts at 120 volts



Soil-Resistivity Measurements

During the period that tests were being conducted on the experimental installation, soil-resistivity measurements were made for use in designing the commercial line. Measurements were made to determine the thermal resistivity of the earth under varying seasonal conditions and for different types and conditions of soil. A cell was used consisting of a copper cylinder twelve inches long and three inches in outside diameter, with a one-eighth-inch wall, and equipped with an internal electric-heating element. This heater was capable of dissipating 200 watts at 120 volts, uniformly over the walls. A copper-constantan thermocouple was embedded in the mid-point of the cylinder wall. The general construction of this cell is shown in Figure 3.

This cell was buried vertically in the ground; the heater supply and thermocouple leads were brought out to a convenient point. Means were also provided for measuring the ambient earth temperature nearby. Sufficient energy was supplied to the heater element to cause a 40- to 50-degree-centigrade rise between cylinder wall and ambient earth. For the soils so far tested an input of 50 watts has been necessary.

The earth thermal resistivity (in degrees centigrade per watt per centimeter cube) may be computed from the formula $g=(128/W)(T_1-T_2)$: when W = watts input, T_1=temperature of cylinder wall, and T_2=temperature of ambient earth. This formula is empirical and was derived by comparison with the results obtained from such a cylinder with those obtained with a sphere.[8]

Figure 4 shows values of resistivity for three types of soil encountered along the route of the commercial line, as well as the variations in resistivity that are caused by the changes in moisture content during the different seasons of the year.

Tests with the thermal resistivity cell at what will probably be the locality where the soil has the highest thermal resistivity along the commercial line (in fine sand) show maximum average values of 120 during the dry season. In other areas where loam prevails, maximum average values of 95 and 75 were measured during the dry and wet seasons, respectively. Corresponding measurements where heavy clay prevails show resistivities of 105 and 95, respectively.

Commercial Line

General Layout

The commercial line consists of a seven-mile circuit installed under paved city streets. The cable used has previously been described under "Manufacture" and was shipped and installed in lengths of approximately 1,500 feet. The pipe line consisted of seven-inch steel pipe protected from corrosion by means of Somastic pipe covering. The line is sectionalized by stop joints, one near each termination and four at intermediate points, thus dividing the line into five approximately equal sections. These stop

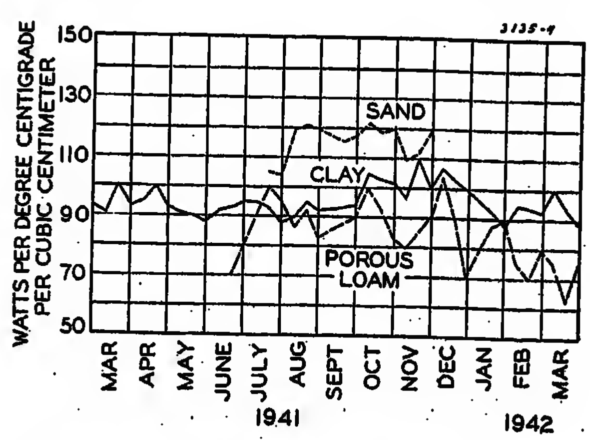


Figure 4. Seasonal soil-resistivity curves

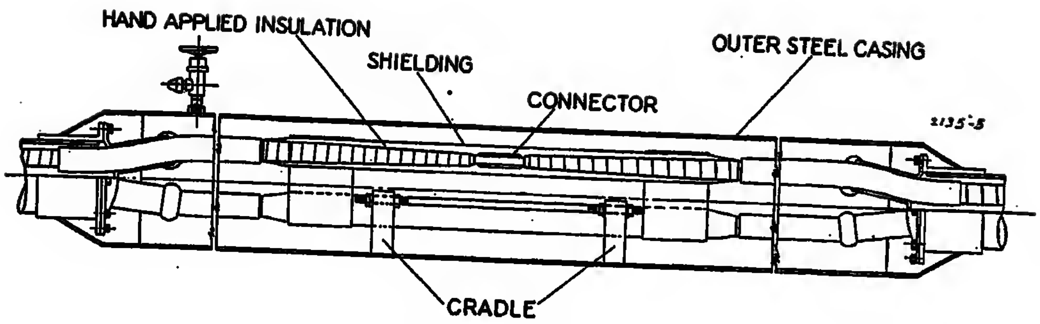

Figure 5. Normal joint for *SMD* type cable

joints are provided so that if repairs to the steel pipe are required, because of corrosion or for other reasons, it will be necessary only to discharge the nitrogen from the section involved. Sectionalizing the line also facilitates the location of a gas leak in the steel pipe if a leak should occur. In normal operation the stop joints are by-passed by a pipe containing a valve which may be closed for sectionalization. Nitrogen tanks were connected through pressure regulators to the ends of the pipe to take care of any leakage. A low pressure alarm was installed to operate when the gas pressure drops to 150 pounds per square inch.

Installation

The temporary lead sheath was scored and stripped by hand, as the three cables were pulled as a unit into the steel pipe. No difficulty was encountered in pulling these 1,500-foot lengths. The maximum pulling stress that occurred on any of the sections was 7,200 pounds which corresponds to a maximum coefficient of friction of 0.37.

For a distance of approximately 15 feet on each end of the cable sections, the lead sheaths were allowed to remain to facilitate making the joints, and to permit sealing the cables in the steel pipe during installation. The cables were sealed in the pipe by means of trifurcating heads, which consisted of a flange and gasket bolted to the pipe ends and three lead nipples wiped to the cable sheaths.

Previous to pulling in the cable, each section of pipe line between manholes was tested for leaks with 500 pounds per square inch air pressure for 24 hours. The pressure was then released, and the pipe filled with dry nitrogen gas at a pressure of 5 to 10 pounds per square inch. This pressure was maintained until the cable was pulled. After the cable was pulled, the ends of each section were sealed by means of the trifurcating heads, and dry nitrogen gas admitted at a pressure of 5 to 10 pounds per square inch. After each section between stop joints was completed, it was evacuated. When all sections of the line were completed, the line as a unit was filled with dry nitrogen gas at 200 pounds per square inch.

Normal Joints

The normal joints, shown in Figure 5, are essentially the same in the experimental and commercial lines and were hand-taped with presaturated paper. Soldered-type countersunk copper connectors having a diameter the same as that of the cable conductor were used. These avoid the regions of high stress that occur near the ends of standard connectors. Stress control was further improved by the use of semiconducting tapes for shielding the connectors. These tapes were applied so as to make good contact with the conductor shielding tapes. Long pencils were made on the factory insulation by tearing each tape individually at points approximately one-eighth inch apart. The paper tapes were applied butt lap to a thickness 20 per cent greater than that of the factory-applied insulation.

The hand-applied insulation was tapered at the ends of the joint by tearing the successive tapes at points $^9/_{16}$ inch apart. The joint was completely shielded with tinsel copper braid. Special rubber sleeves were temporarily pulled over the completely insulated and shielded joints to protect them against dirt and moisture and to permit maintaining low gas pressure on the insulation. The ends of these rubber sleeves were sealed with rubber tape to the short sections of lead sheath left on the cable ends. After all three joints were completed, the rubber sleeves were removed, the wipes at the trifurcating heads melted off, the trifurcating heads moved two inches from the pipe ends and the wipes remade. This procedure permitted entrance of gas into the joint casing and anchored the cables at the joint. The enlarged section of pipe forming the joint casing was then pulled over the joint and welded in place.

Stop Joints

The stop joint, shown in Figure 6, is essentially the same as those used for oil-filled cable. The stop tubes have somewhat greater wall thickness to give strength to withstand safely a differential pressure of 225 pounds per square inch. At one end the three stop tubes are sealed to a diaphragm through which the cables pass. This diaphragm is sealed to the outer joint casing. The condenser unit for each of the three individual joints is similar to the condenser for oil-filled cable except that it is wound with preimpreg-

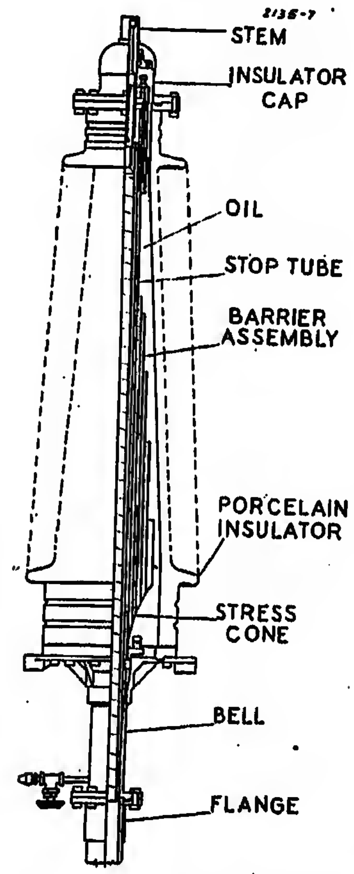

Figure 7. Terminal for *SMD* type cable

nated paper, and no individual oil-tight outer sleeves are used. This allows the gas to come into direct contact with the insulation of the condenser, thus improving its dielectric strength in the same manner as for the cable proper.

Terminals

The terminals used on both the experimental and commercial lines have a brass-fitted bakelite stop-tube assembly similar to those used in the stop joints but of greater length. This stop tube assembly ends in a stem at the upper end and a flange at the lower end. The porcelain insulator, with a barrier assembly and stress cone, metal rings at top and bottom, and an insulator cap, is placed over the stop tube and bolted to the flange. The space between the stop tube and the

porcelain is filled with oil. Thus the terminal is essentially that used for oil-filled cable with the addition of the stop tube. The terminals are installed in a manner similar to single-conductor terminals on oil-filled or solid-type cables. Figure 7 shows the design of these terminals.

Manholes

The 24 normal and 6 stop joints were housed in manholes having brick walls, concrete floors, rail-supported brick ceilings, two chimneys, and built-in pulling eyes. The normal joint manholes were 12 feet long, 4 feet 9 inches wide, 5 feet high, and those housing the stop joints were 17 feet 10 inches long, 5 feet 6 inches wide and 5 feet high. Corrugated galvanized-iron culverts, concentric with the pipe, were used for storing the steel-joint casings out of the way of the splicers during construction. One such culvert was provided in the normal-joint manholes and two in the stop-joint manholes.

Laboratory Tests

Power Factor Versus Pressure and Voltage

The effect of different gas pressures on the power factor at different voltages is shown in Figure 8. This cable operates at approximately 70,000 volts to ground and was designed to show no measurable ionization at double working voltage, or 140,000 volts, when under a nitrogen pressure of 225 pounds per square inch. In general, there was no appreciable ionization at 140,000 volts and 200 pounds per square inch. It is apparent also that at approximately 80,000 volts and 100 pounds per square inch, no appreciable ionization occurs. Thus the minimum safe operating gas pressure for this cable is approximately 100 pounds per square inch. Ionization data on this lot of cable may be summarized as indicated in Table A.

Table A

Gas Pressure (Lb. Per Sq. In.)	Voltage at Which Ionization Begins
Atmospheric	Approximately 23 kv
50	Approximately 50 kv
100	75–90 kv
150	100–120 kv
200	120–140 kv
225	140 kv or above

Compound Migration

The fact that this cable was to be installed in a steel pipe without a lead sheath made it necessary to determine whether at high temperatures the impregnant would flow out of the paper into the pipe, or when installed vertically, the compound would flow longitudinally of the cable. If such migration would be harmful, the effect would become apparent from ionization tests. In Figure 9 are curves showing ionization tests on a sample of cable after heating for 65 days at 100 degrees centigrade in an inverted U position. The sample in the bent position had an over-all height of 15 feet of which only a very small part was consumed by the storage of the small amount of drained compound at the lower ends in the space between the lead sheath and insulation. This offered as complete an opportunity for drainage as for a cable of any height. The cable was allowed to cool for eight hours each day for 38 of the 65 days. Initially and also after 43 days' heating there was no ionization at 140 kv and 225 pounds per square inch, but after 65 days' heating ionization started at 130 kv. Thus it is safe to assume, since there was no change after 43 days' heating at 100 degrees centigrade, and only a slight change after 65 days' heating, that migration is not a problem at normal operating temperatures even in vertical runs.

Radial Power Factor

It has been customary in the industry to measure radial power factor at 60 degrees centigrade. In order to exaggerate effects on power factor of small quantities of contaminants, notably moisture, radial power factor tests on *SMD* type cable were made at 80 degrees centigrade. The greater sensitivity of measurements at 80 degrees centigrade, as compared with 60 degrees centigrade, is markedly shown in Figure 10 where curves *C* and *D* show radial power factor at these respective temperatures. The sample of cable used for these measurements was an experimental section made before the procedure used in the construction of this type of cable had been perfected.

Figure 11 shows the very high degree of correlation that exists between the power factor and moisture content. The radial moisture-content curve has been superimposed on the radial power-factor curve, and the variations in the moisture content are closely followed by variations in the power factor. These measurements were made on samples taken from the section of experimental cable mentioned as having been made before the manufacturing technique was perfected. To obtain an accurate measure of moisture content, groups of tapes were used instead of single tapes. Tests made on a number

B—Radial moisture content on "experimental" cable

C—Radial power factor on "commercial" cable, measured at 80 degrees centigrade

of samples show that when the moisture content is below one half of one per cent, it has no significant effect on power factor.

A very noticeable improvement in the 80-degree-centigrade radial power factor took place after the room humidity was maintained below 20 per cent during the taping operations. This improvement is demonstrated by the comparison of the radial power factor curves *A* and *C* shown in Figure 11 for cable made before and after the adoption of humidity control.

Power Factor—Temperature Characteristic

Figure 12 shows a typical power factor versus temperature curve for *SMD* type cable made by the latest practice. This compares very favorably with the best of other types of cable insulation, including that used on oil-filled cable.

Temperature Stability

The temperature stability of the insulation is as important for *SMD* type cable as for other types. The excellent temperature stability of the cable made for commercial use is shown by curves *A* and *B* of Figure 10. Curve *A* shows the radial power factor at 80 degrees centigrade for the new cable, and curve *B* shows the same characteristic on another sample of the same cable after 113 days at 100 degrees centigrade. In both cases the power-factor curve is essentially flat for the full section of the insulation. The aged sample shows no indication of an increase in power factor; in fact, this sample shows a somewhat lower average power factor than the unaged sample. Other samples show no appreciable change in over-all power factor after aging for 162 days at 100 degrees centigrade. Curves *C* and *E* show a similar radial power-factor comparison of "experimental cable," which was manufactured before moisture control was perfected.

Dielectric Strength

The results of dielectric-strength tests on thirteen 30-foot samples taken from the cable made for installation in the commercial line are shown in Figure 13. These samples were tested at a gas pressure of 225 pounds per square inch. There are shown, also, two tests on cable tested at 30 pounds per square inch pressure, one test on cable drained before voltage application, and one test on cable at high temperature. It will be observed that, for tests of a duration between about 1 hour and 100 hours, the approximate life to failure varies inversely as 7.5 power of the

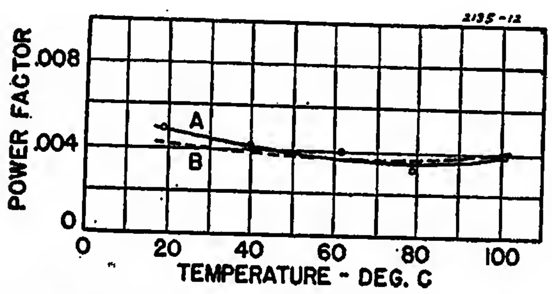

Figure 12. Curves of power factor versus temperature

A—*SMD* type cable "commercial"

B—Typical for oil-filled cable

voltage. There is little or no decrease of strength for periods above 100 hours. For periods less than one hour the strength increases much less rapidly with decreasing time than in the range between 1 and 100 hours. The fact that the dielectric strength for a period of a few hours is reduced no more than about 10 to 20 per cent when tested at 30 pounds per square inch instead of 225 pounds per square inch is rather remarkable. Drainage under very severe conditions, that is, with the cable supported in an inverted U position and maintained at a temperature of 100 degrees centigrade throughout the cross section for a period of 44 days, reduced the strength 10 per cent when tested at a voltage which produced failure in 125 hours. The sample tested hot was held at 75 degrees centigrade by circulating current in the sheath of the cable for about 1,250 hours. Voltage was maintained on it, while hot, for about 530 hours at values increasing from 120 kv to 165 kv. The result of this test was plotted as the equivalent of 108 hours at 160 kv. Even on this basis the test was rather better than the average of the cables tested without heating. It is also to be noted that the power factor at 75 degrees centigrade remained at about 0.3 per cent throughout the test with no tendency to increase.

Figure 8, which shows the power factor versus voltage characteristic, gives a basis for understanding the high long-time strength of this insulation. For a given over-all average stress in the insulation, the actual stresses in the paper and in the oil are lower than in other types of insulation, because of low specific inductive capacity caused by the gas spaces. Thus, as long as there is no breakdown in the gas spaces, it is clear that long-time dielectric strength should be at least as great as for the best of other types of insulation—namely oil-filled insulation. The "ionization" test is one of the best criteria of the beginning of ionization in the gas spaces. It is recognized from extensive tests and engineering experience that the effect of electrical stress in a gas changes sharply and completely at the beginning of ionization (ionization by collision). Above that stress the gas becomes a partial conductor. Even more serious than this is the effect of the bombardment of the solid and liquid insulation at the boundaries of the gas spaces in the gas. This bombardment produces "wax formation," charring of the paper, "coring," and ultimate breakdown. Below the ionization voltage, however, the stress has substantially no effect on the insulation, and, so far as the stress is concerned, the cable should last indefinitely.

A great deal of information has been obtained by dissecting completely (unwinding) the entire length of these many test specimens. In the tests in which complete failure took place after more

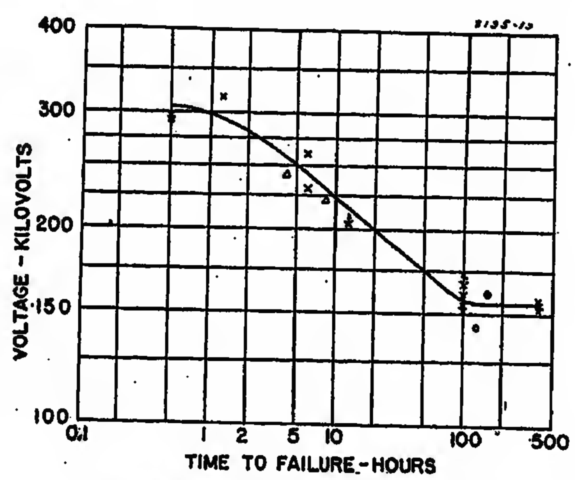

Figure 13. Voltage–time curve

Δ—Tests made at room temperature and 30 pounds per square inch pressure

than 24 hours, there were frequently found one or more partial failures. Because of the small extent of the burning, it was possible to obtain from these partial failures very complete information as to their course. The different partial failures were evidently of similar character but in different stages of development. They originated in the butt space of the tape next to the conductor, usually so close to an edge of the tape as to burn it slightly. When several of these partial failures in different stages were examined, some were found with only a few layers of paper punctured, the size of the hole increasing outwardly from the conductor. In the more advanced stages, the outermost tapes were discolored (brown), usually to a diameter of $^1/_{32}$ inch to $^1/_{16}$ inch, but sometimes to a diameter up to $^1/_8$ inch. In still later stages, "tree design" or "dandrites" appeared at the tip of the advancing puncture. In later stages, these spread radially and outwardly toward final failure. The brown spots were evidently an immediate forerunner of the "tree design," since the first appearance of both occurred when the penetration had reached about five per cent or ten per cent of the total insulation thickness.

Elsewhere than at the complete and partial failures, the insulation seemed only slightly affected by the test. The odor ("mouse-nest odor") which characteristically accompanies insulation tested at high stress was prominent; but no other effects were observed except that on rare occasions traces of wax were found. Several samples were tested after repeated bending produced by rereeling 10 to 15 times around a drum having a diameter of about 16 times the cable diameter. These broke down at 140 kv after durations of 31 to 70 hours. Examination showed that the insulation had been displaced by the handling. This displacement had resulted in regions of wide interturn gaps or valleys between tapes (up to about 0.2 inch as compared with about 0.06 inch before bending) alternating with cross sections where these valleys were practically closed. This characteristic was substantially uniform throughout any cross section. In most of these samples there were several partial failures. All failures and partial failures were in the regions of wide valleys. Most of the cable made for the commercial line was made with slightly smaller valleys and was more resistent to the effect of repeated bending.

Cable handled as severely as required in installation was not affected by the handling. A sample from a length (the leading end of a 1,500-foot length) which had been subjected to excessive pulling strain during installation and had been pulled through about 3,000 feet of pipe, was tested and broke down at about 93 per cent of the voltage of the average new cable.

Impulse Tests

One of the main questions in connection with the *SMD* type cable was whether or not this cable would have a sufficiently high impulse strength if connected to overhead lines or outdoor substations; therefore, impulse tests were performed on samples of this cable. In this paper samples of cable from the experimental line shall be designated as *A*, and samples of cable subsequently produced, each of different construction, as *B*, *C*, and *D*. The *D* construction was used for the commercial installation.

The results of impulse tests on two *A* samples indicated impulse strengths of 680 and 580 kv. These values were not adequate, because a minimum impulse strength of 750 kv was considered necessary to co-ordinate with the 138-kv-class insulation used for the terminals and other apparatus on the system.

Samples designated as *B* and *C* represent two short experimental lengths on which a limited number of 60-cycle and impulse tests were made. On the first of these, satisfactory values of impulse strength were obtained, but the 60-cycle values were too low, whereas on the second type of construction the 60-cycle values were satisfactory, but the impulse strength was too low. Owing to the limited number of tests, the causes of this could not be determined. This became unimportant, however, as tests on cable with the *D* construction indicated satisfactory values both for 60-cycle and impulse tests. Table I shows the results of these impulse tests.

As the maximum potentials produced by the impulse generator did not cause failure in the cable with the improved construction (*D* samples), the actual impulse strength of such cables could not be determined. Breakdowns were obtained, however, on samples on which insulation thickness was reduced by removing a number of tapes from the outside of the insulation. The results of these tests

are shown in Table I, samples D-14 to 19 inclusive. Two reduced insulation thicknesses were selected, so that breakdown voltage values could be conveniently compared with those obtained on other types of cables previously tested.

Figures 14 and 15 graphically illustrate the breakdown voltage values and maximum voltage gradients, respectively, of the samples tabulated in Table I, and compared with the results of previous tests by one of the authors[4] and others,[5,6] on the basis of equal insulation thicknesses. The slanting line on Figure 14 connects minimum breakdown values obtained by the authors and others on oil-

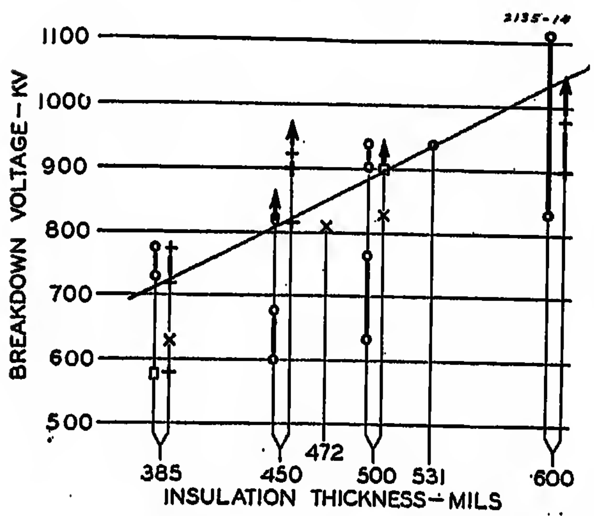

Figure 14. Impulse strength of *SMD* type cable

o—Oil-filled
□—Compression and Oilostatic
X—Solid
+—*SMD*

filled, compression, Oilostatic, solid, and *SMD* cables, having insulation thicknesses of 385, 450, and 500 mils, respectively. These lines were extended to the full insulation thickness range for the D samples, in order to obtain an indication of the impulse strength which otherwise was not obtainable, because of the 1,000-kv limitation of the impulse generator.

From Figures 14 and 15 it is evident that on the basis of *average stress* the *SMD* type cable in the commercial line has an impulse strength as high as has been obtained by various observers for well-made oil-filled cable of standard construction and equal insulation thickness. On the basis of *maximum stress* as customarily calculated, without taking into account the effect of stranding, the impulse strength of the conductor-shielded *SMD* type cable is higher than that of unshielded oil-filled cable. It is thought that the conductor shielding of the *SMD* type cable is responsible for this difference, although the extent of the benefit from this shielding has not been directly determined.

With 600 mils of insulation the impulse strength of the *SMD* cable is in excess of 1,000 kv. These tests indicate that 400 to 425 mils of insulation should be adequate for the desired impulse strength of 750 kv.

Summary

1. Nonleaded high-pressure gas-filled cable can be installed in a steel pipe without the insulation being adversely affected due to atmospheric exposure or mechanical handling.

2. No difficulty was encountered in the installation of 1,500-foot section lengths of cable on the commercial line. Based on the relatively low pulling stresses (7,200 pounds maximum), it appears perfectly feasible to install this type cable in lengths up to 2,000 feet.

3. The use of paper, preimpregnated with viscous compound, prevents migration at normal operating temperatures and allows installation on steep grades or in vertical runs without stop joints or other devices.

4. The satisfactory results on this type of cable are due in part to the development and use of a saturant of high viscosity and of excellent electrical properties.

5. The 60-cycle dielectric strength, both short- and long-time, is equivalent to that of oil-filled cable.

6. The impulse strength is at least the equal of oil-filled cable.

7. Power-factor values are approximately constant over a temperature range of 20 to 100 degrees centigrade.

8. The power factor was not affected even after six months at a temperature of 100 degrees centigrade.

9. The radial power-factor curve is flat even at 80 degrees centigrade, where impurities often cause erratic results.

10. Great uniformity of the insulation is indicated by the fact that on long-time voltage tests there are normally numerous partial failures, in addition to the completed failure.

11. The same insulation thicknesses as used on oil-filled cable can be used on high-pressure gas-filled cable, and all oil-fill cable tests met with a gas pressure of 30 pounds per square inch on reel lengths and 225 pounds per square inch on samples.

12. High-pressure gas-filled cable is practical for handling loads of the order of 100,000 kva and above.

Transient Recovery-Voltage Characteristics of Electric-Power Systems

H. P. ST. CLAIR
MEMBER AIEE

J. A. ADAMS
ASSOCIATE AIEE

1. Introduction

THE existence of transient recovery-voltage phenomena in connection with the interruption of short circuits by circuit breakers has been recognized for a number of years, and from time to time measurements and calculations have been made on actual field circuits.[2,5] However, while these more or less isolated and scattered instances have provided some valuable information, they have not afforded a comprehensive picture of transient-recovery voltage conditions existing in the field.

In order to provide the electric-power industry with a better understanding of and more complete data on transient recovery-voltage conditions, and, perhaps more particularly, to provide such data as a guide to the circuit-breaker designers, a field survey of several representative electric-power systems was recently carried out under the sponsorship of the committee on electric switching and switchgear of the Association of Edison Illuminating Companies. By permission of that organization and the participating electric power companies, some of the outstanding results and conclusions from this survey were made available to the AIEE committee on protective devices for presentation in this paper.

2. Transient Recovery Voltage—Theory and Definitions

While a number of excellent papers covering this phenomenon have been published in the literature,[1-6] a brief review is believed to be in order here.

The term recovery voltage applied to a circuit breaker refers to the voltage established across the open contacts after the arc is extinguished. The initial or transient recovery voltage is produced by a sudden change in circuit conditions, and its characteristics are determined by circuit constants. The normal-frequency recovery voltage is the generated system voltage finally maintained across the open contacts after the transient voltages have disappeared.

Since short-circuit currents are generally limited principally by reactance, it follows that the current is nearly 90 degrees out of phase with the voltage. Consequently, at the point of arc interruption, normally on or near the zero point of the current wave, the generated voltage is close to its maximum peak value. The voltage at the breaker, of course, prior to interruption, is held down to zero or nearly zero by the short circuit, but upon arc interruption attempts to recover immediately to the peak value of the wave. It is prevented from doing so instantaneously, however, by the effective capacitance across the breaker contacts, and there results instead a transient recovery-voltage oscillation. The frequency of this oscillation is determined by the inductance and capacitance of the circuit; the amplitude may reach double the normal-frequency crest voltage. In general, the combination of lumped reactance in the circuit between breaker and power source, with low capacitance-to-ground in the circuit between breaker and reactance, gives rise to the highest oscillating frequencies.

The severity of a given circuit is commonly characterized by the *rate of rise of transient recovery voltage*, which is determined by drawing a line from the zero point of the oscillating voltage wave, either to the peak of the first loop of the transient voltage oscillation, or as a tangent to the first voltage loop. This simple procedure, however, is not always adequate. The circuits involved are generally somewhat complex, so that the *transient recovery-voltage characteristics* are usually compounded of two or more superimposed oscillating frequencies. If, as occasionally happens, the first high-frequency loop has a smaller amplitude than a succeeding lower-frequency crest, the significance of rate of rise based upon the higher frequency but lower amplitude oscillation, may be decidedly questionable and subject to arbitrary judgment.

To avoid this difficulty, the complete transient recovery-voltage characteristic of a circuit should be determined. This characteristic, modified by circuit-breaker and test factors as described below, may be obtained directly from oscillograms taken in short-circuit tests, or it may be calculated from the constants of the circuit. In the AEIC survey of electric-power systems mentioned above, circuit characteristics were calculated in this manner, and the results were obtained in terms of an envelope of the transient recovery-voltage characteristics, composed of two and sometimes three major frequency components. In order to bring the task of calculating such characteristics within feasible limits in terms of man-hours of work required, certain approximations and simplifying assumptions were necessarily employed. A complete description of this simplified method of calculation, including the limits of accuracy obtained, is given in a companion paper.[7]

3. Results of Survey of Power-System Transient Recovery-Voltage Characteristics

The survey, which was made entirely by calculations except for direct measurements of a few circuit capacitances, was carried out on the systems of six power companies, selected as representing both concentrated urban types and distributed types of systems. Practically all of the circuit-breaker locations on these six systems were covered either by actual calculations or by a comparative estimating procedure. Where the system connections varied somewhat with different operating setups, and also where the assumed location of the fault affected the severity of the recovery-voltage characteristics, the calculations were made on the basis of the conditions which would give the most severe characteristics. With these results on the six systems covered by the survey, it was felt that a sufficient cross section had been obtained to draw general conclusions as to the transient recovery-voltage conditions existing throughout the industry.

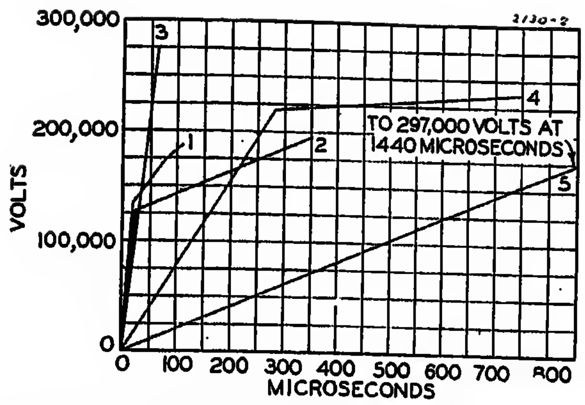

Figure 2. Representative envelopes of transient recovery voltage for 120,000- to 132,000-volt systems

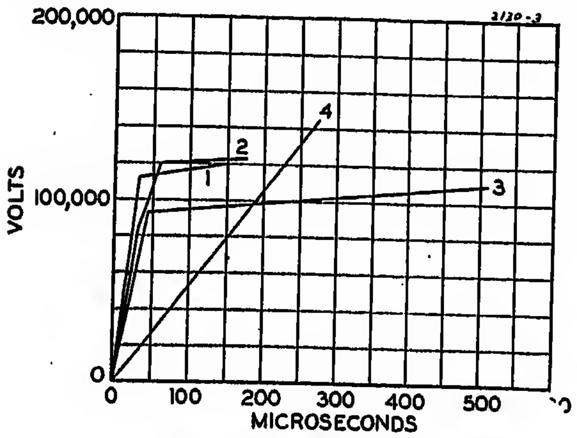

Figure 3. Representative envelopes of transient recovery voltage for 69,000-volt systems

As stated above, the survey was carried out on the basis of determining the envelope of the recovery-voltage characteristic, rather than on the basis of a simple rate of rise of transient recovery voltage. A typical recovery-voltage envelope, together with the complete oscillating characteristic from which it was drawn, is shown in Figure 1. Also groups of typical recovery-voltage envelopes, shown in Figures 2 to 6 inclusive, were chosen as illustrations from each of the following voltage classifications:

120,000- to 132,000-volt systems
69,000-volt systems
22,000- to 34,500-volt systems
11,000- to 13,800-volt systems
4,000- to 4,800-volt systems

For practical purposes, the envelope is sufficient to define the transient recovery-voltage characteristic, since it gives the magnitude of the first peak and the maximum peak, as well as any intermediate peaks found to be significant. Only the first peak and the maximum peak were recorded when the intermediate peaks were found to be less in amplitude than a corresponding point in time on the envelope connecting the first peak and the maximum peak. In other words, an intermediate peak was included if it raised the envelope, but not if it caused the envelope to drop below a straight line drawn between the first and maximum peaks. Also the envelopes were not extended beyond the point of maximum peak.

An analysis of the recovery-voltage curves shown in Figure 2 indicates a wide range of rates of rise for the various curves. Based on the first peak, curve 1 shows a rate of 8,300 volts per microsecond, while curve 5 shows only 210 volts per microsecond. The higher rates shown in curves 1 to 3 were obtained in connection with breaker locations where the fault was limited by a transformer fairly near the breaker, whereas the lower rates of curves 4 and 5 resulted from locations where there was no large lumped reactance in the circuit close to the breaker. Further examination of curve 1 shows that the first peak, which is 71 per cent of the final peak, occurs in 16 microseconds, the second peak in 80 microseconds, while the final and maximum peak is reached at 110 microseconds. Curves 2 and 4 show only

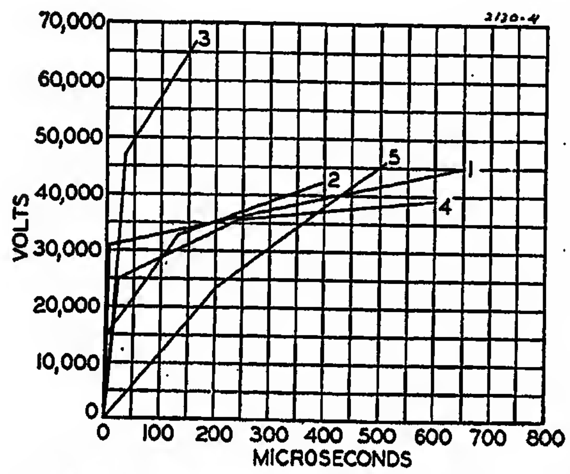

Figure 4. Representative envelopes of transient recovery voltage for 22,000- to 34,500-volt systems

two peaks, while curves 3 and 5 reach maximum values without any significant intermediate peaks. Figures 3, 4, and 6 in like manner show various typical characteristics for their respective voltage classes.

The envelopes shown in Figure 5 have been drawn in two ways:

1. With a scale going to 1,000 microseconds in order to include the complete characteristic.

2. With a scale of only ten microseconds in order to show the relatively high-speed transients in greater detail.

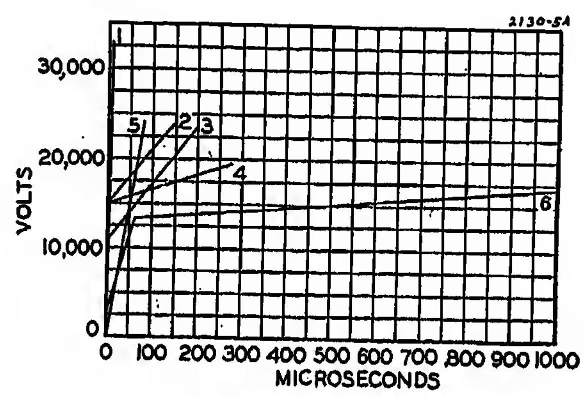
Complete numerical results of the survey were tabulated in terms of the information given on the envelope, that is, in terms of two or three significant peaks, and the time in microseconds required to reach each of these peaks. While these tabulations are not reproduced in this paper, the net results of the survey, in terms of rate of rise of transient recovery voltage, are given graphically in the form of cumulative percentage curves, shown in Figures 7 to 11 inclusive. The rate of rise used in these curves is based upon the first peak of the recovery characteristic, except in cases where this peak was found to be of abnormally low magnitude compared with later peaks.

The abscissae of these curves show the percentage of breaker locations where the rate of rise exceeds the value given by the ordinate. For example, referring to Figure 7, only 15 per cent of the breaker locations may be subjected to rates of rise of 5,000 volts per microsecond or higher. Also, it will be noted that 53 per cent of the breakers are located where the rate of rise does not exceed 1,000 volts per microsecond; the remainder of the breaker locations, or 32 per cent being subjected to rates of rise between 1,000 and 5,000 volts per microsecond.

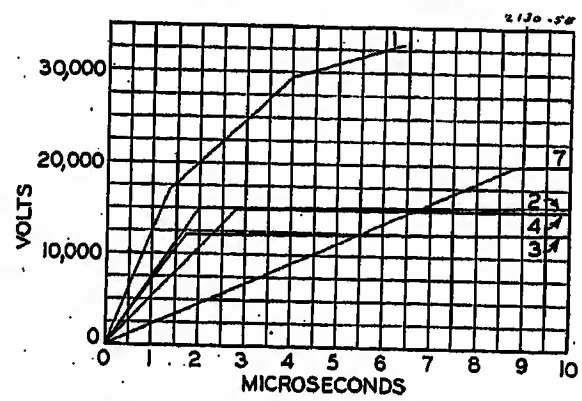
All of these results, of course, are given in terms of the characteristic of the circuits themselves and do not take into account the various factors which tend to modify the severity of the recovery-voltage characteristics actually obtained on a breaker. These factors include:

(*a*). Asymmetry of the current wave.

(*b*). Decay of flux in generators during short circuit.



5A—Envelopes to maximum peak



5B—Envelopes for first ten microseconds only

Figure 5. Representative envelopes of transient recovery voltage for 11,000- to 13,800-volt systems

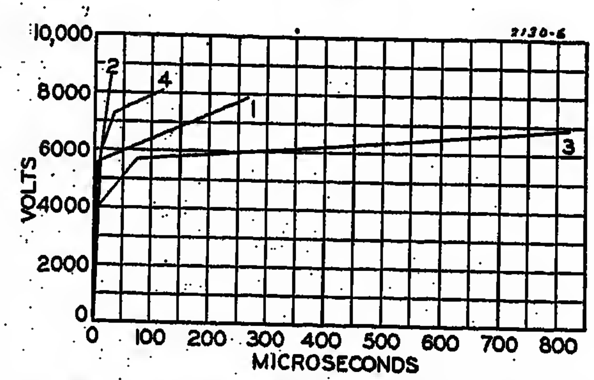


Figure 6. Representative envelopes of transient recovery voltage for 4,000- to 4,800-volt systems

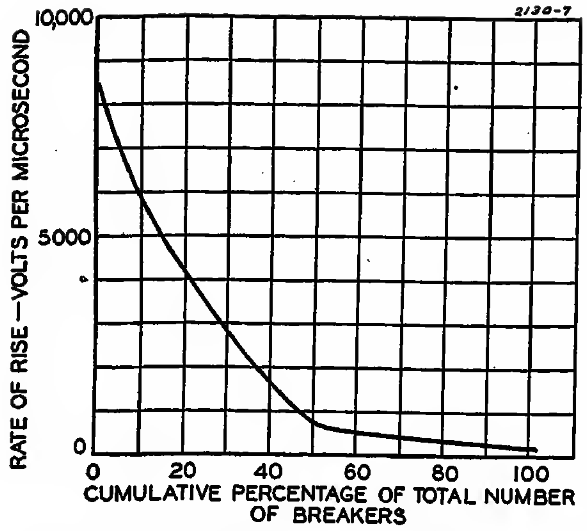

Figure 7. Cumulative percentage curves of rates of rise of recovery voltage for 120,000- to 132,000-volt systems

(Based on 345 breakers)

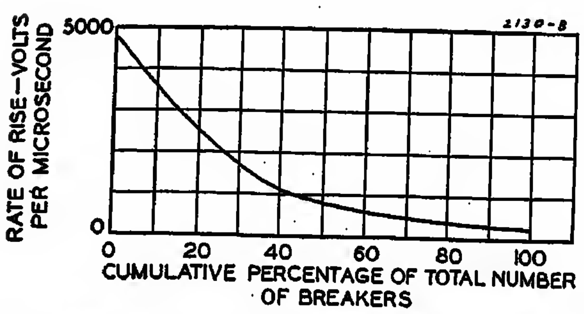

Figure 8. Cumulative percentage curves of rates of rise of recovery voltage for 69,000-volt systems

(Based on 342 breakers)

(*c*). Arc-voltage drop in the fault.

(*d*). Arc-voltage drop in the breaker.

(*e*). Conduction of current in the breaker after current zero.

In general, the above factors tend to reduce the severity of the recovery-voltage characteristic. On an actual circuit-breaker test, it is usually possible to account for the effect of these various factors by analyzing oscillograms of recovery voltage taken on the test and thereby to obtain a check on the calculated values.

The results of the survey, as summarized in Figures 7 to 11 inclusive, have shown that some of the calculated circuit recovery-voltage rates are substantially higher than the maximum rates disclosed by previous scattered information on this subject. Also the results show that the occurrence of high values of circuit recovery-voltage rates (on the order of 5,000 to 8,000 volts per microsecond) is considerably more widespread than had previously been suspected.

4. Significance of Results and Conclusions

In appraising the significance of these results, it is necessary first of all to take into account the modification of the maximum rate of rise of recovery voltage which is brought about in actual circuit-breaker operation. The data presented in a companion paper indicate the possibility that, for certain types of breakers at least, the effect of the breaker in reducing the severity of these transients increases as the calculated circuit values increase. Therefore, this may limit the actual rate of rise which a circuit can impress across the contacts of a breaker, regardless of the constants of the circuit. If this effect is rather general for breakers now in service, it may constitute one of the reasons why few outstanding instances of extreme rates of rise causing difficulty in the operation of circuit breakers have been recorded.

As to the significance of these results to circuit-breaker users, particularly in the operation of the great number of breakers already in service, and in view of the greater prevalence of fairly high rates of rise of recovery voltage than previously suspected, it may be said that there have been some but only a few instances recorded where circuit breakers were subjected to greater distress while interrupting short circuits under high rates of rise than under low rate conditions. In the group of systems covered by this survey, a study of operating records failed to disclose a systematic correlation between recovery rates and breaker distress or failures. Such effects as undoubtedly do exist would be evidenced in increased arc lengths and some additional maintenance due to increased burning and other phenomena. Experience seems to show in general, however, that circuit breakers have been designed with sufficient stroke to take care of even the highest rates of rise of recovery voltage, so that cases of breaker trouble directly attributable to recovery rates have been very rare.

On the other hand, it is believed that the results of the survey will be of major significance and importance in connection with the design and manufacture of circuit breakers. Important elements in the design, such as length of stroke and similar considerations, are determined to a large extent by rate of rise of recovery voltage. Therefore, while it may fortunately be true that liberal design allowances, combined with circuit-breaker modifying effects, have in the past produced breakers capable of withstanding the severe transient recovery-voltage conditions that are now known to exist, it may be more important in the future, particularly in connection with the development of radically new designs of circuit breakers, to have available a true picture of recovery-voltage requirements. It is believed that the results of the survey

Emergency Overloads for Oil-Insulated Transformers

F. J. VOGEL
MEMBER AIEE

T. K. SLOAT
NONMEMBER AIEE

IN periods of high industrial activity transformer loads are generally high, and it is essential that operators know what overloads they can carry safely in emergencies. In order to do this effectively, it is necessary to know what temperatures will be reached after various overloads for different durations of time and the effects of temperature and time on the dielectric and mechanical strength of the insulation. If limitations between these things and the degree of insulation deterioration can be established, it is possible to make recommendations for safe overload times and temperatures.

In Part I of this paper some new data are presented on the effect of temperatures and oil acidity on the insulation, and some recommendations for maximum temperatures and their duration are made. This paper differs from previous studies on this subject in that definite evaluation of the effect of acidity on the insulation strength is given. Acids are formed in service by contact between oxygen and transformer oil. Excluding this contact by blanketing the transformer with inert gas results in a high mechanical strength of the insulation at a given temperature and time, or, conversely, permits a high operating temperature for a given loss in life. In considering this paper, it should be borne in mind that the data refer to the mechanical strength of the insulation only. Neither the 60-cycle nor the impulse dielectric strength are affected to any extent by the conditions of test. The true criterion of insulation deterioration therefore is not mechanical strength alone, but the dielectric strength must be given due consideration. Experience has shown that satisfactory operation can be obtained with much reduced mechanical strength.

Even after the recommendations for temperatures and time duration for insulation are made, it is necessary to know the overloads and times which will give corresponding temperatures. Various sizes and types of transformers vary widely in this respect. Some transformers which are well ventilated may have low gradients and correspondingly high overload capacities; most of the larger power transformers come within this class. Smaller transformers are wound with small wire with many turns in a single coil. They will normally have much higher gradients between copper and oil and correspondingly lower overload capacities. In Part II the characteristics of these various types of transformers are given along with recommendations for safe emergency overloads for given time and temperature limits.

Paper 42-101, recommended by the AIEE committee on electrical machinery for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 10, 1942; made available for printing May 14, 1942.

F. J. VOGEL is consulting engineer of the Westinghouse Electric and Manufacturing Company, Sharon, Pa.; T. K. SLOAT is with the same company.

Part I. Effect of Temperature on Cellulose Insulation

The life of cellulose insulation is decidedly influenced by three factors, namely, temperature, contact with oxygen, and exposure to acidity. Doctor C. F. Hill[1] has shown that cellulose insulation is stable for long periods of time below 90 to 95 degrees centigrade, when protected by an inert atmosphere. Doctor F. M. Clark[2] has classified the mechanical deterioration of cellulose as being caused by oxidation, pyrochemical changes, or both.

The object of this paper is to give additional evidence in regard to the rate of deterioration of cellulose insulation and to show that transformers can be exposed to short-time overloads even at high temperatures without damaging the mechanical strength of the insulation to a great extent.

Figure 1 shows the decrease in tensile strength of Manila paper when sealed at atmospheric pressure in an oxygen-free atmosphere. It is interesting to note the rapid decrease in tensile strength which takes place at 135 degrees centigrade. This occurs when temperatures are maintained at which thermal decomposition takes place. At 120 degrees centigrade, the tensile strength drops to approximately 50 per cent and levels off. It would appear that this 50 per cent strength would be maintained for long periods of time. Figure 2 shows the change in acidity of oil with Manila paper in oxygen-free oil protected by a nitrogen atmosphere. One of the main products of thermal decomposition is the formation of acid which forms a catalyst for further decomposition. The inert atmosphere prevents the formation of acid product at 120 degrees centigrade and below, showing the decided advantage of protecting the oil of a transformer against exposure to air.

The same data for Figure 1 are used to produce Figure 3. The remaining tensile strength of Manila paper after exposure to different temperatures in oxygen-free oil for different periods of time is plotted in this figure with temperature and time as ordinate + abscissae. These curves are of special interest to both the designer and the operator of transformers, because they can be used to predict the amount of mechanical damage done to transformer insulation after it has been operated at given temperatures for specified lengths of time. For example, if not less than 50 per cent mechanical strength is required at all times, it is interesting to see that the total period of operation at 140 degrees centigrade should be not

will have their greatest value in providing this information.

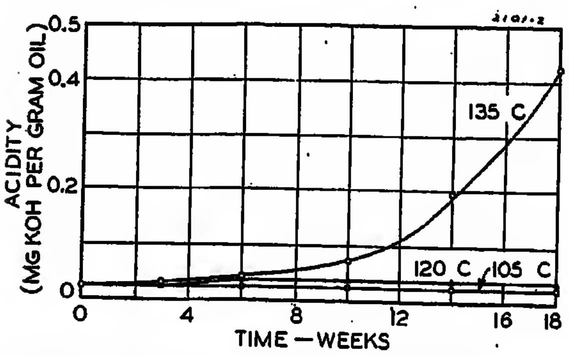

Figure 2. Change in acidity of oil with Manila paper in oxygen-free oil protected by a nitrogen atmosphere

more than two days, because in this time the *cellulose* has decreased in tensile strength to 50 per cent. However, with overloads at which the temperature reached only 135 degrees centigrade, a total of five days would be possible. If 40 per cent of the original mechanical strength is the lowest desired, a total of nine days at a temperature of 135 degrees centigrade may be allowed.

Figure 4 is a plot of the lowest tensile strength for paper insulation after 18 weeks under oxygen-free oil at various temperatures. From this figure one can select the temperature for transformer operation when the ultimate tensile strength has been selected. For example, if not less than 60 per cent of the original strength is required, the operating temperature should never be more than 115 degrees centigrade.

Based on the above data, the following practical conclusion might be drawn. The load which may be carried in the operation of a transformer is governed by the desired life of the transformer. From the experimental data presented here it is felt that an oil-insulated transformer may be operated at temperatures up to 120 degrees centigrade continuously, and even above, during short-time overloads, without seriously damaging the insulating materials, provided an inert (oxygen-free) atmosphere is maintained in contact with the oil at all times, and provided the acidity of the oil in contact with the insulating materials is maintained at a low value. Below 120 degrees centigrade the main deterioration in mechanical strength is caused by oxidation, while above this temperature the thermal decomposition of the cellulose is very detrimental. The thermal change results in the formation of gases, water, and other decomposition products. Oxidation, which takes place below 120 degrees centigrade, is eliminated to a very large extent by the use of an inert atmosphere.

Figure 5 shows the decrease of tensile strength of Fuller board when included with a varnished cotton tape in oxygen-free oil protected by a nitrogen atmosphere and at atmospheric pressure. It is quite interesting to compare this curve with Figure 1. At 135 degrees centigrade, the rate of decrease in tensile strength is quite similar to that of paper with no acids present other than those from decomposition. The decided effect of the acidity can be seen at 120 and 105 degrees centigrade. At 120 degrees centigrade, the final tensile strength is less than twenty per cent as compared with 54 per cent with no acids present; and for 105 degrees centigrade, 44 per cent as compared with 72 per cent. It would appear from these comparisons that it is of utmost importance to maintain low acidity and to avoid acid-forming materials in the construction.

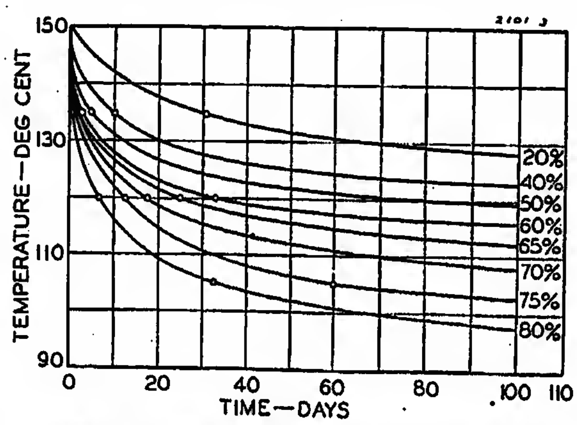

Figure 3. Percentage of initial tensile strength reached by Manila-paper insulation in oxygen-free oil protected by a nitrogen atmosphere

The acidity in contact with the Fuller board samples from the varnished cloth is shown in Figure 6. While these acidities are higher than those of usable transformer oil, it simulates the effect of lower acidities over longer periods of time.

The data for Figure 3 are used again to produce Figure 7. The curves show the part of the initial tensile strength remaining at the end of various periods versus temperature. If we choose 50 per cent as the minimum mechanical strength required, this would be reached in 1.5 days compared with two days from Figure 3. Likewise, at 135 degrees centigrade, the insulation would have reached 50 per cent strength in three days. For 40 per cent strength the total time of overloads could be seven days, compared with nine days with low acidity. A significant difference between this figure and Figure 3 is that the tensile strength continues to decrease even after 100 days, while in the low-acidity oil the decrease in tensile strength shows a greater tendency to reach a constant value for a given temperature.

Figure 8 shows the lowest tensile strength for Fuller board insulation after 18 weeks of exposure to high-acidity oil. If we choose 50 per cent as the minimum required tensile strength, the operating temperature should not be more than 100 degrees centigrade. However, this is for a period of only 18 weeks and since the tensile strength continues to decrease, due to the presence of acids, it would indicate a still lower temperature.

The curves of Figures 5 and 8 show that the presence of acids in contact with cellulose insulation seriously catalyzes not only oxidation changes but also thermal decomposition. Care should be taken to maintain low-acidity oil in order to obtain the longest life from the cellulose insulation. Varnishes and varnished tapes have been a source of acids in transformers. The use of synthetic materials in place of natural varnishes in modern transformer construction has practically eliminated this source of acids.

Figure 9 shows the similarity in behavior between Fuller board and paper insulation. The Fuller board was in contact with oxygen-free oil under the same conditions as for Figure 1. While the Fuller board is some better at 105 and 120 degrees centigrade, it is interesting to note that at 135 degrees, thermal decomposition destroys most of the tensile strength.

Figure 10 shows the rate of increase in acidity of oil samples with the same materials as for Figure 6, except that the oil has free access to the oxygen of the air. Here the acidity shows a decided increase in 18 weeks, much greater than in Figure 2. Comparison of these figures shows that to obtain full advantage of preserva-

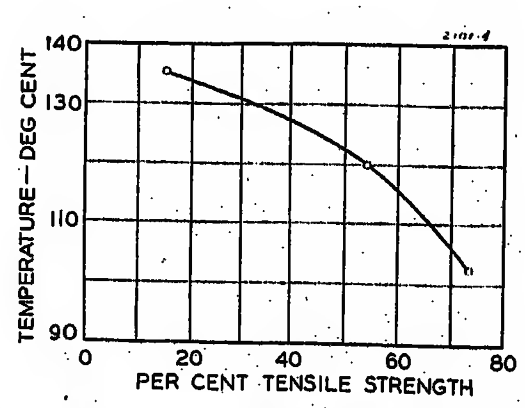

Figure 4. Lowest tensile strength for paper insulation after 18 weeks under oxygen-free oil protected by a nitrogen atmosphere

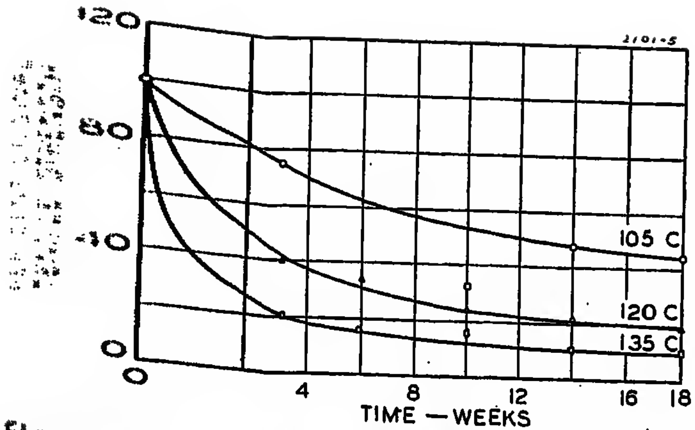

Figure 5. Decrease in tensile strength of Fuller board, together with varnished cloth, in oxygen-free oil protected by a nitrogen atmosphere

tive measures in transformers, no acid-forming varnishes or treatments should be used.

Figure 11 shows test data taken on paper in transformer oil at various temperatures with the samples open to the air. Comparison of these curves with Figure 1 shows the great benefit obtained by protecting the samples from oxygen, particularly at temperatures of 120 degrees centigrade and less.

It is possible from the data given above to make recommendations for short-time emergency overload temperatures of transformers based on given amounts of decrease in mechanical strength of the insulation. One set of values that has been proposed is given in Table A.

Inspection of these values will show that if a given temperature from the table were reached 20 times for the time specified, the insulation would have a tensile strength of approximately 80 per cent of its original value. If emergency overloads of the same character as described in the table were to be applied once a year for 20 years, we would, therefore, not expect that the insulation would be appreciably lower than 80 per cent of its original value. Figure 3 is used in reaching this conclusion. This assumes that there was no deterioration due to steady operation. It would be more practical, however, to consider that the transformer might reach 105 degrees hot-spot temperature for considerable durations of time, and, if this were true, its mechanical strength would be somewhere between 80 and 75 per cent of its original value. If the emergency operations were to take place after this initial deterioration, a method of estimating its ultimate deterioration is as follows:

Suppose we were to consider that there would be 20 overloads for 24 hours which would reach 115 degrees; then the deterioration due to the steady load would be equivalent to approximately 24 days at 115 degrees without the deterioration due to the overload. The additional 20 days would then be equivalent to 44 total days at 115 degrees, which would result in approximately 65 per cent of the original mechanical strength of the insulation. Similar methods of calculation could be used for any of the other emergency overload temperatures. If an operator desired to determine the amount of deterioration under other conditions of loading and time, the curve data provide an easy graphical method for making such an estimate.

It is believed that the decrease in mechanical strength resulting from Table A is reasonable and safe for general use. The ultimate strength requirements depend upon many factors determined by service conditions. The severity and frequency of short circuits is an important factor, as well as whether or not the apparatus remains fixed or is to be transported. Since the dielectric strength remains practically unchanged, a reduction of 40 to 50 per cent in the mechanical strength of the insulation over a 20-year period would not be considered excessive for normal operating requirements.

Summary

New data on the rate of deterioration of cellulose insulation at different temperatures have been obtained. From them a table of time periods and temperatures has been made at which oil-insulated transformers may be operated in order that specific cellulose insulation strengths of approximately 65 per cent of the original value may be maintained. It is expected that this value will be maintained even after operation of a considerable length of time at 105 degrees centigrade.

Part II. Recommended Emergency Overloads for Transformers

After Table A in Part I has been established, it is still necessary to correlate the data with overloads which will result in these temperatures after given lengths of time. In order to do this, it is necessary to know what the characteristics of average transformers are, both in respect to the gradient between the insulation and the oil, and the length of time which it takes for the oil to reach given temperatures under given load conditions. Data may be found in several places for estimating the gradients between oil and insulation and also the rate of oil rise during transformer overloads. One such reference is a recent paper on "Hot-Spot Temperatures in Transformers."[8] Before these data can be used, however, it is desirable to establish available characteristics for several sizes of transformers.

It is suggested that seven classes of

Time constant	3	4	2.5	6	4	4	2.5

transformers be considered. These classes may be described as follows:

Class 1. Many transformers use round wire, and there is a considerable gradient between the center of such coils and the oil. There are also some ribbon-wound coils, which have several layers and several turns per layer. We suggest that this class include transformers up to 150 kva, 25 kv, and transformers with windings of all voltage classes rated at 15 amperes or less. This class is to be oil-insulated, self-cooled.

Class 2. The next larger transformers than those described in class 1 generally have strap windings with at least one side or edge of each conductor exposed to oil. Surely, up to 69 kv such transformers would not have heavy conductor insulation; therefore, this class is limited to power and distribution transformers up to 69 kv, oil-insulated, self-cooled.

Class 3. This class is similar to class 2 except that it is for forced air-cooled transformers.

Class 4. Some transformers include regulating equipment and are used as unit substations. Such transformers are very similar to the ordinary self-cooled transformer with the exception that the tank is larger, and there is much more oil used than in the ordinary self-cooled transformer. The result is that the transformer has a longer time constant than the ordinary self-cooled transformer. It is suggested, therefore, that class 4 include transformers such as unit substation transformers and be similar to class 2 except for longer time constants.

Class 5. It is suggested that this class include oil-insulated unit substation transformers, which are cooled with forced air. This class is then the same as class 3, except that the transformers have longer time constants.

Class 6. Large high-voltage power transformers may require heavier insulation on the conductors than smaller transformers. This, in turn, will result in higher gradients between the copper and the oil. Therefore, slightly different characteristics should be used for these transformers than for smaller units exemplified in class 2; class 6 should be approximately the same as class 2 except for higher gradients.

Class 7. It is suggested that class 7 correspond to class 6 except that the transformers have forced air-cooled ratings.

A tabulation of the proposed characteristics of these various classes is given in Table I, and it might be well to describe how the various values were obtained. For example, in class 1 the designer can calculate the watts per square inch of losses transmitted from the coil surface to the oil. From this, he can make an approximate estimate of the gradient between the coil and the oil, based on designs in common use. For class 1 this gradient should be in the order of and not exceeding 20 degrees centigrade at normal load. Likewise, the top oil rise is in the order of 40 degrees for such transformers. The difference between average oil and top oil is in the order of five degrees. The loss ratio refers to the ratio of the copper loss to the iron loss at rated load, and this loss ratio approaches limits now commonly used. Time constants are given in hours. These values are average values for transformers of the ratings referred to above.

In a previous paper[3] a method was indicated for calculating transformer hot-spot temperatures. In this paper it was shown that changes in viscosity tend to decrease gradients at high oil temperatures. These decreases further tend to counteract increases in gradients due to losses. Therefore, no great error should result if the change in copper resistance were ignored. This is not exactly true but probably is within reasonable error, considering that average characteristics of transformers are being considered. On this basis, it would be reasonable to assume that the gradient between the copper and oil varies approximately as the 0.8 power of the copper losses, which, in turn, are assumed to vary as the square of the load.

In the paper[3] previously mentioned, a method was shown for calculating oil temperatures after short-time loads. Cal-

ations were made on the basis of aver- oil temperatures, and an approxi- te constant value added to them. The thod in common use before was to :ulate the top oil temperatures directly. nparative calculations show that there 10 great difference between the two :hods of calculation. For the purpose implicity and also for greater conserv- m, it is intended to use the older and pler method in this paper.

'or example, suppose we take class 1 calculate the overload, which can be ied for eight hours to reach a tempera- of 120 degrees centigrade, at an ient temperature of 30, following full . As shown in the preceding paper, easiest to use "cut and try" methods, a value of 135 per cent load can be med as a basis. At 135 per cent load copper losses will be 1.82 times as t as at full load. If the total losses at load in the first case were 3.5 times ron loss, in the second case it would be times the iron loss. If the top oil were 40 degrees in the first case, it d be ultimately, $\frac{(5.55)^{0.8}}{(3.5)}\times 40$ degrees)proximately 58 degrees centigrade. change in load from full load to 135 ent results in an ultimate change in emperature of 18 degrees. This ge will not be entirely completed in hours, and the rise which will result it time will be:

$=18(1-e^{-8/3})=$ approximately 17 de-

means that the oil rise after eight will be 57 degrees.

: gradient at full load is given as grees. At 135 per cent load the r loss is 1.82 times the value at full and the gradient should be $1.82^{0.8}$ times as great as the gradient at ad. 1.6×20 degrees is 32 degrees. otal temperature would be the sum ambient temperature, 30 degrees, e gradient between air and top oil, rees, plus the gradient between oil pper, 32 degrees, or a total of 119 s centigrade. Since this tempera- s slightly below the 120 degrees d, this percentage was considered ntly accurate for use in Table II.

ill be seen upon inspection of Table : the proposed overloads are much than those previously recom- d for use in the American Stand- ssociation Guides for Operation ansformers. This occurs, partly the original guides did not tiate between different types of rmers, and partly because tem- e rises which were permitted were lower than those proposed in Part I of this paper. Still another reason is that the number of emergencies was not specifically limited, and in the present paper 20 are assumed, on the basis of 20-year life and one emergency per year on the average. It is felt that sufficient information is given in this paper to permit the operator to use judgment and discretion in specifying safe overloads for his application.

A New Jewel for Indicating Instruments

F. K. McCUNE
ASSOCIATE AIEE

J. H. GOSS
ASSOCIATE AIEE

IT has been almost universal practice to use highly polished sapphire jewel bearings, cut approximately in the form shown by Figure 1a, in electric indicating instruments. Such a jewel is commonly known as a "Vee." The other member of the bearing is a cone-shaped piece of hardened steel or other hard metal also accurately cut and highly polished. Figures 2 and 3 show both the common proportions of these parts and the clearances involved. Figure 2 shows an instrument which has the moving shaft vertical, and Figure 3 an instrument with the moving shaft horizontal. Figure 4a shows typical moving systems and jewel settings.

The making of sapphire Vees is a very highly specialized art, and the great majority of machine equipment and trained personnel has been concentrated in a small area in Europe, the principal production being in Switzerland.

The present conflict has cut off the source of supply of instrument bearings and has left this country with inadequate facilities for their production. Accordingly, it has been necessary to find substitutes. Furthermore, because of the vital part that instruments play in devices for the armed forces and industry, it has been necessary to find a substitute which would not in any way impair the usefulness of the instruments even under abnormally severe conditions of use.

Fortunately, instrument manufacturers have a good deal of experience to fall back on. About 30 years ago, the present so-called "miniature instruments" (Figure 4) were introduced, and the demand for them has steadily increased, particularly in the communication industry. Because of the light weights of the moving systems and proportionately lower torques available, the radius of the pivot used was considerably smaller than that used in larger instruments. This created a demand for a sapphire jewel with a correspondingly smaller radius of the spherical surface in the bottom of the Vee.

In general, the problem of producing a sapphire jewel of the required shape resolves itself into that of cutting very accurately to shape a piece of sapphire, which is in a group of materials next in hardness to diamonds. The reason that the shape is particularly difficult is that the apex of the Vee must be accurately spherical, with a radius of from 0.002 to 0.004 inch, and the side tangent to the spherical surface must be straight. At the center of the spherical surface if, for example, the cut in the sapphire is made in a lathe, the linear cutting speed is zero and even at a speed of, say, 30,000 rpm at a distance of 0.001 inch from the center, the cutting speed is only 0.3 foot per sec-

(*a*). For a-c instruments
(*b*). For d-c instruments

ond. Also, as can be seen from the dimensions (Figure 1a), the cutting tool must be small in size. Therefore, the tendency in cutting, smoothing, or polishing is to produce a surface which is not truly spherical, but has either a lump in the center because of the low cutting speed, or a hollow which may be produced by crushing the center instead of cutting it.

As mentioned before, the small sapphire jewel for miniature instruments was necessary to limit the amount of side play in the jewel. As can be seen from Figures 2 and 3, the side play may amount to more than the end play. It is of importance both from the standpoint of its effect on mechanical clearances, and because excessive side play introduces uncertainty of pointer position. The latter is of most concern when the instrument may be used sometimes with shaft horizontal and at other times with shaft vertical. Referring to Figure 3, it is obvious that the only way to get a small degree of side play in a jewel of inherently large radius is to reduce the clearance between the pivots and the bottom of the jewels to a small fraction of a thousandth of an inch. This is an impractical solution, because of the hazard of very slight dimensional changes causing stickiness in the instrument, and because of the wedging action caused by the very small angle of slope of the jewel near the center.

The generally unsatisfactory contour in jewels available at the time led manufacturers to look for substitutes which could be produced by other methods. As a result of a large amount of development work done in the General Electric Company laboratories about 25 years ago, a method of producing a jewel by forming a drop of fused "hard glass" was developed. These jewels had very accurately controlled contours, since the glass could be made to almost any desired shape. The general shape is shown in Figure 1b. They also had very smooth highly polished surfaces. In respect to shape they were far superior to the sapphire then readily available. Such jewels had, however, two defects:

1. The manufacture had to be very carefully controlled and was not quite as simple as the description above may sound.
2. The jewel would show a microscopic indentation under an impact such as that produced by dropping the instrument, or by a heavy blow on the mounting panel.

This microscopic blemish in the surface would, however, in general not be noticeable in the performance of the instrument unless the pivot happened to run on the exact spot where the blemish had been made. Even in the latter case, the performance of the instrument would not be materially affected, unless a large number of pointer oscillations or the presence of vibration caused excessive wear at the roughened spot.

As has been mentioned before, a large number of these jewels were used, and their use probably served as an incentive to better the quality of sapphire jewels. In any event, after the hot-formed jewels had been used for several years, sapphire jewels became available with much improved contour, smaller radius of the spherical surface in the bottom of the Vee,

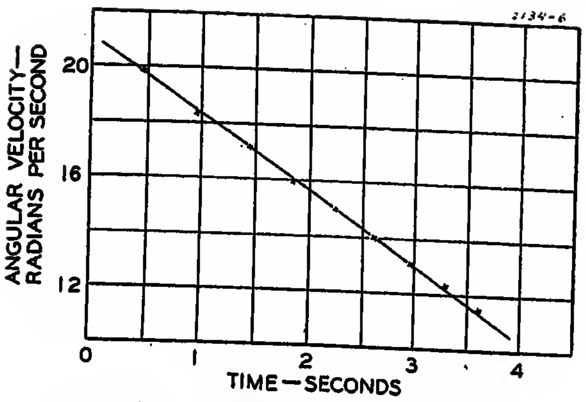

Figure 6. Velocity versus time curve

Deceleration 2.66 radians per second per second

and in every way suitable for instrument use. As a result, the use of the hot-formed jewel was practically abandoned although they have been used in certain instruments from time to time with satisfactory field performance.

The present emergency made necessary a review of the whole situation and the following steps were taken:

1. The performance of the hot-formed jewels and sapphire jewels was carefully re-evaluated.

2. A search for the optimum material for a hot-formed jewel was started, since it was recognized that new materials might be available which would be distinctly superior to that chosen as the best 10 or 15 years ago. The evaluation of relative performance of the hot-formed jewel and the sapphire jewel was carried out in the following manner with results as shown in the corresponding tables and figures:

(*a*). *Friction.* One criterion of instrument performance is that portion of the error in an instrument with a horizontal shaft caused solely by the friction between the pivot and jewel. This, when measured by noting the difference between upscale and downscale readings untapped in an instrument free from magnetic hysteresis, is known as jewel roll. Jewel roll, expressed in radians, is a function of moving system weight, restoring torque, radius of the pivot, and coefficient of friction between pivot and jewel. The formula has been given as follows: for the usual case where the end of the pivot is spherical and the surface of the jewel conical:[1]

$$\text{Jewel roll} \propto \frac{WCr}{K}$$

W—weight of the moving system in grams

C—coefficient of friction between the pivot and jewel

r—radius of the spherical end of the pivot in millimeters

K—restoring force in gram-millimeters per radian

In order to determine the friction between an instrument pivot and the corresponding jewel surface, two jewels of the material to be tested and a rotating member made up to approximately duplicate an instrument moving system were mounted in a vacuum (Figure 5). The moving system was made to rotate, the force causing this rotation was removed, and the deceleration measured. Figure 6 is a typical deceleration curve. From this deceleration, the moment of inertia, and dimensions of the parts involved, the coefficient of friction was calculated. While not having direct bearing on this investigation, certain data taken on ringstone jewels are included.

Table I. Measured Coefficient of Friction When Run Against a High-Carbon Steel Pivot

Material	Form	Coefficient of Friction
Sapphire	Ring	0.140
Leaded Brass	Ring	0.188
Plastic *A*	Ring	0.160
Plastic *B*	Ring	0.190
Graphite	Ring	0.160
Sapphire	Vee	Range 0.15 to 0.19
Glass	Vee	0.18
Material *H* (Figure 11)	Vee	0.18
Ceramic polished	Vee	0.28
Ceramic unpolished	Vee	0.33

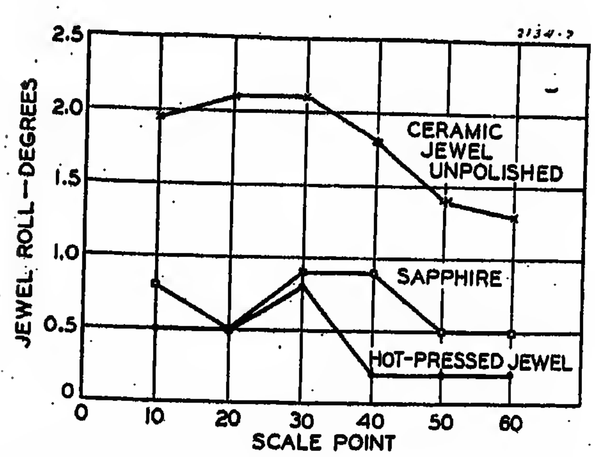

Figure 7. A comparison of jewel roll in a single instrument taken from three different sets of Vee jewels

(*b*). Actual measurements of jewel roll with three materials involved were made using a very low torque instrument, with the results shown in Figure 7. These measurements were, of course, not nearly as accurate as the measurements under (*a*), but were simply confirmation that the measurements as taken in (*a*) are directly applicable to the problem.

(*c*). An impact device was prepared, two views of which are shown in Figure 8. After some experimentation, a test schedule was worked out as follows: The pendulum was raised ten degrees from the vertical, allowed to fall and strike the panel, and caught on the rebound. The instrument jewel roll was measured and the process repeated, the angle of drop being increased each time by ten degrees until 180 degrees was reached. Figure 9 shows the performance of two instruments mounted as shown on the same panel, one with sapphire jewels and one with hot-formed jewels from material *G* (Figure 11), which was the material used for jewels in the past.

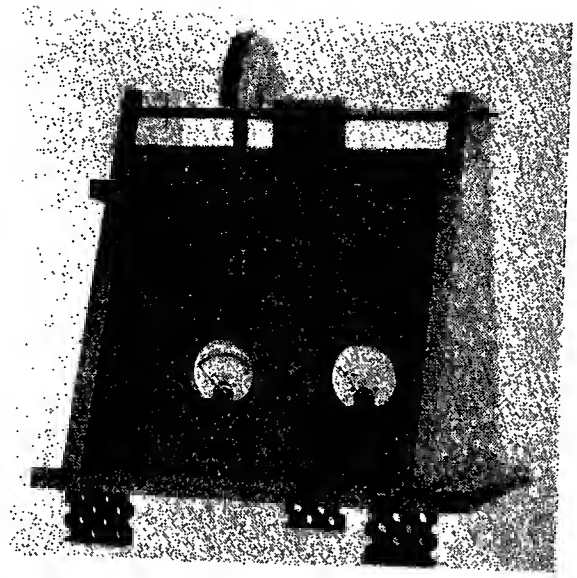

Figure 8a. Impact testing device—front view

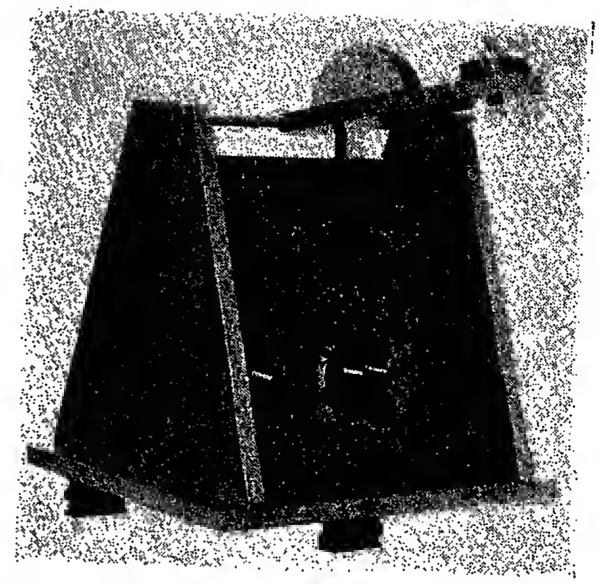

Figure 8b. Impact testing device—back view

(*d*). After impact a group of instruments, half with sapphire and half with hot-formed jewels of material *G*, were run from zero to full scale and back approximately 900,000 times, and the jewel roll again noted with results as shown in Table II.

All of the above were done with several different instrument designs and torques, and representative values are given in the tables. Conclusions from the above were that it was highly desirable to increase the impact strength of the hot-formed jewel.

(*e*). An arrangement as shown in Figure 10 was made by which a jewel could be accurately located below the opening of a glass tube. A hardened steel instrument pivot was placed in the Vee and struck by dropping a pellet weighing 0.1 gram upon it. As shown in the figure, the pellet was raised by a magnet to an exact height and released by removing the magnet. After each drop, the jewel was carefully examined under the microscope for any traces of fracture of the surface and another trial made if no fracture occurred. The method finally worked out as giving the most consistent results was to

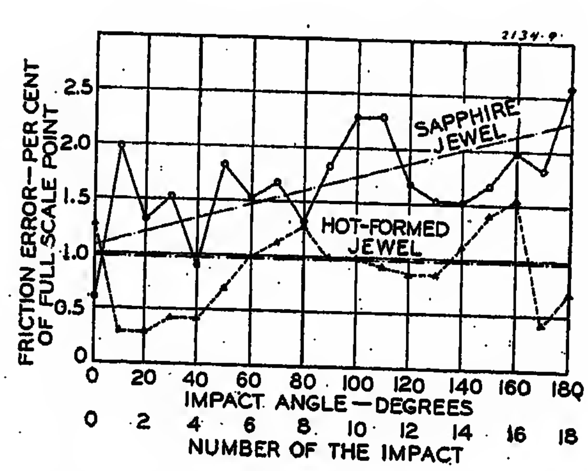

Figure 9. Increase of instrument friction as a result of successive impacts in ten-degree steps on panel impact device

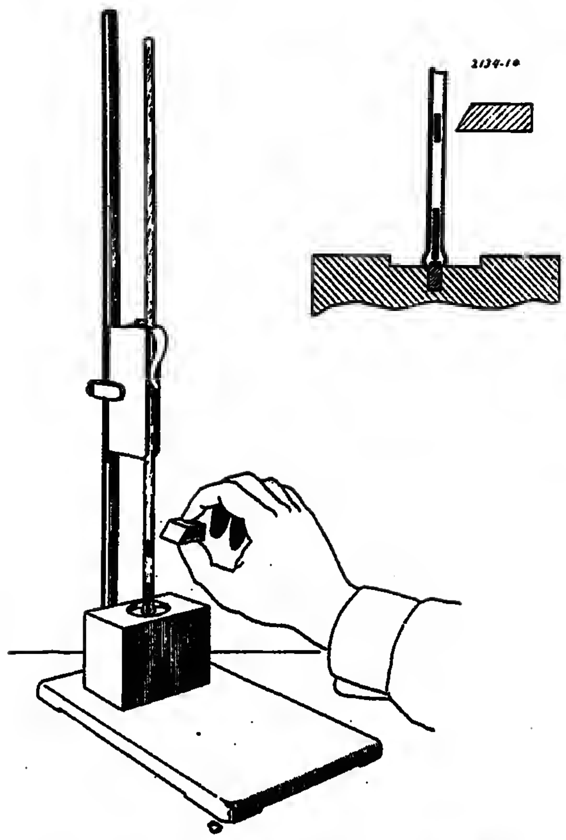

Figure 10. Jewel impacting device

drop the weight five times from a distance of 2 inches, five times from a distance of 6 inches, and five times from a distance of 12 inches. A jewel would be given a score of one for each time it successfully withstood a 2-inch drop, a score of three for each time it successfully withstood a 6-inch drop, and a score of six for each time it withstood a 12-inch drop. The total score of a group of five jewels was used in making the evaluation in each case. It should be noted that the pivots were initially selected by 100-diameter contour measurement and a 40-diameter visual inspection to be sure that they did not introduce another variable.

Figure 11 shows the comparative values of a number of different materials including material G which had been in use for many years.

It should be noted that the impact strength is not a function of material only, since jewels were actually produced from material H which varied in impact strength from practically zero when overstrained to a value of 30 when completely annealed as shown at I. The value plotted at H is the average which can be held for the optimum manufacturing process worked out.

The materials investigated covered ordinary soft glass A; a considerable range of so-called "hard glasses," B, C, D, E, F, G, the material used some years ago, and H. Material H has a very high softening point and is unique in having a large percentage of alumina.

Since vibration is present in many instrument applications, H jewels were compared to sapphire in respect to bearing life under vibration. A table which gave each point in the instrument a circular motion in a plane 45 degrees from the horizontal with a diameter of 0.020 inch and a frequency of 1600 rpm was used. Results showed the two bearings to be comparable.

From an analysis of the above data and examination of the pivots and jewels it was obvious that material H represents very distinct progress over the previously used glass jewel. Since sapphire is harder than the steel pivot, the effect of heavy impact is to cause a deformation of the pivot. When this deformation occurs, the precision of the instrument is impaired, because the moving system is no longer supported by a smooth bearing, but is rolling on an irregularly shaped mushroomed pivot. This effect will always be present and will be noticeable at any part of the scale, since the whole end of the pivot is deformed. In the case of material H, the point at which the jewel material deforms is approximately the same as that at which the pivot deforms, so that up to this critical point, impact has no effect. Beyond this point, there is very slight deformation of the pivots, and a minute area of the jewel surface is crushed. Because of the fact that the pivot flies up from its regular seat under impact, this deformed part of the jewel is very likely not to be at the point where the pivot usually travels and, therefore, is unlikely to affect the performance of the instrument in any way.

The technique of manufacturing instrument jewels with carefully controlled dimensions to give the impact strength of H has been worked out, and these can now be produced in quantities sufficient to assure that the jewel bearings will not be a limiting feature in the quantity of instruments which may be produced.

In conclusion, the original result desired was a jewel which could be produced in quantity, and which would involve the least possible sacrifice over sapphire for miniature instruments. The data indicate that there is little to choose between the new jewel and sapphire for actual miniature instrument application.

Table II. Jewel Roll of Instruments After Approximately 900,000 Pointer Movements Up and Down Scale

	Instrument No.	Angle* (in Degrees)
Hot-formed jewels	1	3.2
	2	3.2
	3	0.3
	4	1.5
	5	0.6
Sapphire jewels	1	1.0
	2	0.9
	3	1.0
	4	1.0
	5	1.2

Initial jewel roll was negligible.

A New Single-Phase-to-Ground Fault-Detecting Relay

W. K. SONNEMANN
ASSOCIATE AIEE

Synopsis: In the application of differential relays the need for a supervising relay which will detect the existence of a single-phase-to-ground fault condition to the exclusion of all others has frequently arisen. Heretofore, the only scheme available has been to utilize a relay energized by zero-sequence quantities. Generally, the relay has been energized by a current transformer connected in the station ground. Such a relay, however, will also detect the existence of a two-phase-to-ground fault and only partially solves the problem. The new relay described in this paper derives its operating force from the zero-sequence voltage at the bus and is restrained by the negative-sequence voltage at the bus. The addition of properly proportioned negative-sequence restraint provides the relay with a means of recognizing a single-phase-to-ground fault only. It is applicable on those systems where the zero-sequence impedance of the system exceeds the negative-sequence impedance by a reasonable margin.

Application

IN the application of differential relays to the protection of generating station busses, it is frequently the case that single-phase-to-ground fault protection only is desired. In such cases, the differential relay is connected in the residual circuit, or zero-sequence network, from the current transformers. Again, it is sometimes desirable to supplement three-phase differential relays with a fourth differential relay connected as above in order to obtain increased sensitivity for phase-to-ground faults. This latter condition is frequently encountered when systems are grounded through an impedance, so that the maximum value of phase-to-ground fault current is distinctly limited. In such cases the setting of the fourth or ground relay is considerably more sensitive than that of the phase relays, and the problem then becomes one of keeping the residual differential relay from tripping erroneously for heavy external phase-to-phase short circuits. Where conventional relays are used with current transformers, the major difficulty arises when a false differential current appears in the ground relay caused by unequal saturation of the various current transformers in the faulted phases, this condition being particularly emphasized by the presence of d-c transient. When the linear coupler relay scheme[1] is used, the fourth or ground relay set sensitive may also operate falsely for heavy external phase faults, not because of saturation, but depending upon the relative values of the maximum fault currents, the sensitivity of the relay, and the accuracy of the linear coupler transformers.

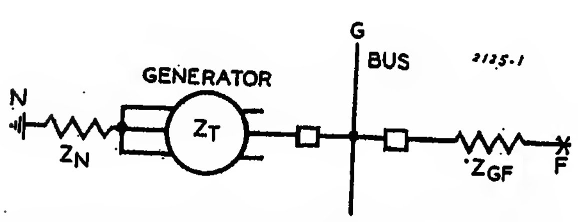

Figure 1. Schematic diagram of generator bus with fault on feeder circuit

Z_N—Grounding impedance
Z_T—Impedance of generator
Z_{GF}—Impedance from bus, G, to fault F
1, 2, 0—Where necessary, these subscripts are used in addition to those shown above to indicate the sequence network involved

A solution to this problem is to block out the ground relay for every type of fault except single-phase-to-ground. This applies whether conventional relays and current transformers, or the new linear-coupler scheme is used. The method is to connect the contacts of the supervising, or single-phase-to-ground fault-detecting relay, in series with the contacts of the main differential relay. If the latter relay then closes its contacts in error upon the occurrence of a heavy external two-phase-to-ground fault, for example, but the supervising relay properly maintains its contacts in the open position, no harm results. Up to now, no such supervising relay has been available which would recognize the existence of a single-phase-to-ground fault to the exclusion of all other types of faults. The new relay described in this paper is such a relay.

Paper 42-125, recommended by the AIEE committee on protective devices for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted May 6, 1942; made available for printing May 22, 1942.

W. K. SONNEMANN is design engineer with Westinghouse Electric and Manufacturing Company, Newark, N. J.

Operating Principle

The new relay operates in accordance with the magnitude of the negative-sequence voltage and the zero-sequence voltage at the bus. The contact-closing force in the relay is developed in proportion to the zero-sequence voltage, while the restraining force opposing contact closing is proportional to the negative-sequence voltage.

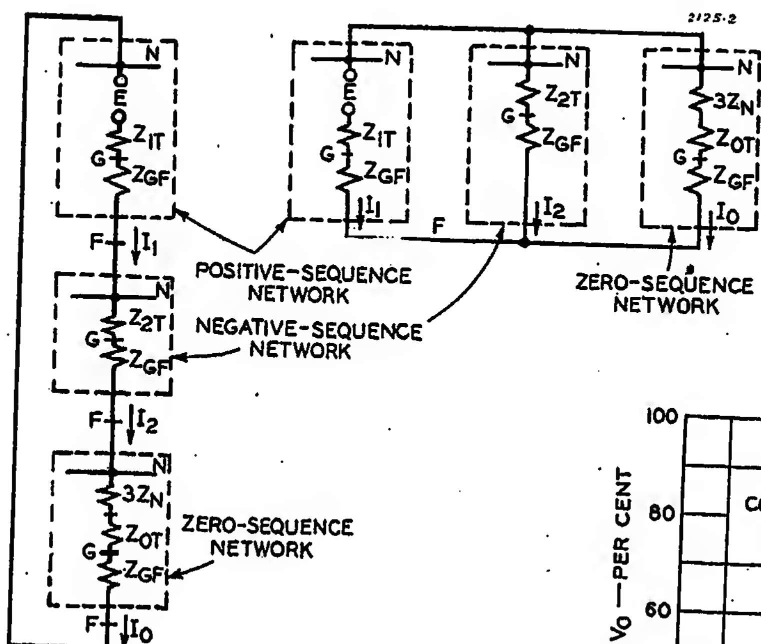

Figure 2. Sequence network connections for

(*a*). Single-phase-to-ground fault
(*b*). Two-phase-to-ground fault

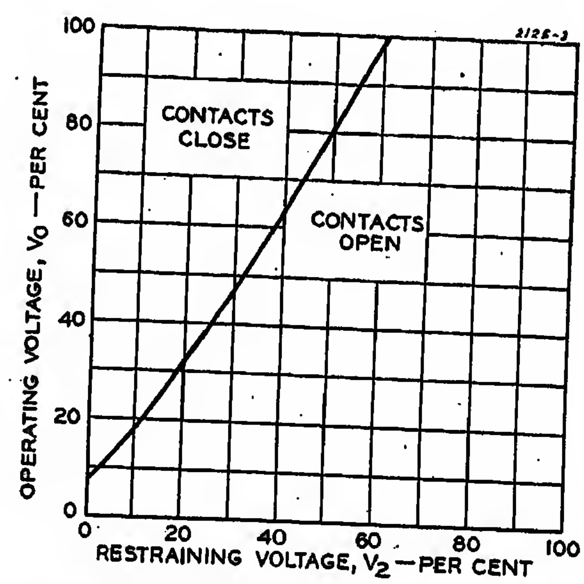

Figure 3. Typical operating characteristics of relay

The voltages shown are measured on the input side of the sequence filters
V_0—Zero-sequence voltage
V_2—Negative-sequence voltage

The proper application of the relay requires that the zero-sequence impedance of the system must exceed the negative-sequence impedance of the system by a reasonable margin. This requirement goes hand in hand with the need for the

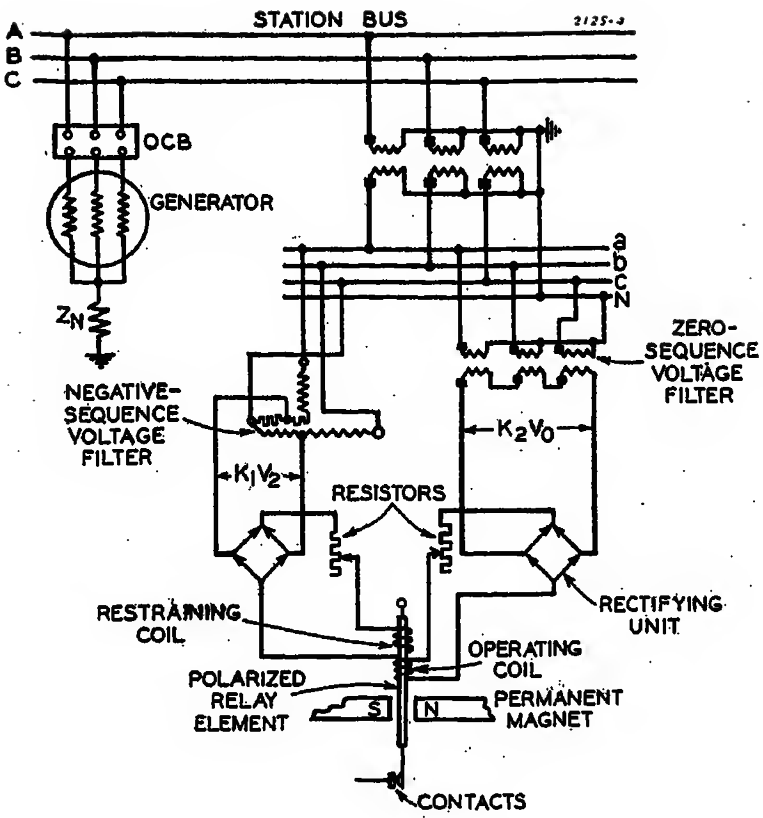

Figure 4 (left). Schematic diagram of connections of relay elements to station bus

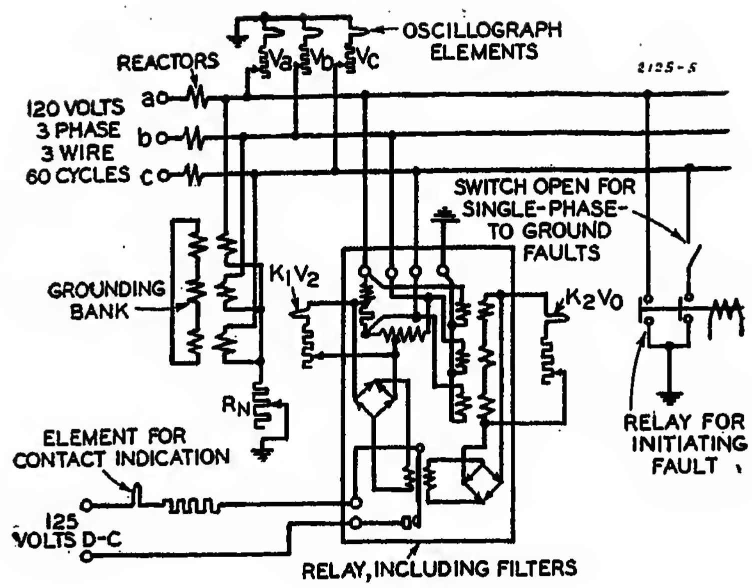
K_1 and K_2 are design constants of the filter units

Figure 5 (right). Diagram of test connections



relay. On solidly grounded systems, where the ratio of zero-sequence to negative-sequence impedance at the generating station bus is low, ground-fault protection will generally be obtained by means of the phase differential relays, thus eliminating the need for the supervision of a nonexistent sensitive ground relay. When a grounding impedance is used, however, the need for the ground differential relay appears. At the same time, the use of the grounding impedance makes possible the application of the new supervising relay.

Figure 1 shows a schematic diagram of a generator bus with a fault on a feeder circuit. The generating capacity has been shown as an equivalent single generator. To make the case more general for the detailed derivations in the appendix, an impedance, Z_{GF}, has been assumed between the generator bus, G, and the fault at F.

Figure 2 shows the sequence network connections for single-phase-to-ground and two-phase-to-ground faults.[2] Phase-to-phase and three-phase faults need not be considered, inasmuch as no zero-sequence voltage is involved for these faults, and hence the relay would not experience any operating force. For convenience in simplifying the explanation of the relay operation, consider for the moment that the impedance, Z_{GF}, between the generator bus and the fault, F, is zero. This is equivalent to assuming that the fault occurs directly on the bus. Referring to Figure 2b for the two-phase-to-ground fault condition, it will be seen that the negative-sequence voltage to neutral at the bus is of necessity equal to the zero-sequence voltage to neutral, since the two networks are connected in parallel. Under this condition the relay will receive equal negative- and zero-sequences voltages from potential transformers connected to the bus and must not operate. The restraining coil of the relay must, therefore, be so proportioned as to be more powerful than the operating coil of the relay when both of these relay circuits receive equal voltages. Referring to Figure 2a for the single-phase-to-ground fault condition, it will be noted that the zero-sequence voltage will exceed the negative-sequence voltage in the same ratio as the impedance of the zero-sequence network exceeds that of the negative-sequence network. It will be noted that the value of the grounding impedance, Z_N, has been inserted in the zero-sequence network at three times its actual value in accordance with the conventional theorem. Since the same numerical value of current flows through the negative-sequence and zero-sequence network of Figure 2a, it follows that it is only necessary for the impedance of the zero-sequence network to be sufficiently high with respect to the impedance of the negative-sequence network to cause relay operation. The ohmic value of the grounding impedance, Z_N, will generally run quite high compared to the negative-sequence impedance of the generator, so that this condition is not difficult to meet.

Assume that the negative- and zero-sequence networks of Figure 2 are equal in ohmic value. It then follows that the negative- and zero-sequence voltages would be equal for each of these two cases. This is the limiting value in that if the relay-restraining and operating coils were so proportioned that the relay would be on the verge of closing its contacts for a two-phase-to-ground fault, Figure 2b, then it would also be on the verge of closing its contacts for a single-phase-to-ground fault, Figure 2a. It follows more or less obviously that if Z_0 is greater than Z_2, the relay can be properly proportioned to discriminate between single-phase-to-ground and two-phase-to-ground short circuits. (Discrimination is automatic for phase-to-phase and three-phase short circuits, since no zero-sequence voltage is involved in these faults.)

It is desirable to establish a criterion for limits of application, and in this case it is felt that if the ratio Z_0/Z_2 is equal to or greater than 2/1, then a relay having characteristics similar to those illustrated in Figure 3, will meet the requirements satisfactorily.

Typical Application

Assume that Figure 1 represents a 13.2-kv installation and that the equivalent single generator has a rating of 20,000 kva. This is a relatively small capacity but is so chosen as to be on the pessimistic side in that the negative-sequence impedance will be relatively high. Typical values for the subtransient and negative-sequence reactance have been taken at 12 per cent each, and a zero-sequence reactance of four per cent has been assumed for the machine. The grounding impedance, Z_N, is assumed to be a two-ohm resistor, inasmuch as this is a value very frequently encountered. Using the above values of impedance and taking 7,620 volts to neutral as 100 per cent voltage, single-phase-to-ground and two-phase-to-ground faults on the bus were calculated. For the single-phase-to-ground fault, the negative-sequence voltage is 16.2 per cent and the zero-sequence voltage is 93.2 per cent. From the curve, Figure 3, when $V_2 = 16.2$ per cent, the required value of zero-sequence voltage, V_0, to operate the relay is 26 per cent. It is thus seen that the margin of the zero-

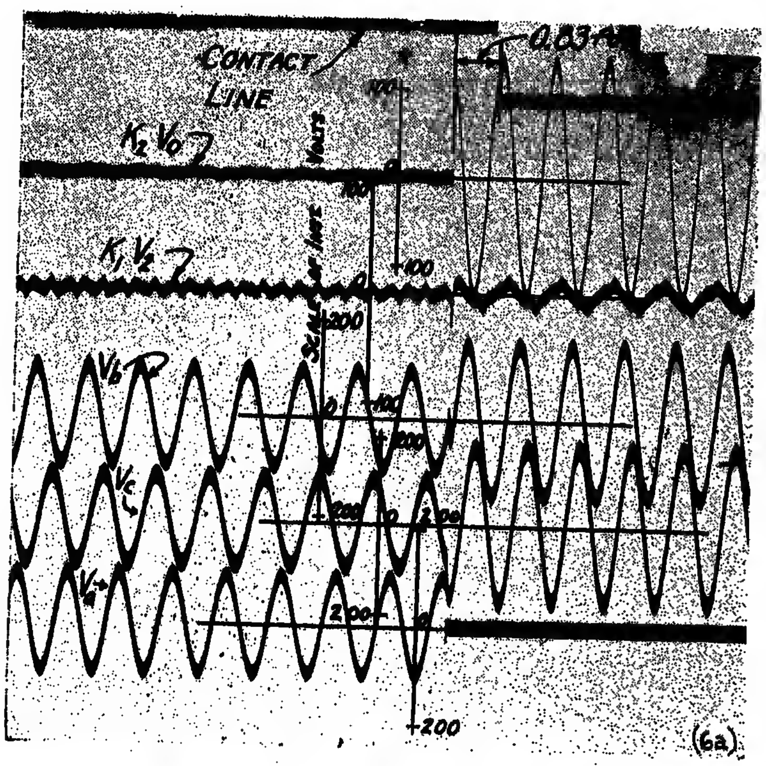
sequence voltage available over and above that required to barely operate the relay is ample. For the two-phase-to-ground fault, values of $V_2=49.5$ per cent and $V_0=49.5$ per cent were calculated for the assumed system. From the curve, it is found that at 49.5 per cent restraint voltage, the operating voltage, V_0, would have to be 79.5 per cent. Thus, the relay will not operate for the two-phase-to-ground fault. The calculations have been based on using the subtransient reactance of

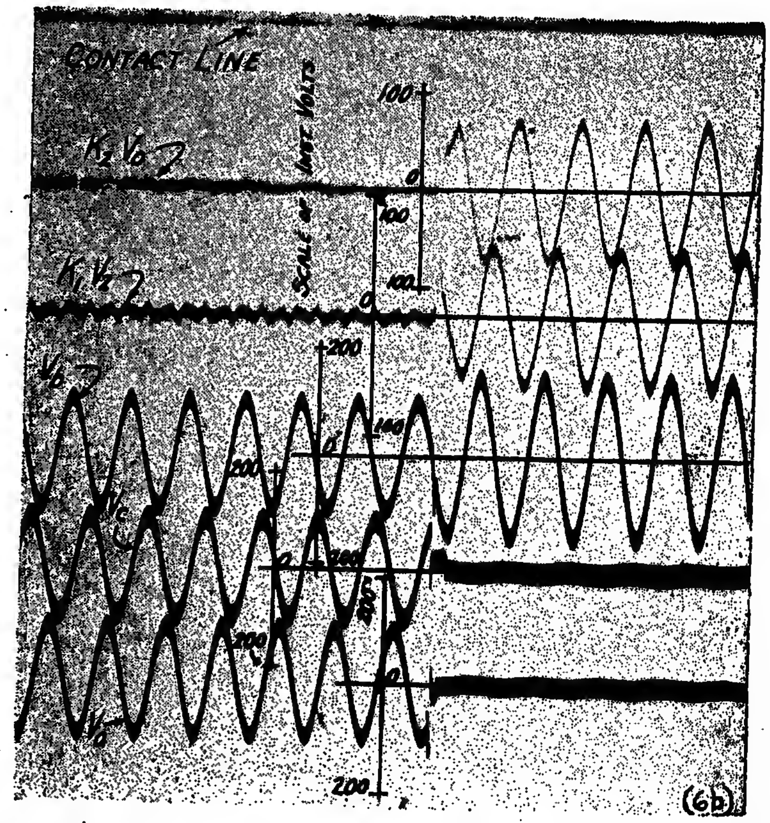
Tests

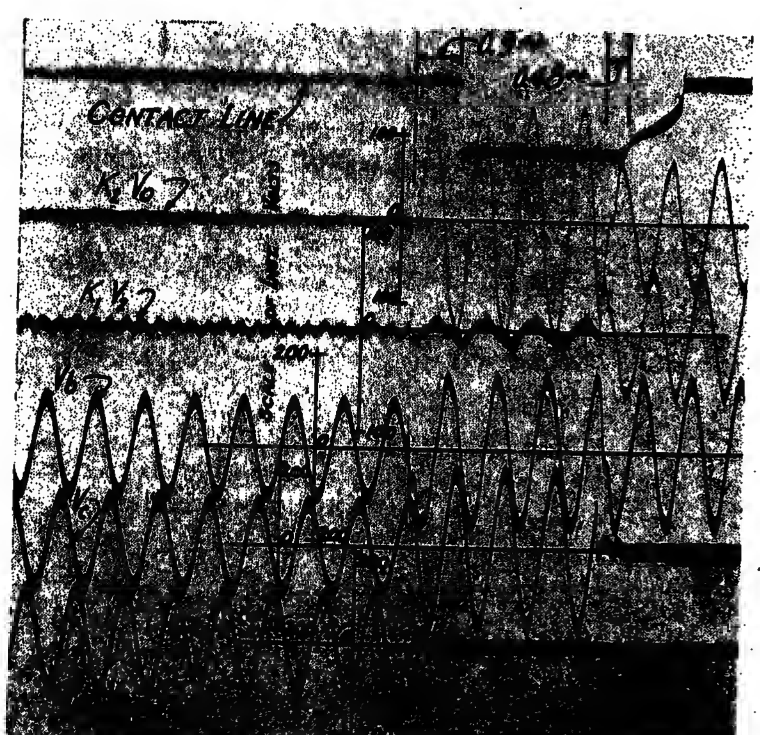
In order to check the actual operation of the relay against the theory, a test setup was made as shown in Figure 5. A system was represented in miniature. A variable resistor, R_N, was utilized as a grounding impedance in order that a minimum value for proper relay operation might be obtained and this checked against the calculations.

The location of oscillograph elements is

Figure 6a shows the results of a test where phase a was faulted to ground. The ratio Z_0/Z_2 was 14.8 for this test. It will be observed that the relay properly closed its contact in 0.83 cycle. It will also be noted that there is a slight 60-cycle component and an appreciable harmonic component in the output of the negative-sequence filter prior to the fault. The 60-cycle component is explained by the fact that the filter was not perfectly balanced in its adjustment, and neither were







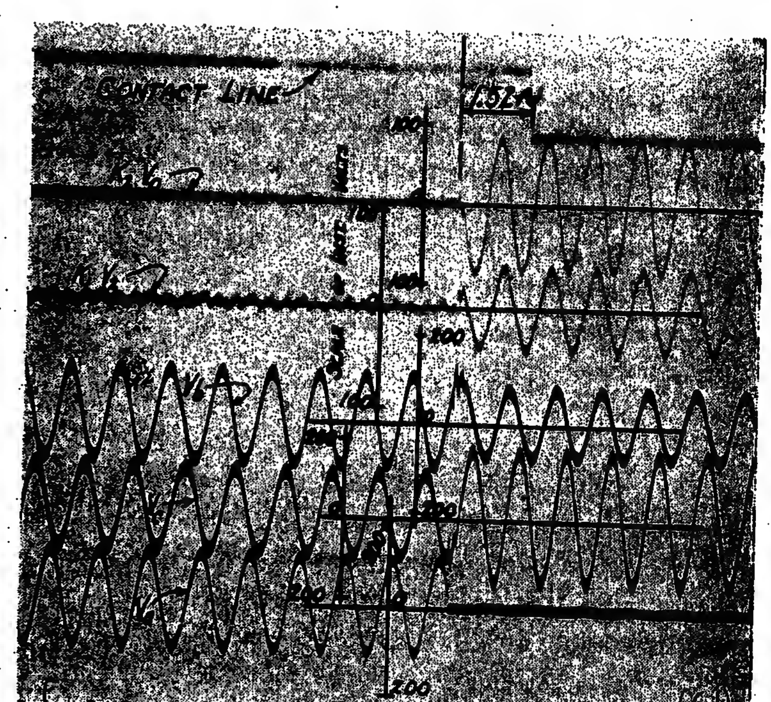


Figure 6. Test oscillograms

K_1V_2 = Negative-sequence voltage output of filter

K_2V_0 = Zero-sequence voltage output of filter

the machine in the positive-sequence network, since the relay is a high-speed relay.

While the relay has actually been made in the high-speed form, operating in one cycle or less, the principles involved are easily applied to other types of design so that the relay could be made "slow speed" if desired.

Figure 4 shows a schematic diagram of connections illustrating how the relay is energized from potential transformers connected to the station bus.

shown in Figure 5. Elements were used to obtain traces of the phase-to-neutral voltages, V_a, V_b, and V_c, and the negative- and zero-sequence voltages, K_1V_2 and K_2V_0. The sixth element was used to obtain an indication of the operation of the relay contact. It should be noted that the output of the sequence filters is not numerically equal to the input quantities; hence the constants of proportionality, K_1 and K_2, have been used as indicated above.

the three-phase-to-neutral voltages perfectly balanced in the miniature setup. The existence of the harmonic component is occasioned by the fact that an iron core reactor is utilized in the filter design. In practice, the fact that the negative-sequence filter will have a combined output of fundamental and harmonic frequencies on the order of two volts or less under normal balanced conditions does not do any harm.

Figure 6b shows the results of a two-

phase-to-ground fault on phases *a* and *c*. The ratio $Z_0/Z_2=14.8$ was kept the same as before. The calibration of the oscillograph elements remained the same, as in all cases to follow. The contacts of the relay did not operate. The relative magnitude of the deflections of the elements measuring K_1V_2 and K_2V_0 should be compared for Figures 6a and 6b.

In Figure 6c, the results are shown for a fault which started as one phase-to-ground and developed into a two-phase-to-ground fault. As before, the ratio of Z_0/Z_2 was kept at 14.8. The contacts first closed, as they should, in 0.9 cycle. When the second phase faulted to ground, the contacts opened in 0.48 cycle. The film indicates that the contacts were slow in opening the contact circuit. This is for the reason that the d-c current used in this element was kept high—just about at the limit that the relay contacts would successfully break. In practice, these contacts would not be expected to open heavy currents.

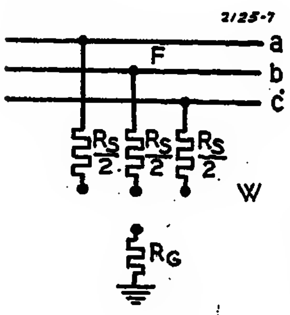

Figure 7. Diagram showing arc resistance at the point of fault

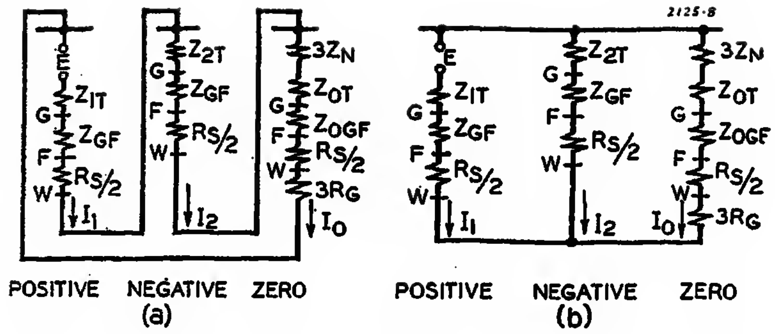
The resistance, R_N, was next reduced to such a value that the relay would just discriminate satisfactorily between one-phase- and two-phase-to-ground faults and the film, Figure 6d, was taken. For this case, the ratio Z_0/Z_2 was 1.7. Using the impedance values for the miniature system, a single-phase-to-ground fault condition was calculated. The calculated values were: $V_0=58.4$ per cent and $V_2=34.2$ per cent. At a negative-sequence restraining voltage of 34.2 per cent, the curve, Figure 3, indicates that the zero-sequence operating voltage required to just overcome this restraint should be not more than 54 per cent. An apparent error of 8.2 per cent is indicated in the calculations. This is explained on the basis that there were errors in the miniature setup which could be eliminated if it were found necessary to run the test with precision laboratory accuracy. The errors include the slight unbalance in the negative-sequence filter which was previously mentioned, a slight mutual coupling which existed between the reactors used in the supply circuit, and the fact that the burden of the sequence filters was appreciable with respect to other constants of the

Figure 8. Connections of sequence networks for

(*a*). Single-phase-to-ground fault

(*b*). Two-phase-to-ground fault



miniature system. None of these factors was taken into consideration in the calculations.

In Figure 6d, the contact closing time 1.52 cycles under minimum operating conditions is still reasonably fast.

Conclusion

A relay design is now available which will properly discriminate between single-phase-to-ground faults and all other types of faults on grounded systems when the ratio of the zero-sequence impedance of the system to the negative-sequence impedance is greater than unity.

Appendix

Let it be assumed that the fault occurs at the point, *F*, of Figure 1, and that the arc resistances are represented as shown in Figure 7. The sequence network connections are shown by Figure 8 for the single-phase-to-ground and two-phase-to-ground faults. The points *G*, *F*, and *W* are shown in these diagrams.

Case I—Single-Phase-to-Ground Fault

Referring to Figure 8a, let

$$Z_1=Z_{1T}+Z_{GF}+R_s/2 \tag{1}$$

$$Z_2=Z_{2T}+Z_{GF}+R_s/2 \tag{2}$$

and $$Z_0=3Z_N+Z_{0T}+Z_{0GF}+R_s/2+3R_G \tag{3}$$

In the series connections of networks

$$I_1=I_2=I_0 \tag{4}$$

and $$I_1=\frac{E}{Z_1+Z_2+Z_0} \tag{5}$$

The negative- and zero-sequence voltage drops at the bus, *G*, are

$$E_{2G}=0-I_2Z_{2T} \tag{6}$$

and $$E_{0G}=0-I_0(3Z_N+Z_{0T}) \tag{7}$$

Substituting I_2 for I_0 (since these are equal, equation 4) in equation 7, and dividing equation 6 by equation 7, a ratio, R_1, is obtained

$$R_1=\frac{E_{2G}}{E_{0G}}=\frac{Z_{2T}}{(3Z_N+Z_{0T})} \tag{8}$$

Equation 8 gives the relationship existing between the negative-sequence restraining voltage and the zero-sequence operating voltage when the relay must operate.

Case II—Two-Phase-to-Ground Fault

Referring to Figure 8b, let equations 1, 2, and 3 stand as before. In this case, however

$$I_1=\frac{E(Z_0+Z_2)}{Z_1Z_0+Z_1Z_2+Z_2Z_0} \tag{9}$$

$$I_2=-I_1\frac{Z_0}{Z_2+Z_0} \tag{10}$$

$$I_0=-I_1\frac{Z_2}{Z_2+Z_0} \tag{11}$$

As in Case I,

$$E_{2G}=0-I_2Z_{2T} \tag{6}$$

and $$E_{0G}=0-I_0(3Z_N+Z_{0T}) \tag{7}$$

Substituting for I_2 and I_0 in terms of I_1, equations 6 and 7 become

$$E_{2G}=0+I_1\frac{Z_0}{Z_2+Z_0}Z_{2T} \tag{12}$$

$$E_{0G}=0+I_1\frac{Z_2}{Z_2+Z_0}(3Z_N+Z_{0T}) \tag{13}$$

A new ratio, R_2, between the negative-sequence restraining voltage and zero-sequence operating voltage, is obtained by dividing equation 12 by equation 13

$$R_2=\frac{Z_0Z_{2T}}{Z_2(3Z_N+Z_{0T})} \tag{14}$$

Summary

If the relay is to discriminate properly between the conditions of case I and case II, then the ratio, R_2, must be greater than the ratio, R_1. Dividing equation 14 by equation 8, there results

$$R_2/R_1=\frac{Z_0}{Z_2} \tag{15}$$

Equation 15 indicates that if $Z_0/Z_2>1$, then $R_2/R_1>1$, and the relay will receive more restraining voltage in proportion to operating voltage for the two-phase-to-ground fault condition than it will for the single-phase-to-ground fault.

On Eddy Currents in a Rotating Disk

W. R. SMYTHE
NONMEMBER AIEE

A DEVICE which often occurs in electric machines and instruments consists of a relatively thin conducting disk rotating between the pole pieces of a permanent magnet or electromagnet. The author has received inquiries as to the method of calculating the paths of the eddy currents and the torque in such cases. The following rather simple method, which is quite accurate for a permanent magnet, seems not to be described in the literature. It assumes that the disk is so thin that the skin effect can be neglected. This is true for all frequencies that can be produced mechanically. To facilitate calculation in the special case of circular poles it is also assumed that $2\pi\omega ab\gamma=\epsilon a$ is much less than one where ω is the angular frequency of rotation in radians per second, a the pole-piece radius, b the disk thickness, and γ the electric conductivity, all in centimeter-gram-second electromagnetic units. This produces a fractional error of less than ϵa in the eddy current densities and of less than $(\epsilon a)^2$ in the torque. In the case of the electromagnet the situation is complicated by the presence of the permeable pole pieces in the magnetic field of the eddy currents. This may send a large demagnetizing flux through the electromagnet. An approximate solution for this case will be considered.

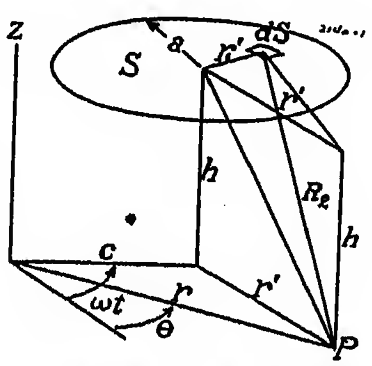

Figure 1. Geometrical relations for derivation of formulas for stream function

Maxwell's Formula

This calculation starts from a formula given by Maxwell in 1873,[1] but apparently little known to engineers. To apply it one should know its derivation which, as given by Maxwell, is difficult for modern students to follow. A simplified proof which brings out the points essential for our problem is given below.

The object is to calculate the magnetic induction $\boldsymbol{B}$ produced by the eddy currents of density $\boldsymbol{i}$ induced in a thin plane sheet of thickness b, unit permeability and conductivity γ lying in the xy plane by a fluctuating magnetic field of induction $\boldsymbol{B}'$. Evidently the only components of $\boldsymbol{i}$ effective in producing magnetic effects parallel its surface. Let the eddy currents be confined to a finite region of the sheet which may or may not extend to infinity, and let us define the stream function $U(x, y)$ at any point in the sheet to be the current flowing through any cross section of the sheet extending from P to its edge. The line integral of $\boldsymbol{B}$ or $\boldsymbol{H}$ over the closed path that bounds this section equals $4\pi U$. From symmetry the contribution from the upper and lower halves of the path is the same so we may write

$$4\pi U=\oint \boldsymbol{B}\cdot d\boldsymbol{s}=\pm 2\int_x^\infty B_x dx = \pm 2\int_y^\infty B_y dy \qquad (1)$$

where the choice of sign depends on the side of the sheet chosen for the integration. Differentiating this equation gives

$$bi_x=\frac{\partial U}{\partial y}=\pm\frac{B_y}{2\pi} \qquad bi_y=-\frac{\partial U}{\partial x}=\mp\frac{B_x}{2\pi} \qquad (2)$$

These equations connect the eddy current density with the tangential components of the magnetic induction $\boldsymbol{B}$ produced by $\boldsymbol{i}$ at the surface of the sheet.

The eddy currents are generated not only by the changes in the magnetic induction $\boldsymbol{B}'$ of the external field, but also by the changes of the magnetic induction $\boldsymbol{B}$ of eddy currents elsewhere in the sheet. One of Maxwell's equations combined with Ohm's law gives the induced current to be

$$\nabla\times\boldsymbol{E}=\nabla\times\frac{\boldsymbol{i}}{\gamma}=-\frac{\partial}{\partial t}(\boldsymbol{B}'+\boldsymbol{B}) \qquad (3)$$

Writing out the z component of this equation and using equation 2 give

$$\frac{1}{\gamma}\left(\frac{\partial i_y}{\partial x}-\frac{\partial i_x}{\partial y}\right)=\mp\frac{1}{2\pi b\gamma}\left(\frac{\partial B_x}{\partial x}+\frac{\partial B_y}{\partial y}\right)=-\frac{\partial}{\partial t}(B_z'+B_z) \qquad (4)$$

Another of Maxwell's equations states that

$$\nabla\cdot\boldsymbol{B}=\frac{\partial B_x}{\partial x}+\frac{\partial B_y}{\partial y}+\frac{\partial B_z}{\partial z}=0 \qquad (5)$$

Combining equations 4 and 5 gives

$$\pm\frac{\partial(B_z'+B_z)}{\partial t}=\frac{1}{2\pi b\gamma}\frac{\partial B_z}{\partial z} \qquad (6)$$

When $\partial B_z'/\partial t$ is known, this equation gives the boundary condition on B_z in the plane of the sheet. This, combined with the equations $\nabla\times\boldsymbol{B}=0$ and $\nabla\cdot\boldsymbol{B}=0$ which hold outside the sheet, and the fact that $\boldsymbol{B}$ vanishes at infinity serves to determine $\boldsymbol{B}$ everywhere. By equations 1 and 2 the current density and stream function anywhere in the sheet can be found.

The explicit expression for $\boldsymbol{B}$ in terms

Paper 42-140, recommended by the AIEE committee on basic sciences for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted December 12, 1940; made available for printing May 20, 1942.

W. R. Smythe is professor in the department of physics, California Institute of Technology, Pasadena, Calif.

of $\boldsymbol{B}'$ which was given by Maxwell[1] can be obtained as follows. The right side of equation 6 is finite at all times which means that if $\Delta t \rightarrow 0$ then $\Delta(B_z'+B_z)\rightarrow 0$. Thus an abrupt change in $\boldsymbol{B}'$ instantaneously induces eddy currents such as will maintain $\boldsymbol{B}'+\boldsymbol{B}$ unchanged in the sheet. Therefore, for a specified change in $\boldsymbol{B}'$ the initial value of $\boldsymbol{B}$ is known, and, if no further changes in $\boldsymbol{B}'$ occur its subsequent values as the eddy currents decay are found by putting $\partial \boldsymbol{B}'/\partial t=0$ in equation 4 and solving. A second abrupt change in $\boldsymbol{B}'$ produces a second set of eddy currents, and so forth. At any instant the actual field of the eddy currents is a superposition of these. As the magnitudes of the discontinuous changes in the external field become smaller, and the intervals between them shorter, we approach as a limit a continuously changing magnetic field.

Suppose that the sources of the inducing field lie above the xy plane where $z>0$. At $t=0$ the source changes abruptly the induction being $\boldsymbol{B}_1'=F_1(x, y, z)$ when $-\infty<t<0$ and $\boldsymbol{B}_2'=F_2(x, y, z)$ when $0<t<\infty$. As just shown the eddy currents generated at $t=0$ initially keep the field on the negative side of an infinite sheet unchanged. When $z<0$ we have therefore

$$\boldsymbol{B}_{t=0}=\boldsymbol{B}_1'-\boldsymbol{B}_2'=F_1(x, y, z)-F_2(x, y, z) \quad (7)$$

Since $\boldsymbol{B}_2'$ is not a function of t, equation 6 reduces to

$$\pm\frac{\partial B_z}{\partial t}=\frac{1}{2\pi b\gamma}\frac{\partial B_z}{\partial z} \quad (8)$$

These equations, 7 and 8, are satisfied by

$$\boldsymbol{B}=F_1\left(x, y, z\pm\frac{t}{2\pi b\gamma}\right)-F_2\left(x, y, z\pm\frac{t}{2\pi b\gamma}\right) \quad (9)$$

Because the eddy currents must die out, and their magnetic field must be symmetrical about the sheet, we take the plus sign when z is positive and the negative sign when z is negative. Thus equation 9 shows that, in addition to $\boldsymbol{B}_2'$ which would exist if no sheet were present, there is a decaying field due to eddy currents which appears, from either side of the sheet, to be caused by a pair of images receding with uniform velocity $1/(2\pi b\gamma)$. Suppose our inducing field has the form

$$\boldsymbol{B}'=F(t, x, y, z) \quad (10)$$

The change in this field in an infinitesimal time interval $d\tau$ is given by

$$\frac{\partial \boldsymbol{B}'}{\partial t}d\tau=\frac{\partial}{\partial t}F(t, x, y, z)d\tau \quad (11)$$

The initial field of the eddy currents formed in that interval must be equal and opposite to this and must die out as if their source moved away with a uniform speed $1/(2\pi b\gamma)$. Thus the eddy currents at a time t due to a change in the interval $d\tau$ at a time τ before t is given by

$$d\boldsymbol{B}=-\frac{\partial}{\partial t}F\left(t-\tau, x, y, z\pm\frac{\tau}{2\pi b\gamma}\right)d\tau \quad (12)$$

This is Maxwell's formula. It has many applications.[2] When the field is produced by moving permanent magnets, it is convenient to express U in terms of the scalar magnetic potential Ω. Since we have unit permeability we may write

$$U=\frac{1}{2\pi}\int_r^\infty B_r dr=\frac{-1}{2\pi}\int_r^\infty\frac{\partial\Omega}{\partial r}dr=\frac{\Omega}{2\pi} \quad (13)$$

Application to Magnet Moving in a Circle

We now take the case of a magnetic field produced by a long right circular cylinder of radius a, uniformly and permanently magnetized parallel to its axis, so as to give a total flux Φ. The magnetic pole density in the face is therefore $\Phi/(2\pi a)^2$. This magnet moves in a circle with a uniform angular velocity ω its axis being c centimeters from the z axis, and its lower end h centimeters above the $z=0$ plane in which lies an infinite plane sheet of thickness b and conductivity γ. Its upper end is too remote for consideration. Polar co-ordinates will be written unprimed or primed according as they refer to the axis of rotation or to the pole-piece axis. The scalar magnetic potential Ω' of its lower face, of area S, at the point P is seen from Figure 1 to be

$$\Omega'=\frac{\Phi}{(2\pi a)^2}\int_S\frac{dS}{R_2}=\frac{\Phi}{(2\pi a)^2}\times\int_0^a\int_0^{2\pi}\frac{r_1'dr_1'd\theta'}{\sqrt{h^2+r_1'^2+r'^2-2r_1'r'\cos\theta'}}$$

where $r'^2=r^2+c^2-2rc\cos(\omega t+\theta)$. This combined with equations 12 and 13 give the stream function to be

$$U=\frac{\Phi}{(2\pi)^3a^2}\int_0^a\int_0^{2\pi}\int_0^\infty\frac{\partial}{\partial t}\times\left(\frac{r_1'dr_1'd\theta'd\tau}{\sqrt{h_\tau^2+r_1'^2+R_\tau'^2-2r_1'R_\tau'\cos\theta'}}\right) \quad (14)$$

where $R_\tau'^2=r^2+c^2-2rc\cos(\omega(t-\tau)+\theta)$ and $h_\tau=h+\tau/(2\pi b\gamma)=h+u$. Let us now bring the pole piece down close to the plate so that $h_\tau=\tau/(2\pi b\gamma)$, and bring up a similar pole of opposite sign from the other side, so that the eddy current density is doubled. We now carry out the differentiation with respect to t and set $t=0$ so that the $\theta=0$ line bisects the pole piece when $t=0$. The integral then becomes

$$U=\frac{rc\Phi\epsilon}{\pi(2\pi a)^2}\int_0^a\int_0^{2\pi}\int_0^\infty\frac{\sin(\theta+\epsilon u)(R_u'-r_1'\cos\theta')r_1'dr_1'd\theta'du}{R_u'(u^2+r_1'^2+R_u'^2-2R_u'r_1'\cos\theta')^{3/2}} \quad (15)$$

where $\epsilon=2\pi\omega b\gamma$ and $R_u'^2=r^2+c^2-2rc\times\cos(\theta+\epsilon u)$. For 3,000 rpm with a copper sheet 0.25 millimeter thick $\epsilon\approx 0.01$ so that u^2 in the denominator has reached the value 100 when ϵu reaches 0.1. In calculating such a quantity as the torque where the current density is integrated over the pole piece, the neglect of ϵ produces a fractional error less than $(\epsilon/a)^2$, so that the result should be good to one per cent for a sheet one millimeter thick. We may therefore drop the ϵ terms so that R_u' becomes the r' in Figure 1 and integrate with respect to u giving

$$U=\frac{K\sin\theta}{r'}\times\int_0^a\int_0^{2\pi}\frac{(r'-r_1'\cos\theta')r_1'dr_1'd\theta'}{r'^2+r_1'^2-2r'r_1'\cos\theta'} \quad (16)$$

where we have written K for the coefficient of the integral in equation 15. The integral with respect to θ', from Dwight's table of integrals 860.2, is zero when $r'<r_1'$ and π/r' when $r'>r_1'$. Thus the upper limit for the r_1' integration is a when $r'>a$ and r' when $r'<a$, which gives

$$r'>a \qquad U=\frac{\omega rcb\gamma\Phi\sin\theta}{2\pi r'^2} \quad (17)$$

$$r'<a \qquad U=\frac{\omega rcb\gamma\Phi\sin\theta}{2\pi a^2} \quad (18)$$

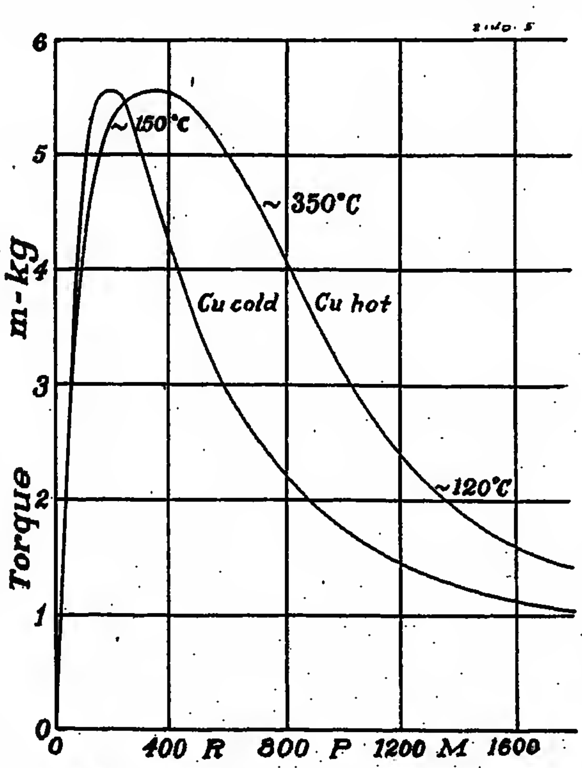

Figure 5. Curves showing torque versus speed for large disk rotating between the four rectangular pole pairs of an electromagnet, measured by Lentz

The next question is how to restrict the eddy currents to the interior of the disk bounded by the circle $r=A$. We observe that if we use equation 15 to calculate U for a second magnet also carrying a flux Φ but with circular pole pieces of radius $a''=Aa/c$ centered at $c''=A^2/c$, so that $R_u''^2=r^2+(A^2/c)^2-2r(A^2/c)\cos(\theta+\epsilon u)$, and change the variables of integration from r_1' to $r_1'A/c$, and from u to Au/c, then the resultant expression is identical with equation 15, except that we have cR_u''/A instead of R_u' and $A\epsilon/c$ instead of ϵ. But when $r=A$ we see that $cR_u''/A=R_u'$, so that both magnets, one outside and one inside the circle $r=A$, give the same U on this circle. Furthermore by taking the air gap in each magnet small, the fluxes are confined to the areas under the pole pieces, so that neither induces directly eddy currents on the other side of the circle $r=A$. It is evident that if the fluxes from the two magnets cut the sheet in opposite directions, then $U=0$ when $r=A$ and the currents induced by the inner pole are kept inside the circle. This is exactly the boundary condition for a disk of radius A, except that the calculated system includes the currents induced in the region $r<A$ by the magnetic field of the eddy currents in the region $r>A$, which does not exist in the case of the disk. This field is proportional to $\Phi\epsilon$ which is, by hypothesis, small compared with Φ, and in addition the source is further away, so that the fractional error in U will be less than ϵ. We should note also from the symmetry that the radial component of these secondary currents is opposite in sign on the two sides of the $\theta=0$ line, so that their effect cancels out completely in calculating the torque which therefore should be accurate to terms in ϵ^2. The contribution to U from the outer magnet is found by putting $c^2R''^2/A^2$ for R^2 in equation 17. Adding this to equations 17 and 18, we obtain for the stream function of the eddy currents in the disk

$$R>a \quad U=\frac{\omega rcb\gamma\Phi\sin\theta}{2\pi}\left(\frac{1}{r^2+c^2-2rc\cos\theta}-\frac{A^2}{c^2r^2+A^4-2rcA^2\cos\theta}\right) \quad (19)$$

$$R<a \quad U=\frac{\omega rcb\gamma\Phi\sin\theta}{2\pi a^2}\left(1-\frac{A^2a^2}{c^2r^2+A^4-2rcA^2\cos\theta}\right) \quad (20)$$

The torque may be calculated by integrating the product of the radial component of the current by the magnetic induction and by the lever arm and integrating over the area S of the pole piece. Thus, using equation 2, we have

$$T=\int_S\frac{rbi_r\Phi}{\pi a^2}dS=\frac{\Phi}{\pi a^2}\int_{c-a}^{c+a}\int_{-\theta_1}^{+\theta_1}r\frac{\partial U}{\partial r}rdrd\theta$$

where θ_1 and r are connected by the relation $r^2+c^2-2rc\cos\theta_1=a^2$. Substituting for U from equation 20 and integrating with respect to θ give

$$T=\frac{\omega cb\gamma\Phi^2}{\pi^2a^4}\times\int_{c-a}^{c+a}\left(r^2\sin\theta_1-\frac{a^2A^2r^2\sin\theta_1}{c^2r^2+A^4-2A^2rc\cos\theta_1}\right)dr \quad (21)$$

The integration is simplified by taking a new variable u so that $4acu^2=r^2-(c-a)^2$ which gives the limits 0 and 1. Thus we obtain, writing out ϵ,

$$T=\frac{\omega b\gamma\Phi^2c^2}{2\pi a^2}\left(1-\frac{A^2a^2}{(A^2-c^2)^2}\right)=\omega\gamma\Phi^2D_1 \quad (22)$$

This formula gives the torque in dyne centimeters when ω is in radians per second, Φ in maxwells, a, b, c, and A in centimeters and γ in electromagnetic units. If we are given the volume resistivity ρ of the disk in ohm-centimeters $\gamma=10^{-9}/\rho$.

If the magnet is fixed, and the disk rotates, the arrangement described exerts an undesired force on the disk axis which may be avoided by using two identical magnets on opposite sides of the axis and equidistant from it. This approximately doubles the torque given by equation 22. The additional torque from the eddy currents of one magnet flowing under the poles of the other may be found by an integral similar to equation 21 which is

$$T'=\frac{\omega b\gamma\Phi^2c}{\pi^2a^2}\int_{c-a}^{c+a}\left(\frac{r^2\sin\theta_1}{r^2+c^2+2rc\cos\theta_1}-\frac{r^2A^2\sin\theta_1}{r^2c^2+A^4+A^2rc\cos\theta_1}\right)dr \quad (23)$$

Integrating by the same substitutions as equation 21, adding to equation 22 and multiplying by two give

$$T=\frac{\omega b\gamma\Phi^2c^2}{\pi a^2}\left(\frac{4c^2+a^2}{4c^2}-\frac{2a^2A^2(A^4+c^4)}{(A^4-c^4)^2}\right)=\omega\gamma\Phi^2D_2' \quad (24)$$

This holds when the two magnet fields are antiparallel. If we subtract the integral of equation 23 from equation 22 and multiply by two we get

$$T=\frac{\omega b\gamma\Phi^2c^2}{\pi a^2}\left(\frac{4c^2-a^2}{4c^2}-\frac{4a^2c^2A^4}{(A^4-c^2)^2}\right)=\omega\gamma\Phi^2D_2'' \quad (25)$$

This holds when the two magnetic fields are parallel. The arrangement of equation 24 gives more torque than that of equation 25. The eddy-current flow lines corresponding to constant values of U as calculated from equations 19 and 20 applied to the cases of equations 22 and 24 are shown in Figures 2 and 3 where $a=\sqrt{7}$ cm, $c=7$ cm, $A=10$ cm and $\omega b\gamma\Phi/(2\pi)=3.5$. The value U on the outer boundary is zero and changes by steps of one in Figure 2 and steps of two in Figure 3.

Demagnetizing Effects

So far the magnet pole pieces have been assumed to be so hard that they do not short-circuit the flux of the eddy currents. This is not true for the permeable pole pieces of an electromagnet, whose effect may be calculated approximately by observing that the current $2U$ is enclosed by the rectangular path 1-2-3-4-1 in Figure 4, which lies in the upper and lower pole pieces except where it cuts across the disk and gap normally at $r=r_1$ and $\theta=\pm\theta_1$. If the reluctance of this circuit lies entirely in the air gaps, each of length g, then the magnetic flux density B_e due to the eddy currents alone at r_1, $\pm\theta_1$ is $4\pi U/g$. Substituting for U from equation 20 and writing as before $\epsilon=2\pi\omega b$ gives

$$B_e=\frac{c\epsilon r_1\Phi\sin\theta_1}{\pi a^2g}\left(1-\frac{A^2a^2}{c^2r_1^2+A^4-2r_1cA^2\cos\theta_1}\right) \quad (26)$$

This shows that when b and g are comparable in size B_e cannot be neglected compared with the original flux density $\Phi/(\pi a^2)$. The $\sin\theta_1$ term shows that the radial component of the eddy currents induced by B_e have opposite signs under the two halves of the pole piece, so that they contribute nothing directly to the torque, but on the other hand they form closed circuits about the central portion and so produce a demagnetizing magnetomotive force in the electromagnet. The

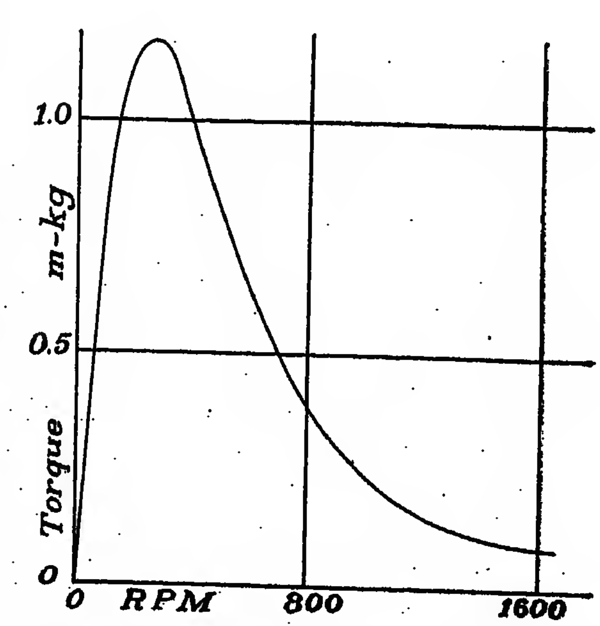

Figure 6. Curves showing torque versus speed for a large disk rotating between the single pair of circular pole pieces of an electromagnet as given by equations 22, 27, and 28

stream function U_e of these eddy currents is calculated as U is, but to simplify matters we carry out the operations from equations 14 to 16 for a single element of the pole face, along with its image element outside the circle $r=A$. We then give each element the strength indicated in equation 26 and set up a definite integral for U over the pole-piece area. This method is less exact than setting up equation 14 for the whole face, because it ignores that part of the flux threading dS from the current induced by B_e outside this area, which is of the order $\epsilon B_e dS$. The eddy currents U_e are evidently equivalent to a magnetic shell of variable strength U_e in the sheet and to get $\mathfrak{F}_e$ the demagnetizing magnetomotive force we must find the equivalent uniform shell. Thus we have

$$\mathfrak{F}_e=\frac{1}{\pi a^2}\int_S U_e dS$$

where S is the area of the pole face. We now have a complicated quadruple integral involving the variables r', R', θ' and θ_1' whose evaluation can be simplified somewhat by integrating in the proper order. The result is

$$\mathfrak{F}_e=\frac{\omega^2 b^2\gamma^2 c^2}{4g}\Phi\left(1-\frac{2a^2A^2(A^2+c^2)}{c^2(A^2-c^2)^2}+\frac{2A^4}{c^4}\log_e\frac{(A^2-c^2)^2}{(A^2-c^2)^2-c^2a^2}\right)=\beta^2\gamma^2\omega^2\Phi \quad (27)$$

If the flux penetrating the sheet at rest is Φ_0, then when in motion we have, if $\mathfrak{R}$ is the reluctance of the electromagnet, $\Phi=\Phi_0-\beta^2\gamma^2\omega^2\Phi/\mathfrak{R}$, so that

$$\Phi=\frac{\mathfrak{R}\Phi_0}{\mathfrak{R}+\beta^2\gamma^2\omega^2} \quad (28)$$

The expressions for the torque now become

$$T=\frac{\omega\gamma\mathfrak{R}^2\Phi_0^2D}{(\mathfrak{R}+\beta^2\gamma^2\omega^2)^2} \quad (29)$$

where D has the values given in equations 22, 24, or 25, according to the pole arrangement. There is now a definite speed for maximum torque which is found by setting $\partial T/\partial\omega=0$ to be

$$\omega_m=\frac{1}{\beta\gamma}\sqrt{\frac{\mathfrak{R}}{3}} \quad (30)$$

Putting this in equation 29 gives

$$T_m=\frac{3\sqrt{3\mathfrak{R}}\Phi_0^2D}{16\beta} \quad (31)$$

This is independent of the conductivity which is surprising, although there is some evidence for it in Lentz's experimental curves shown in Figure 5 which give hot and cold copper disks the same T_m for different ω_m.

These calculations of demagnetizing effects have been worked out for a single pole. For an even number of poles with alternating signs, we have seen that the torque per pole is increased, but the demagnetizing forces are also increased so that the torque obtained by multiplying equation 29 by the number of poles will probably not be far wrong. The speed for maximum torque given by equation 30 will certainly be decreased, perhaps considerably, because of the increase in β.

The only formula we can find for this torque is one derived by Rüdenberg.[3] This formula is written as a double infinite series and is derived by considering a thin conducting strip bounded by straight lines which moves lengthwise in the narrow gap between magnetic poles with rectangular faces. The fields of adjacent poles are antiparallel, so that the inducing fields can be expanded in a double series of odd harmonics. This formula was checked qualitatively by Zimmermann,[4] but could not be verified quantitatively, as the theoretical and experimental boundary conditions did not agree. Lentz found only those terms involving the lengthwise harmonics were of importance and dropped the rest. His experimental brake had the center of the disk removed to simulate a ring whose width roughly equaled that of the postulated strip. His four poles were so far apart that their action was nearly independent. We have redrawn in Figure 5, his experimental curves giving the torque in meter kilograms against angular velocity in revolutions per second. The ring had inner and outer radii of 5 centimeters and 25 centimeters and was 0.4 centimeter thick. The air space was 1.2 centimeters, and the centers of the rectangular pole pieces were 20.75 centimeters from the rotation axis and were 6 centimeters (radial) by 8 centimeters (tangential). The inducing field was 2,150 gauss at rest. The figures on the hot copper curve show the estimated stable mean temperature for that speed.

A direct quantitative comparison of our formula with Lentz's data is difficult, because he used rectangular poles, his air gap was so large as to spread the inducing field over an unknown area, the center of his disk was cut away, and we do not know where his flux density was measured. Although our formulas are inaccurate for such large dimensions at the high speeds, it is interesting to see what results they give for a comparable case. Let us take $b=0.4$ cm, $A=25$ cm, $a=4$ cm, $c=21$ cm, $g=0.6$ cm, $B=2{,}000$ gauss and assume the reluctance entirely in the air gap. In equation 22, $D_1=1.23$, in equation 27, $\beta=3.85$ and in equation 28 $\mathfrak{R}=0.012$. The angular velocity for maximum torque for copper ($\gamma=1/1{,}700$) is given by equation 30 to be 27.9 radians per second or 267 rpm. T_m is 1.15×10^8 dyne cm or 1.17 kilogram-meters for this single pole and roughly four times this for four poles. Expressing T' in kilogram-meters and ω' in rpm, equation 29 becomes

$$T'=\frac{0.00785\omega'}{(1+0.0000047\omega'^2)^2}\text{kg-m}$$

This formula is plotted in Figure 6. A comparison of Figure 5 with Figure 6 indicates that our formula gives too rapid a falling off in torque at high speeds. It should be pointed out that other conditions, such as the degree of saturation of the iron in the magnet will upset the assumed relation between magnetomotive force and Φ and may modify equations 28, 29, 30, and 31 considerably.

The methods given in this paper may be extended to any number of poles by the method used for two and to other than circular faces. Several such calculations have been carried out, but it is doubtful if the additional theoretical accuracy justifies publishing them. The difference between the ideal boundary conditions used here and those found in apparatus is such that we recommend that the torque for one pole be calculated by equation 22 for permanent magnets or by equation 29 for electromagnets, and the result multiplied by the number of poles to give the total torque. In power apparatus the heating of the disk will change its resistivity and may cause it to expand and buckle and otherwise upset the calculations.

Poles and Pole Treatment

REGINALD H. COLLEY
NONMEMBER AIEE

TO write about poles and the preservative treatment of poles today is like writing the review of a very successful play that has been running a long time. The players are not men, but inanimate poles. The natural backdrop is the forest. The stage is as broad as the United States and the setting is a criss-cross of thousands of miles of utility and communication lines. The engineers of these lines are the producers and directors of the play; and it is they who assign the parts to the various actors and write a changing script as the play progresses. It is the purpose of this paper to present certain highlights of the more important scenes, such as pole use and the drain on the forest, pole manufacture and treatment under standard specifications, and pole strength, and to discuss some possible rearrangements in the setting that may become necessary.

An Outline of the Pole Problem

In the forest are standing trees of various diameters and heights, some of which become poles. There are broad-leaved trees called hardwoods, and needle-leaved trees or conifers, called softwoods. In any tree there is a central core of more or less durable, nonliving wood known as the heartwood, which is surrounded by a layer of living wood known as the sapwood. There are durable woods in both the hardwood and softwood groups. The durable woods have relatively large heartwood cores and relatively thin sapwood; and the nondurable woods, on the other hand, are likely to have relatively thick sapwood.

The history of change in practice that has taken place since the first chestnut lines were built is a story of the shift from naturally durable woods to nondurable woods, and this change has involved the introduction and use of preservative materials to give the nondurable woods an economic service life.

One of the most important reasons for the shift was a national disaster in the form of the chestnut blight disease which has wiped out completely the commercial chestnut forests of the United States.

At the same time the supply of northern cedar became inadequate, at least as far as the sizes required for joint use were concerned. The question of selecting proper pole size became more and more important. The growth of the electrical industry had not followed a simple pattern, and the need for correlation of ideas and a rational standardization of pole practice led to the writing and acceptance of the American Standard Specifications for Wood Poles.[1] These specifications have had a most important influence on modern pole production. They were written around the natural poles of the forest; and they were designed to make suitable species interchangeable and to encourage the use of the greatest possible number of pole-size trees.

Other specifications had to be written or rewritten to cover the preservative treatment. The writers of these specifications focussed their attention on the finished pole, leaving only so much of process control in the specifications as was necessary to protect the timber from injury. This focussing generally took the form of defining acceptable limits for penetration. Practically speaking, the only universally accepted preservative was coal tar creosote. One major objective only was held in view in the preservation processes, namely, to fill the nondurable sapwood, whether it was very thin as in chestnut, or whether it made up 95 per cent of the pole as in many southern pines, with enough toxic creosote to prevent the growth of wood-destroying fungi.

Pole Use

Figure 1 is a copy of an old map made about the turn of the century to show the economic limits for the distribution within the Bell system of certain pole timbers. For the greater part of the country chestnut and northern cedar were favorites. In the western states western cedar was a natural selection. Creosoted southern pine had just begun to spread up from the southern pine forests, reaching as far north as St. Louis. The contrast between Figure 1 and Figure 2, which represents conditions in 1941, is striking. Chestnut is gone. The eastern scene is almost completely dominated by southern pine. Western cedar is distributed from the northwest and from the concentration yards at Minneapolis. Northern cedar is confined to parts of the New England states and the Lake states. Lodge-pole pine serves the Mountain states area. Douglas fir is being shipped from the fog-belt forests of Oregon and Washington, either directly or through Minneapolis to the eastern and southern states. The lines of distribution cross and recross in a perplexing pattern woven from preference, policy, price, and freight rates.

Many of the changes indicated in Figure 2 have been inevitable. Expansion of joint use, which has been easier since the standard pole specifications have become more widely accepted, has had a tendency to increase the length of the poles required for certain services. This has inevitably thrown the demand back on southern pine and western red cedar; and within the last two years the practical difficulties in securing large quantities of long southern-pine and western-cedar poles have practically forced the production and use of Douglas fir.

Figure 3 is a composite diagram, worked out by Doctor J. G. Segelken of the Bell Telephone Laboratories, presenting in a new fashion a picture of the relative use by the Bell system of some sizes of the pole species shown in Figure 2. Certain facts stand out plainly. One is the relative use of northern cedar and western cedar in the 30-, 35-, and 40-foot groups. Another is the major position of creosoted southern pine. A few years ago the Bell system bought between 30 and 50 per cent of all creosoted-pine poles produced in any one year. Now only about 15 per cent of the production goes into Bell system lines; but the predominance of creosoted southern pine in the Bell system use picture is a factor of major importance.

The Drain on the Forest

The degree of this importance is illustrated by Figure 4, derived from the annual reports prepared by R. K. Helphenstine, Jr.,[2] of the United States Forest Service. Piles and poles are much alike, and they come from the same forests, so that one cannot speak of a natural supply of trees for poles without taking the demand for piles into consideration.

The number of standing trees per acre in the pine forest that will make either piles or poles 35 feet or more in length is relatively small. Therefore, any increase in the demand for long poles inevitably means the working over of a larger num-

Paper 42-144, recommended by the AIEE committees on communication and power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted April 13, 1942; made available for printing June 8, 1942.

REGINALD H. COLLEY is timber products engineer with Bell Telephone Laboratories, Inc., New York, N. Y.

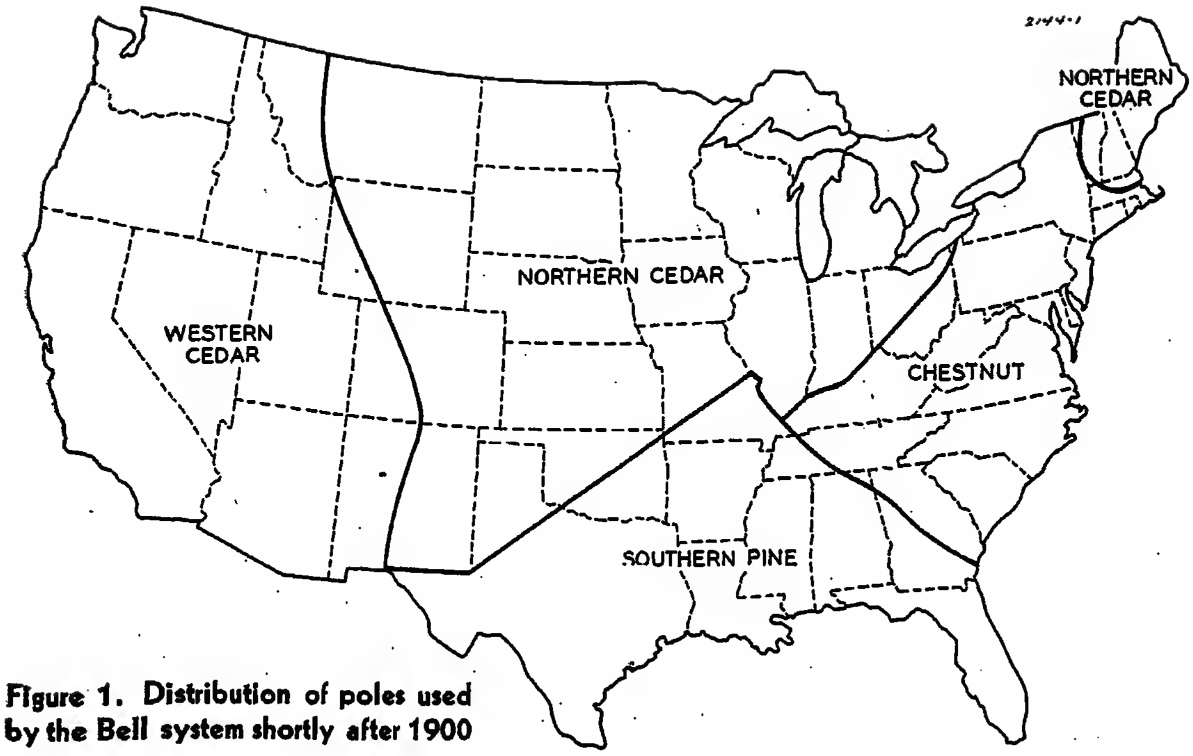

Figure 1. Distribution of poles used by the Bell system shortly after 1900

ber of acres with consequent increased labor and longer hauls. The Southern Forest Experiment Station at New Orleans conducted a unique survey in 1934–1936 which revealed that there was a more than adequate supply of pole trees of small diameter under 25 feet in length, but that the number of suitable trees in the larger sizes was relatively small. Figure 5 shows the relative use within the Bell system and outside of the Bell system for 35-, 40-, and 45-foot southern-pine poles, classes 1 to 7, American Standard. The 35-foot class 5 pole, which is a favorite for joint use makes up roughly 10 per cent of the total requirements. The relative natural occurrence in the forest of trees to make these poles is only one per cent of the total forest stand. The survey figures indicated that the number of trees suitable for 35-foot class 5 poles and for piles of about the same size taken together was approximately 3,500,000. This looks like an adequate supply. But approximately 23 per cent of the poles required for use outside of the Bell system are for 35-foot poles of smaller diameter, and the heavy demand for 30-foot class 6 and class 7 poles for cross-country lines and rural extensions during the last few years has meant cutting trees which, had they been left standing, might have furnished an entirely satisfactory supply of 35-foot poles at some later date.

The current requirements for 35- and 40-foot southern-pine poles are relatively much in excess of the occurrence of standing trees. The rapid expansion of the pulp and paper industry in the southern states and the heavy emergency demand for southern-pine lumber and piles have probably changed the relative proportions of the various sizes of standing trees since the survey. If the demand for creosoted-southern-pine poles 35 feet and longer were to continue at the present rate, a situation would soon develop in which these poles would be at a premium, and rigid straightness requirements would have to be relaxed in order to facilitate production. It would seem to be the better part of wisdom to use as many sizes as possible and to broaden the use of species to include western-cedar and Douglas-fir poles whenever it is practicable to do so.

Pole Manufacture and Standard Framing

Since the establishment of standard dimensions for the different species, there has been a definite trend toward greater mechanization in pole production. The most evident result of this trend is the pole-shaving machine for removing inner bark and smoothing the pole surface. Under Bell system specifications southern-pine poles are now trimmed by approved machine, and the trimming is limited so that the average size of the poles shall not fall below certain minimum circumferences at six feet from the butt, at mid-point, and at the top. The shaving machines are finding their way into the cedar industry, and western cedar is shaved to facilitate preservative treatment or to reduce the sapwood thickness so that it will not hold enough moisture to support decay. Machine trimming has improved the appearance of the southern-pine pole by removing the natural bumps at the knots, and by reducing the exudation of creosote, or "bleeding," from the pole surface. It also accelerates drying and facilitates production-line operation.

Generally speaking, the majority of the southern-pine poles manufactured for Bell system use are manufactured and framed to a standard pattern. At present the roof is cut square with the pole axis, and instead of the individual mortises for the crossarms, a slab gain is provided by machining a flat surface on the appropriate side of the upper part of the pole. The slab-gained pole is an economical all-purpose pole that takes the place of the mortise-gained pole, cable pole, guy stub, and push brace. There are, of course, cases in which special framing may be necessary or desirable; but special framing is a kind of custom job, and unless production orders are placed well in advance, it generally happens that specially framed poles must be produced on order.

The acceptance of standard framing has met with less resistance in southern pine than in western cedar. It is only within the last few years that the concept of a standard finished western-cedar pole has begun to take form. In the case of southern pine the principle of complete manufacture before treatment was established as a practically universal procedure before

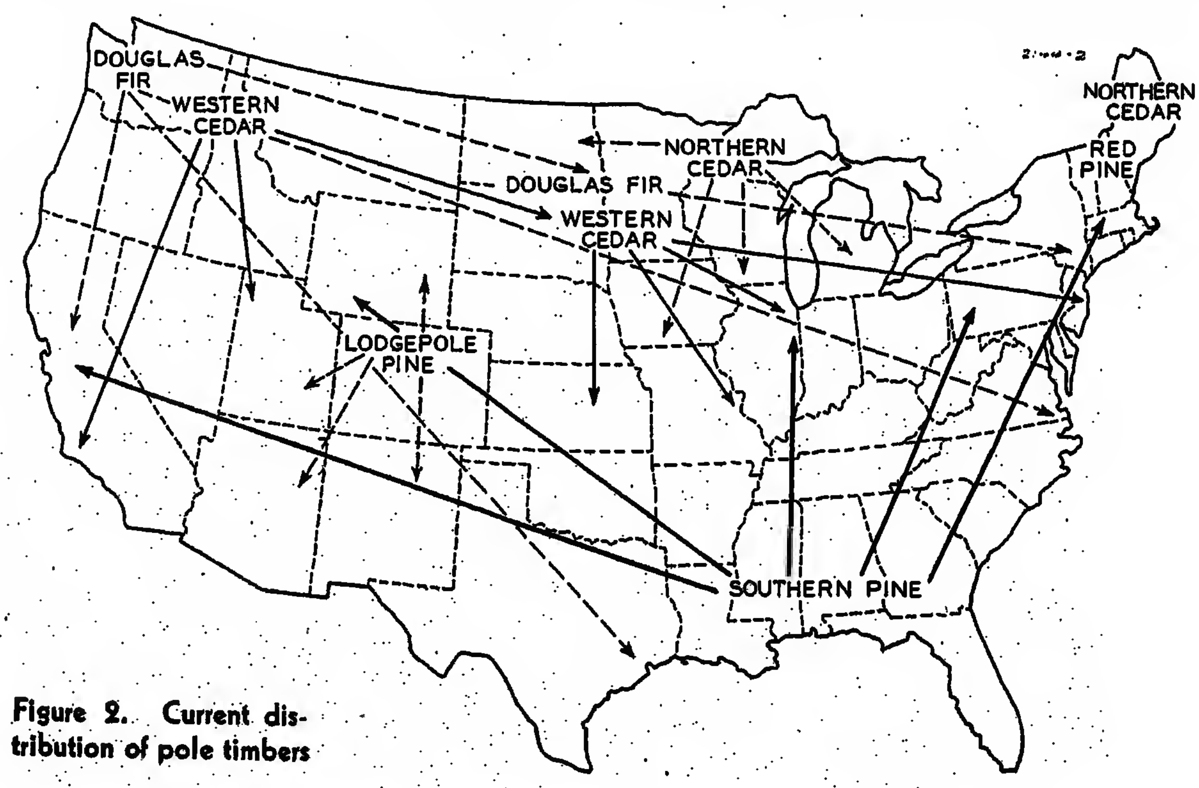

Figure 2. Current distribution of pole timbers

the creosoted-pine pole began to be accepted as a regular piece of line equipment, and the development of standard framing followed more or less naturally. In all cases gaining and boring the bolt holes is permitted after treatment in southern pine if the sapwood is 100 per cent penetrated.

Pole Preservation

The main purpose of pole preservation is to protect the nondurable sapwood from decay. The principles are relatively simple. A toxic substance is put into the wood in sufficient quantity to make the wood unpalatable to the wood-destroying fungi that cause decay. The addition of the toxic substance must be accomplished without material damage to the wood itself.

The preservative most in favor is coal tar creosote. The wood is impregnated by soaking the pole butts in open tanks or by applying pressure to the whole pole in closed cylinders. The butt-treating method has been applied with greatest success to the naturally durable thin sapwood species like chestnut and cedar, the aim being to put a protective layer of sapwood saturated with creosote around the naturally durable heart. In the case of cedar it is necessary to puncture the sapwood to secure satisfactory penetration. The open-tank method has also been used for the treatment of the thicker sapwood of lodge-pole pine, and it is now being employed as a supplementary process to the butts of poles that have been given a full-length treatment with a preservative salt.

Current treating specifications for full-length pressure treatment place the emphasis upon the product. Penetration is relatively more important than quantity of preservative retained. The Bell system, after some years of observation and experimentation, now specifies that the treatment of southern pine shall be by an empty-cell process, that the penetration shall be at least $2^1/_2$ inches unless 85 per cent of the sapwood is penetrated, and that the net retention shall average eight pounds of creosote per cubic foot of wood. Detailed discussion of the development of these requirements may be found in the *Proceedings* of the American Wood-Preservers' Association. The double requirement, based on both depth and per cent of sapwood penetrated, is necessary, because the sapwood thickness varies in poles of different lengths and circumferences.

A relatively low-residue creosote has been specified, defined by limiting the residue that remains after distillation has been carried to 355 degrees centigrade. Much of this low-residue creosote has been imported. At present such importation has practically ceased, and some adjustments are in order. The purpose of the low-residue creosote requirement was to make the product as acceptable as pos-

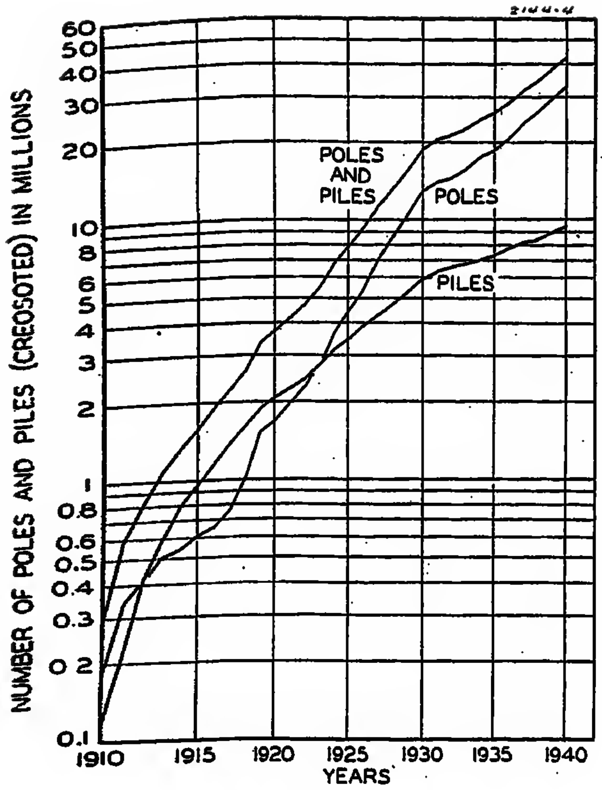

Figure 4. Creosoted-southern-pine poles and piles produced in the United States since 1910

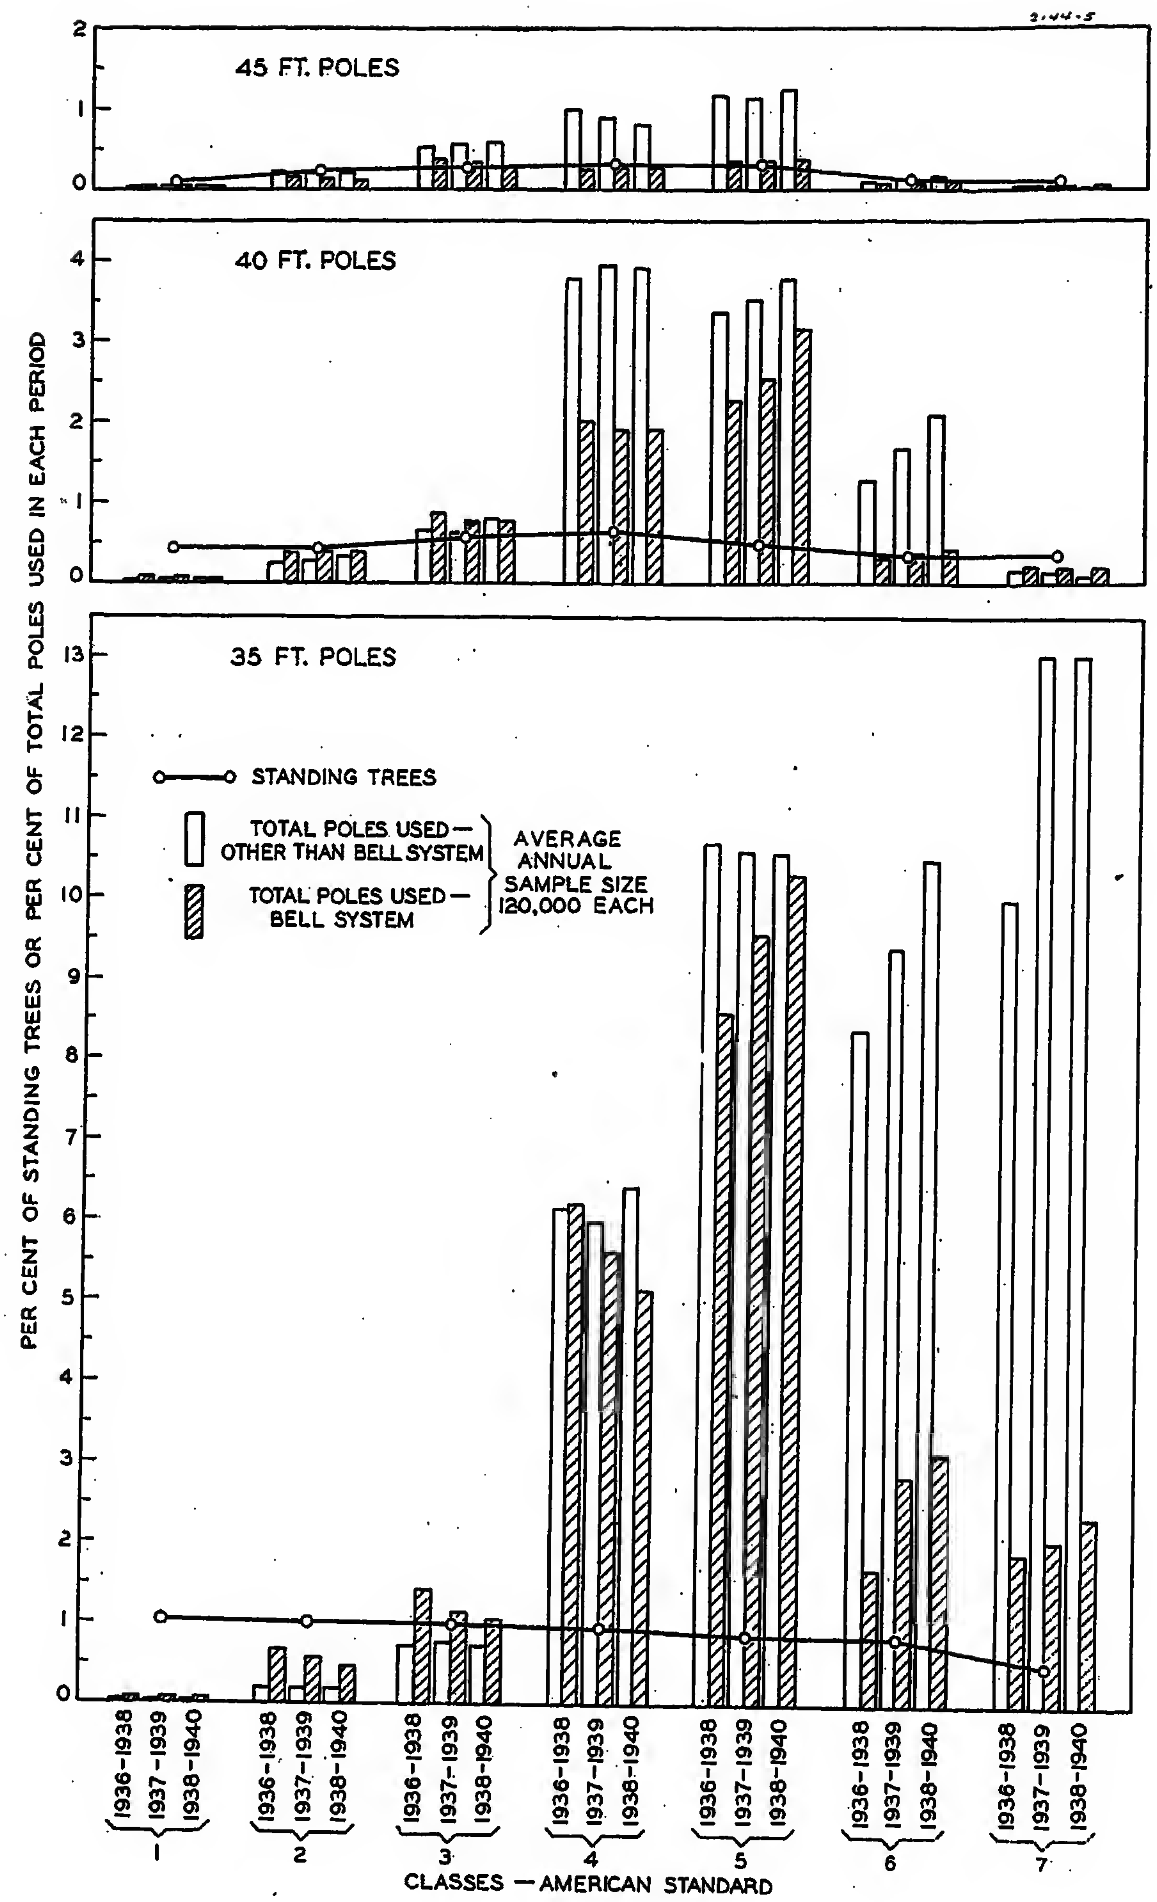

Figure 5. Forest supply and use in and outside the Bell system of 35-, 40-, and 45-foot southern-pine poles

sible to all parts of the Bell system and for all types of lines, whether urban or rural. At the time the requirement was written into the specification, the heavier residue creosotes available had a tendency to bleed badly, that is, to ooze from the poles after the poles were set in line, often for months or years. A black sticky pole is a dirty pole, and it makes trouble for the construction crews and the public alike. In adapting the creosoted-pine pole to urban use it has been found expedient to reduce the standard retention of creosote from 12 pounds per cubic foot to 8 pounds per cubic foot, to specify low-residue creosote and, in some cases, to require steam baths after treatment to clean the poles.

Full-length pressure treatment with creosote is also being applied to red pine, lodge-pole pine, western cedar and Douglas fir. In the case of Douglas fir the treatment usually takes several times as long as treatment of southern pine; and although the sapwood of Douglas fir is thinner, it is sometimes hard to treat as high a proportion of the sapwood as in southern pine.

In expanding the use of red pine, lodge-pole pine, and Douglas fir, it was necessary to focus attention on adequate penetration and to reduce the retention as far as practicable to prevent bleeding. In making compromises of this type one is forced to sidestep the main argument that has been so often advanced, that the reduction of retention from 12 pounds to 8 pounds in southern pine, for example, might mean inadequate service in line. The compromises appear to be working out fairly well, and, as a matter of fact, the actual concentration in the thinner sapwoods of Douglas fir and lodge-pole pine are at about the same level as the concentration in the sapwood of southern pine.

Penetration, Nonconformity, and Risk of Early Failure

Only in the case of southern pine has the evidence on the practicability of the penetration and retention requirements been fairly well established. The latest available information on southern-pine treatment by an eight-pound empty cell process is illustrated by Figure 6, which shows the smooth distribution of 17,556 poles, nonconforming for penetration, representing approximately 3.5 per cent out of a total sample of 525,000 produced in 1941. The distribution has been divided into nonconformity zones, numbered 1 to 5. The interpretation of the distribution is illustrated in Table I. From studies of the behavior of creosoted-southern-pine poles in line[3,4], certain failure factors have been determined which

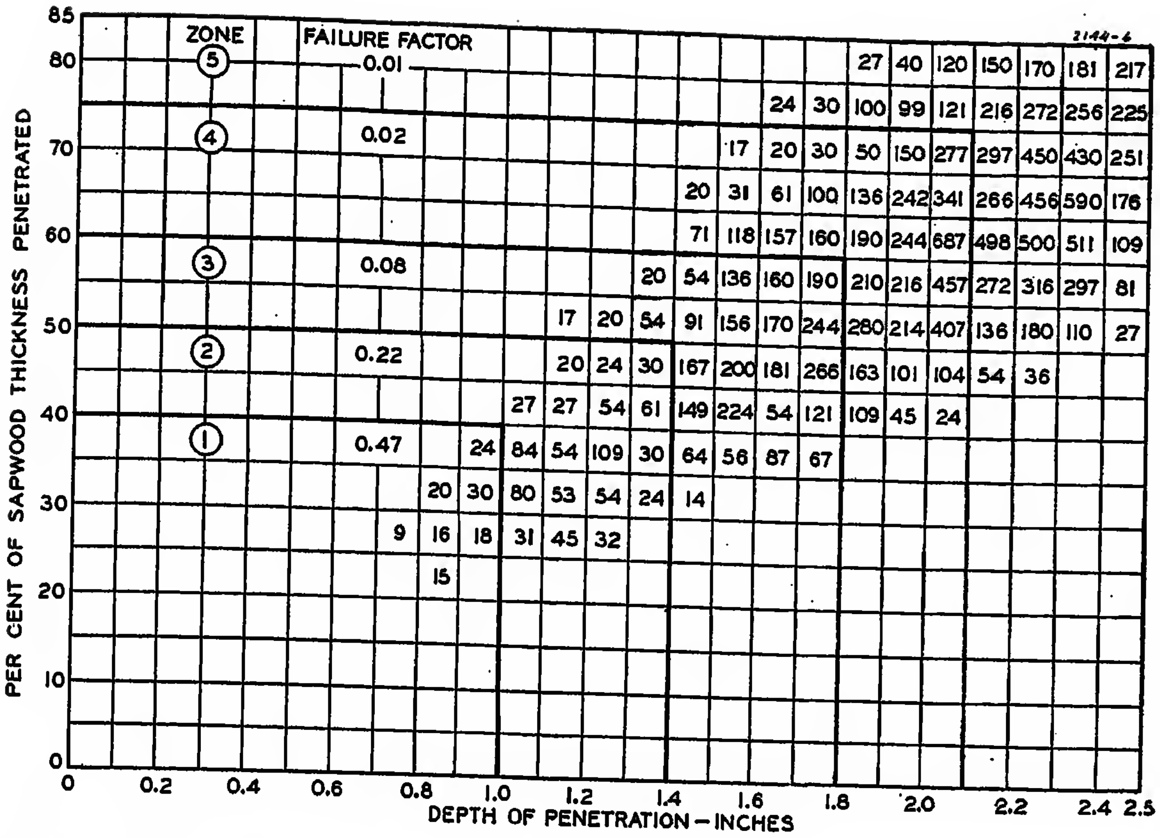

Figure 6. Distribution of southern-pine poles nonconforming for creosote penetration, 1941 production, arranged in nonconformity zones according to risk of early failure in line

are applicable to the percentage of poles in the respective nonconformity zones. These failure factors may be defined as the percentage of the poles within these zones which may be expected to fail within 15 years of installation. Recent experience indicates that these failure factors are probably high. It appears likely that the total risk of early failure in a group of poles like those under consideration is less than the estimated 0.128 per cent. The method of interpretation illustrated was first advanced several years ago, and up to the present no reason has been brought forward for changing it. Broadly, it means that poles which meet the penetration requirements of current standard specifications should have an entirely adequate service life.

Green Salt Treatment

A new preservative for this country, called green salt, a mixture of five parts potassium dichromate, three parts copper sulphate, and one part arsenic acid, in a cold water solution, has been used recently for the commercial treatment of seasoned southern-pine poles. The treating solution contains about seven per cent of the salts. The penetration has averaged about 98.5 per cent of the depth of the sapwood, which is better than the average generally obtained in creosote treatments; and the number of nonconforming poles was approximately three per cent. The distribution of nonconformity appears to be of the same order as that shown in Figure 6, with fewer poles in zones 1 and 2. The finished product is cleaner, lighter in weight, and stiffer than the creosoted pole, and the outer fibers are somewhat harder, making the green salt poles somewhat more difficult to climb than the creosoted pole. Generally speaking, the reaction of the field forces to the new poles has been excellent.

Immersion Treatments—Creosote, Petroleum, and Pentachlorphenol

The virtual shutting off of creosote importation by the war has stimulated the use of other types of preservatives such as mixtures of creosote and petroleum, with or without the addition of some other material such as pentachlorphenol; or the use of a five per cent solution of pentachlorphenol in petroleum alone.[5] The latter solution is being used for the full-length treatment of western cedar by an open-tank immersion process as well as for pressure treatment of southern pine.

Machine-shaved western cedar poles are being creosoted by immersion in hot creosote, followed by the usual butt treatment. The end in view in these western cedar treatments is to produce poles in which the hazard to linemen from sapwood decay will be eliminated.

Salt-Creosote Poles

During the last 15 years approximately 800,000 southern-pine poles treated with zinc meta arsenite have been placed in line. The majority of them have been purchased and set by power and light utilities. The deterioration that has occurred in these poles has happened at or below the ground line and, in most cases, the reduction in circumference at that point has taken place slowly. Above ground line the condition of the poles is excellent. To prevent the deterioration at the ground line, poles that are treated full length with zinc meta arsenite are now being given a butt treatment with creosote. Specifications for this double treatment call for a penetration in the above ground part of the pole of $2^1/_2$ inches unless 85 per cent of the sapwood is penetrated, as in the case of creosoted southern pine. Below ground a full sapwood penetration of creosote is not required. The aim of the specification is to provide for adequate protection of the butt without the use of too much creosote. This salt-creosote pole is being distributed in the northeastern states on the bases of strength and life expectancy equivalent to creosoted southern pine. Other salts than zinc meta arsenite, such as those covered by the current Federal specifications for use in treatment of timber not in contact with the ground, are under consideration. It is interesting to note in this connection that double treatment using zinc chloride followed by a creosote butt treatment was in use in Texas prior to 1910. Some of the poles of this vintage have given at least 34 years' service in line and are still good.

Conditioning Poles for Treatment

This brief discussion of preservation cannot be dropped without some mention of the problem of preparing poles for treatment. In theory at least, it would be desirable to dry poles of all species before treating them. Practically speaking, it is almost impossible, except at certain seasons of the year, to air-season southern-pine poles for either creosote or salt treatments without great risk of the poles becoming infected with molds and strength-reducing fungi during the process. The larger the pole, the harder it is to dry it. Charges of either green or dry poles may be treated satisfactorily with

Table I. Southern-Pine Poles—1941 Production—Estimate of Risk of Early Failure in Line

Nonconformity zone	Number of Poles	Per Cent of Total Poles	Failure Factor	Risk of Early Failure Per Cent of Total Poles
1	132	0.025	0.47	0.012
2	839	0.160	0.22	0.035
3	2,862	0.545	0.08	0.044
4	5,432	1.035	0.02	0.021
5	8,291	1.579	0.01	0.016
	17,556	3.344		0.128

due care in the control of the treating process. Partially seasoned poles, either alone or in mixture with seasoned or green poles, may make the treating results very variable. The Bell system specification requires steam-conditioning for at least six hours at 259 degrees Fahrenheit before impregnation with creosote, in order to smooth out some of the variables and to sterilize the wood.

To prevent deterioration during seasoning, some producers follow the practice of pretreating all pole stocks as soon as they have dried down to the point where such treatment can be given economically with approximately four pounds of creosote per cubic foot. The poles are then stacked in the yard and held for orders. The additional poundage required to meet the minimum retention specified is added by a second treatment. In other cases the poles are treated under pressure with weak solutions of preservative salts.

The kiln-drying of southern-pine poles[6] has been carried far enough experimentally during the last few years to show that it is a distinctly promising method of preparing the poles for treatment. Ironically enough, it begins to look as if the creosoted kiln-dried poles would have to be steamed for a short period at the end of the creosoting process in order to clean them and prevent subsequent bleeding of the creosote from the pole surface.

In the case of certain of the salt preservatives organic matter in the green or partially seasoned pole causes a very rapid chemical reduction of the preservative solution if either the wood or the solution is heated; and this reduction does not occur to the same degree if the wood is dried before treatment, and the solution is applied cold. In any event a dry pole treats quickly, and the plant is able to save cylinder hours, and a pole that has once been dried and then given either a creosote or a salt treatment dries out subsequently more rapidly than a pole that was not seasoned before treatment.

Electric Resistance

It is extremely important to bear in mind the practical difficulties involved in seasoning and treating timber before entering on a discussion of the conductivity of the treated wood. Measurements made by improved methods[7] confirm the generally accepted conclusion that the electric resistance varies inversely as the moisture content. There is a temperature factor, but it can be more or less ignored if the measurements are made within certain temperature limits. It is not so easy to control moisture content. The moisture may come from two sources, that is, it may be the moisture that is left in the sap that was in the tree when it was felled, and it may be moisture absorbed from rain or melting snow as the pole is lying in a concentration yard or standing in line.

The sapwood of a green pole may contain more water than its own dry weight. At a moisture content equal to 27–30 per cent of its dry weight, wood is said to be at the fiber saturation point, that is, at a point where there is no free water in the wood cells. If the moisture content is above this fiber saturation point, the electric resistance of the wood is low. Below the fiber saturation point electric resistance increases sharply as the moisture content decreases.

Suppose that, either as the result of well-considered seasoning practice on the part of the producer, or on the insistence on the part of a possible customer, a group of relatively high-resistance poles has been produced and shipped. It would be quite wrong to assume that these poles would all have high resistance at the time they were placed in line and equipped for service. During shipment moisture may get into the open seasoning checks and be absorbed by the inner sapwood and untreated heartwood of the pole. Or the poles may be exposed to rain and snow for months before they are erected. In fact, any method of open flat storage previous to line use is almost certain to bring about a great variation in the resistance of poles that may have started out on a relatively high resistance level. Even the best of storage conditions, under cover or in vertical piles, is no guarantee of high resistance of the pole in line. Driving rains, sleet, or snow storms may wet the windward side of the pole and bring it to practical saturation during the course of a storm. The character of the preservative itself simply adds another variable to these general conditions over which very little control can be exercised.

Aside from drying a pole properly before treatment so that it will dry out more quickly after treatment, there is little that can be done in writing specifications, or in actually producing poles, that will make it possible to turn out high resistance units; and after the poles have once been produced, each stick becomes an independent variable in its resistance characteristics. In practical operation, therefore, no pole can have a high resistance all the time.

Pole Strength

In writing the American Standard Specifications for Wood Poles,[1] all of the species were dimensioned so that they would have approximately equal resisting moments at the ground-line for any given class and length. These strength requirements have been translated into what may be called standard breaking loads starting at 1,200 pounds for class 7 and running to 4,500 pounds

* The standard breaking loads were taken as 100 in each case. These standard loads are: class 4—2,400 pounds; class 5—1,900 pounds; class 6—1,500 pounds, and class 7—1,200 pounds.

** The standard ultimate fiber stress for creosoted-southern-pine poles—7,400 pounds per square inch—was taken as 100 in each case.

† No standard breaking load for class 9 has been established. For the three poles listed the average breaking loads for the poles and for the pole-top sections were 1,317 pounds and 1,840 pounds, respectively.

§ The averages for the whole poles were taken as 100 for comparison with the top sections.

for class 1, approximately on a 25 per cent geometric progression.

Three years ago R. C. Eggleston of the Bell Telephone Laboratories began a series of breaking tests on machine-shaved southern pine treated with creosote, and with green salt. A novel scheme was introduced. The top sections of the poles as well as the poles as a whole, have been tested whenever possible. The results of part of these tests, on 92 poles and pole-top sections, are summarized in Table II. The poles averaged well above their rated class breaking loads, above the American Standard fiber stress—7,400 pounds per square inch—and within the expected variation for modulus of rupture. The modulus of rupture of the pole-top sections averaged 90 per cent of the modulus of rupture of the poles as a whole. The top sections of the poles were broken with short lever arms and, in spite of lower modulus of rupture, were on the average still sufficiently strong to meet their specified pole-class breaking load.

The position of the maximum knot and the maximum-knot group in relation to the point of break for the poles as a whole and for the pole-top sections are shown in Figure 7. Each line in the figure represents one of the groups defined by columns 1, 2, and 3 in Table II, and within given class length groups the creosoted-pole and the green-salt-pole diagrams are placed side by side to facilitate comparison. The independence of maximum knot position and break position is obvious. Only the pole-top sections, which had to be clamped in the holding device to represent the point of guying, broke at conspicuous knot groups. In some instances the very first point of break seemed to be at small knots an inch or less in diameter or even in hidden knots which did not appear on the surface of the poles at all. Occasionally poles will break during unloading. Apparently, such breakage is the result of impact shock far in excess of what the poles could stand. Generally, this impact shock comes from dropping the pole or from catching it between others as it is rolled off the car or trailer. The breaking in such cases at knot groups is coincidental with the shock and point of application and does not indicate dangerous weakness in the pole itself.

Ground-Line Treatment

One other subject remains for brief mention, namely the prolongation of the life of the existing pole plant. The evidence from test plot experiments and observation of poles in service indicates that some sort of ground-line treatment should be applied to untreated poles that are worth saving at the time of inspection, as a part of the regular inspection procedure. When one looks back over the years, it appears that the mistake, if any, that was made in earlier ground-line treatments was not in the treatment itself, but rather in the assumption that a single application would be effective for the life of the pole. The methods now recommended are the Osmose process or the simplified procedure that consists of the regular inspection and excavation, and treatment with a water-soluble salt and creosote. Originally a pound of sodium fluoride was dumped into the excavation around the pole, and the hole lightly backfilled. Then, after making a narrow V-shape trench against the pole, about one gallon of cold creosote was poured into the hole by letting it run against the pole, at a height of about 12 inches above the ground line, from the flattened spout of a watering can. The backfill was then finished, leaving the earth around the ground line fairly saturated with creosote and leaving a water-soluble salt to be taken up by the moisture in the wood. Sodium fluoride has been replaced in part by borax in the general plan as a result of the shortage of the former salt. The protection afforded by such a treatment seems to be good for about five years.

Interim Report on Guides for Overloading Transformers and Voltage Regulators

AIEE COMMITTEE ON ELECTRICAL MACHINERY
Transformer Subcommittee*

THE present war emergency has crystallized the need for additional information concerning the maximum load capability of modern-design transformers and voltage regulators in order that these apparatus may be utilized to a greater extent for meeting present and new load requirements with a minimum amount of new equipment, thus conserving critical war materials. It will be noted that the papers[1–3] presented at the AIEE convention June 24, 1942 give somewhat divergent views on permissible overloads and on the effect of temperature on transformer insulation.

The relation between the life expectancy of insulation as indicated by laboratory tests and the actual life of a transformer is largely theoretical, so that the use of such information must be tempered by sound judgment based on operating experience. This report represents a compromise of views that is considered conservative and satisfactory for immediate general use, subject to the limitations and cautions given herein.

Consideration is given to operation with normal life expectancy and also with moderate sacrifice in life expectancy, thus taking into account the effect of the following factors:

(*a*). Characteristics and limitations of the apparatus involved.

(*b*). Ambient temperature.

(*c*). Load factor.

(*d*). Supplemental cooling.

(*e*). Sacrifice of life expectancy.

Normal Life Expectancy

In this report normal life expectancy is based on continuous operation at rated load with a daily average ambient temperature of 30 degrees centigrade for self-cooled or forced-air-cooled transformers, 25 degrees centigrade for water-cooled transformers, and other usual service conditions as given in American Standard *C*-57, Section 2.000. The "Guides for Operation of Transformers" included in American Standard *C*-57 give general recommendations for the loading of oil-immersed transformers and voltage regulators for recurrent and emergency overloads with small effect on normal life expectancy, while this report will supply, in addition to other information, data for heavier overloads with moderate sacrifice of life expectancy.

Loading for Normal Life Expectancy

The maximum load capability is determined to a considerable extent by the type and the electrical characteristics of the specific piece of apparatus. However, some general guides may be set up, based upon the more usual comparatively modern design characteristics, and with provision for taking into account the factors of temperature of the cooling medium, load factor, thermal ability of bushings and accessories, expansion of oil due to temperature increase, possible pressure in sealed transformers, method of cooling, and so forth.

Design Characteristics

The general information on transformer loading in this report applies to the comparatively modern-design transformers built since about 1928. The information will not apply in the usual case to the older-design apparatus without consideration of the design characteristics of each piece of apparatus.

Ambient Temperature

For low ambient temperatures the continuous kilovolt-ampere loading may be increased one per cent for each degree that the daily average temperature is below 30 degrees centigrade for self-cooled transformers, three fourths of one per cent for each degree below 30 degrees centigrade for forced-air-cooled transformers, and one per cent for each degree below 25 degrees centigrade for water-cooled transformers.[4] Similarly, the loading should be decreased two per cent for each degree that the daily average ambient is above these temperatures. For continuous loading these rules result in normal life expectancy, the same as for operation at rated load with ambient temperatures of 30 degrees centigrade and 25 degrees centigrade respectively. Detailed applications of these rules are given in the American Standard *C*-57, "Guides for Operation of Transformers."

Under some conditions greater permissible overload capability can be obtained by using "equivalent annual ambient" instead of the daily average ambient when applying the rule for overloads due to change in ambient. The equivalent annual ambient is the temperature which, if maintained constantly, would result in the same aging as that occurring under the actual ambient temperature throughout the year. This matter is being given further consideration.

Load Factor

For daily load factors below 100 per cent the loading may be increased 0.3 per cent for each per cent that the daily load factor is below 100 per cent,[5] with normal life expectancy. More nearly accurate corrections based on an actual load curve are not usually justified for normal loading. In no case should the overload permitted by this factor exceed 15 per cent, corresponding to 50 per cent daily load factor.

Acknowledgment is made of the assistance given by R. T. Henry, H. W. Hartzell, J. S. Lennox, and D. L. Levine.

TEMPERATURE RISE OF WINDINGS

The information in this report is based on apparatus designed for the standard 55 degrees centigrade rise. If a transformer has been designed for other than 55 degrees centigrade rise, a rating to give 55 degrees centigrade rise can be calculated, and then the correction factors stated herein can be applied.

SUPPLEMENTAL COOLING—EXISTING TRANSFORMERS

The load that can be carried on existing transformers can be increased by adding auxiliary cooling equipment such as radiator fans, external forced oil coolers, or water spray equipment. The amount of additional loading that such devices permit varies widely depending on

(*a*). Design characteristics of the transformer.

(*b*). Type of cooling equipment.

(*c*). Permissible increase in voltage regulation.

(*d*). Limitations of associated equipment.

Specific data should be obtained for each individual transformer.

When applying supplemental cooling to existing transformers, the permissible overloads should be based on the hottest-spot temperature rise instead of on average winding temperature rise. Usually the hottest-spot temperature rise over top oil temperature increases as the 1.6 power of the load.

If it is found that the bushings, leads, or other accessories are not a limiting feature, oil-insulated self-cooled transformers by the addition of fans may have the output increased in many cases 25 per cent and in some cases up to 33 per cent. Similarly, the addition of external forced oil cooling to oil-insulated self-cooled or oil-insulated water-cooled transformers may increase the output in many cases 25 per cent and in some cases up to possibly $66^2/_3$ per cent.

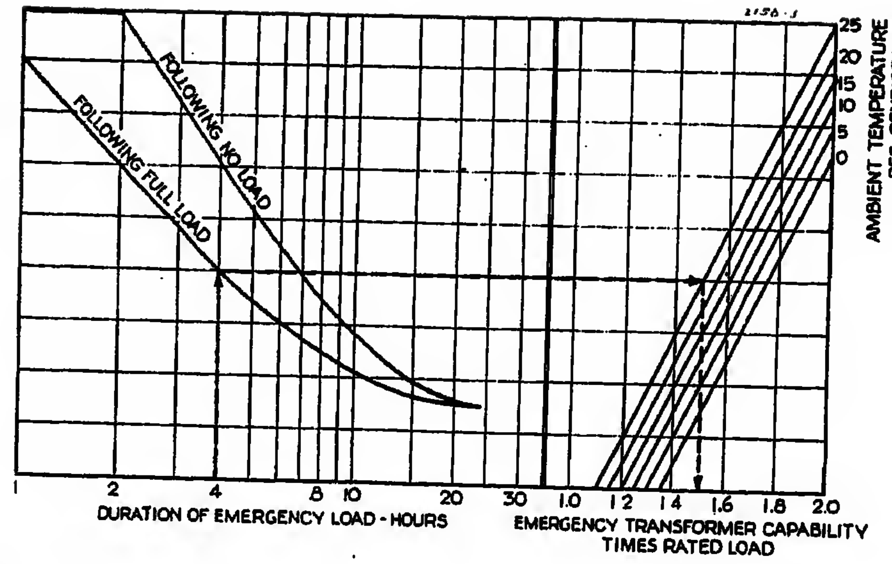

Figure 3. Emergency load capability of water-cooled transformers larger than 500 kva

See text for cautions and limitations

Water-spray equipment may be used in some cases as an emergency method of additional cooling. It is not generally considered satisfactory as a means of obtaining continuous additional capacity or for year-round operation. The added capacity obtainable by the use of water spray on oil-insulated self-cooled transformers is dependent on the air and water temperature, humidity, design of bushings, leads, and other accessories of the transformer. The water spray equipment may increase the capacity in many cases 25 per cent and in some cases up to possibly 60 per cent.

Emergency Loading With Moderate Sacrifice of Life Expectancy

The foregoing discussions have dealt with loading of transformers on the basis of normal life expectancies. In this section loading with moderate sacrifice of life expectancy during infrequent emergencies to values above those given in the American Standard *C*-57 "Guides for Operations of Transformers" is discussed.

On the basis of available data it is reasonable to consider that hottest-spot temperatures for durations shown in Table I represent an average sacrifice of life with each such emergency operation of not more than one per cent of the normal life expectancy as determined by the tensile strength of the winding insulation.

Table I. Temperatures for Short-Time Emergency Loads With Moderate Loss of Life of Insulation

Duration of Load—Hours	Hottest-Spot Temperature—Degrees Centigrade
1	137
2	130
4	125
8	120
24	110

With the above temperature limits and where specific data on the individual transformer are not available, the following loads are considered satisfactory for modern transformers and regulators with average ambient temperature during the overload period of 30 degrees centigrade for self-cooled and forced-air-cooled transformers and a water temperature of 25 degrees centigrade for water-cooled transformers. These overload values apply to the normal continuous name-plate kilovolt-ampere rating for output voltages equal to or above name-plate rating, and

24	1.2	1.2	1.2	1.2

* Special consideration should be given to installations involving exceptional heavy-current designs.

** Values for operation "Following No Load" are on the basis that the transformer has been excited for at least several hours' time prior to application of the load. The loads that can be carried following partial load can be determined with sufficient accuracy by direct interpolation.

‡ It is considered that 1.5 times rated load is the maximum that should be carried, regardless of time, without special consideration.

to normal continuous rated amperes for output voltages below name-plate rating. It is assumed that the emergencies will occur not more than once on any one day and not more than 25 or 30 times during the normal life of the transformer, and that the insulation, windings and oil are reasonably clean and free from excessive amounts of moisture and sludge.

Table II shows permissible loads for infrequent emergencies for modern sealed-type transformers rated above 500 kva which have the oil effectively protected from exposure to air and moisture. Table III shows permissible loads for infrequent emergencies for modern transformers rated 500 kva and below and for modern regulators.

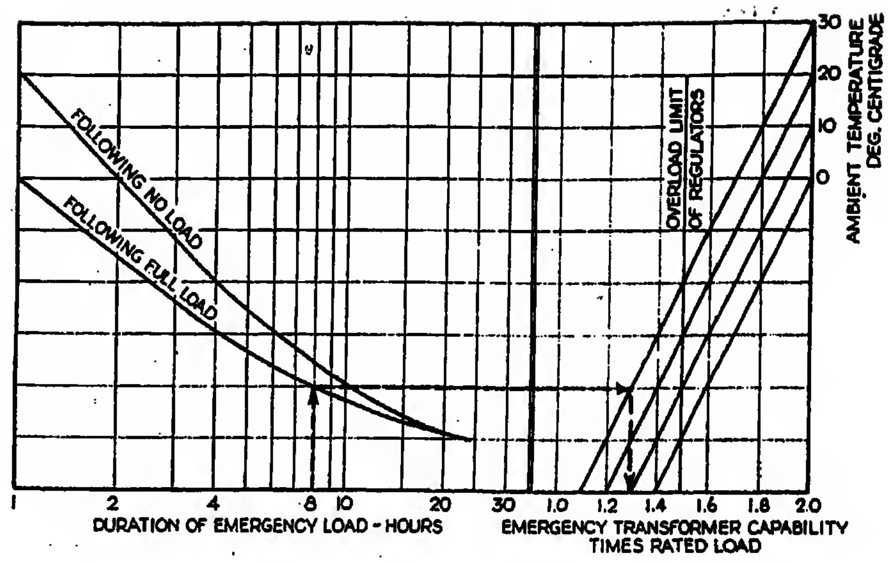

Figure 5. Emergency load capability of self-cooled transformers (500 kva or less) and of regulators

See text for cautions and limitations

Conclusions

Information has been presented herein concerning the effects of the characteristics of specific apparatus, ambient temperature, load factor, supplemental cooling, and so forth, in determining the load capability of transformers and voltage regulators for both normal and emergency conditions.

The effects of these factors are cumulative, as follows:

For *normal operation* with normal life expectancy the effects of load factor, ambient temperature, and supplemental cooling may all be added in determining the load capability. Figure 1 illustrates the application of factors for ambient temperature and low load factor in determining the normal capability for transformers and regulators.

For *short-time emergency operation* with moderate sacrifice of life the effect of the actual ambient temperature during the emergency and of supplemental cooling should be considered in addition to the values given in Tables II and III. Figures 2 to 5 inclusive illustrate the application of these values to determine emergency load capabilities.

The principles and facilities described in this report may be applied to existing or proposed new equipment and should be effective in conserving critical war materials.

Caution: It must be recognized that overloads should not be applied to transformers or regulators without a thorough study of the various limitations involved. Among these limitations are oil expansion, pressure in sealed-type units, bushings, leads, soldered connections, tap-changers, and so forth, and the thermal capability of associated equipment, such as cables, reactors, circuit breakers, disconnecting switches, current transformers, and so forth. These may constitute the practical limit in load-carrying ability.

Before overloading transformers or regulators to the full extent covered in this report, it is recommended that the overload capabilities of the equipment be checked with the manufacturer.

A Compressed-Air Operating Mechanism for Oil Circuit Breakers

R. C. CUNNINGHAM
ASSOCIATE AIEE

A. W. HILL
MEMBER AIEE

General Field of Application

THE recent trend toward better use of existing lines and power sources has brought a demand for faster operation of oil circuit breakers and further simplification of control. In the past it has been common practice to use a solenoid or motor to provide closing energy for these breakers, either of which requires a substantial battery, means for keeping it up to full charge at all times, large conductors between the battery and the breaker to handle the heavy currents which exist for approximately one second while the breaker is closing, and generously proportioned control equipment. Consequently, the cost of apparatus associated with the breaker, but actually installed apart from the breaker, becomes a significant item.

Compressed air can be used as a source of energy to close these breakers, and with several obvious advantages. In the first place, the electrical drain on a battery at the instant of closing is only the control relay current, not the full solenoid closing coil current. This may be a reduction of the order of 1 to 100 which is reflected in smaller batteries and chargers, lighter control cables, and contactors. Another advantage is that full air pressure is instantly available to start closing the breaker, whereas a solenoid builds up in power at a slower rate, depending on the inductance of the coil. Thus it is possible to secure faster breaker operations.

In a fundamental way the apparatus required for closing a breaker with compressed air consists of:

(*a*). A source of air comprising a compressor and reservoir.

(*b*). A cylinder and piston within which the air can be released to force the breaker to the closed position.

(*c*). Suitable means for controlling the flow of air by means of magnetically operated valves operated from a distant point.

Paper 42-114, recommended by the AIEE committee on protective devices for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted April 20, 1942; made available for printing June 1, 1942.

R. C. Cunningham is with Westinghouse Electric and Manufacturing Company, and A. W. Hill is with the switchgear engineering department of Westinghouse Electric and Manufacturing Company, both in East Pittsburgh, Pa.

Obviously, it is not practical to build the commercial apparatus in quite such simple form, and various requirements of operation have made it desirable to add refinements as the following will disclose.

The Air Supply

It is desirable that an air reservoir be located close to each operating cylinder, as air flowing a long distance through small pipes will lose pressure to such a degree that the delivered air may not be able to accomplish the work of closing the the breaker in the required time. Hence, a 20- or 30-gallon reservoir is installed in the same housing with the operating mechanism and control and mounted on the end of the breaker.

For reliable service it has been recommended that a motor-driven compressor be mounted in each housing, thus making each breaker entirely independent of any other. It could be argued that this is an unnecessary expense where several breakers are installed in close proximity to each other, and where one compressor could perhaps handle the several reservoirs. However, it appears that most operating men look at the possible dollar saving as overbalanced by the hazard of shutting down the entire group of breakers, in case of the failure of the one compressor, and the possible difficulty of maintaining interconnecting air piping clear and tight.

If it is preferred to use a single compressor unit for an entire station, it is recommended that a double compressor be used so as to provide increased reliability. Also, proper consideration must be given to protection against mechanical damage to piping and to the drainage of any water which might condense in the air line. If freezing temperatures will be encountered in the locality of installation, adequate sizes of pipe and sumps must be provided to prevent blocking with ice.

The assembly of compressor and reservoir is built to exceed the standards required for industrial systems and railway brake installations, in which continuity of performance has been an important factor worked out years ago. It is designed to meet all usual safety code inspection requirements, and the reservoir carries the stamp of the boiler code inspector of The American Society of Mechanical Engineers. An automatic governor maintains a maximum pressure of 200 pounds per square inch, starting the compressor whenever the pressure drops to 15 pounds below the preset maximum. A safety valve limits the reservoir pressure to 225 pounds. Ordinarily only one-half or three-fourth horsepower is required in the compressor motor so that little current is drawn from the a-c supply line. In ordinary service the motor will run only a few minutes each day, as required for the occasional breaker operation and in order to overcome slight leakage loss. Starting with an empty reservoir, a full charge can be pumped in one-half hour. The motor need not run each time the breaker operates, as the amount of air used is frequently so small as not to drop the reservoir pressure to the point where the automatic governor picks up. In case of the failure of the supply voltage to the compressor motor, a full reservoir contains enough air to operate the breaker at least five times. Further, if there should be no immediate demand for an operation, it would require more than 12 hours for a normally tight air system to leak down to a dangerously low pressure, giving a wide margin of time to re-establish compressor power or service. A low-pressure switch indicates through an alarm circuit when the drop in reservoir pressure is becoming acute, and another switch locks out the closing relay circuit so as to prevent the attempt to close, when the air pressure is too low to insure completion of the operation.

The Lever System

Figure 1 shows a typical mechanism assembly mounted on the tank of a 138-kv outdoor oil circuit breaker. The compressor and reservoir occupy the space at the right of the assembly. At the left and center is the operating mechanism itself, with a magnetically operated inlet valve conveniently located directly in front of the main cylinder. The current demand of this magnet valve is well under two amperes.

One requirement for a mechanism of this type is that it shall be capable of reclosing the breaker promptly, under some conditions in not over 20 cycles (one-third second). This mechanism meets the demand by retaining a positive mechanical connection between the breaker and the operating piston at all times, so that at any time it may be desired air admitted to the cylinder will immediately act to close the breaker, regardless of

whether it may have reached the full open position or not. A single lever, hinged at one end, and carrying a roller at the other end to be held under the hook shaped latch when the breaker is closed, is attached to both the piston and the breaker pull rod at the center.

The breaker is closed under the effect of the compressed air and latched in the closed position, so that the air can be cut off at the end of this stroke. When the breaker is called upon to open, the latch is released by a trip magnet, and the usual accelerating spring on the breaker furnishes the impetus needed to secure the proper contact opening speed. The opening is therefore independent of the condition of the air supply, and required interrupting time of the breaker is controlled entirely by the mechanical time of unlatching the mechanism and accelerating the contacts by springs which were preloaded during the closing stroke of the breaker.

It is evident that when a direct mechanical connection exists between the breaker and the piston, closing and reclosing operations are easily obtained. Experience with solenoids has shown that it is necessary to provide them with mechanically trip-free linkages so as to permit full opening speed without the contacts being delayed by the magnetic drag of the closing solenoid. The mass of the solenoid core also acts as a drag to prevent full opening speed. These difficulties are not present in the air mechanism when a light piston is used, and when some means is provided for dumping from the operating cylinder, the air still under pressure, so that it will not restrict the opening speed of the contacts.[1] The latter demand is met by a series of exhaust ports—on the side wall of the main cylinder, near the fully closed position—which are opened simultaneously with the operation of the breaker trip coil. The total area of these ports is approximately four square inches, and oscillographic pressure records show that the collapse of pressure is so fast that less than 25 pounds remains in the cylinder at the time the contacts part. The extreme speed of this dump valve is secured by utilizing the high-pressure air on the end of the cylindrical valve, after it has once been cracked by a pilot piston or small magnet.

While the single-lever design adequately meets the requirements of quick reclosing, some modification is necessary where manual operation of the smaller breakers is concerned. In this class of apparatus, one man can complete the closing operation with a single quick stroke of the removable handle, but must be protected against holding the breaker in on a fault, as would be the case with the non-trip free mechanism. A solution to this problem is shown in Figure 2, where the single-lever system for power operation is modified when it is to be manually operated, by unlocking the fixed hinge point and temporarily restraining the automatic latch over its roller, so that, if necessary, the breaker can be tripped in the manner of the conventional double-lever system. Thus, the benefits of trip-free action can be secured, while in the same parts the inherently fast reclosing possibilities of the non-trip free action are retained.

Controlling the Air Flow

There is a characteristic mechanical load curve for all breakers having the general shape of that marked "Breaker Load" in Figure 3. It is made up of the dead load, balance and accelerating springs, and the extra load of contact pressure springs at the closed position. The breaker toggles may alter the magnitude of these combined loads at different parts of the stroke, but the fundamental characteristic remains. The simple solenoid pull curve is well adapted to this, since it develops a greater pull as the cores come together (see curve marked "Solenoid Mechanism" also in Figure 3). The surplus of power shown for the solenoid

Figure 1. Type CAS-8 mechanism for outdoor service

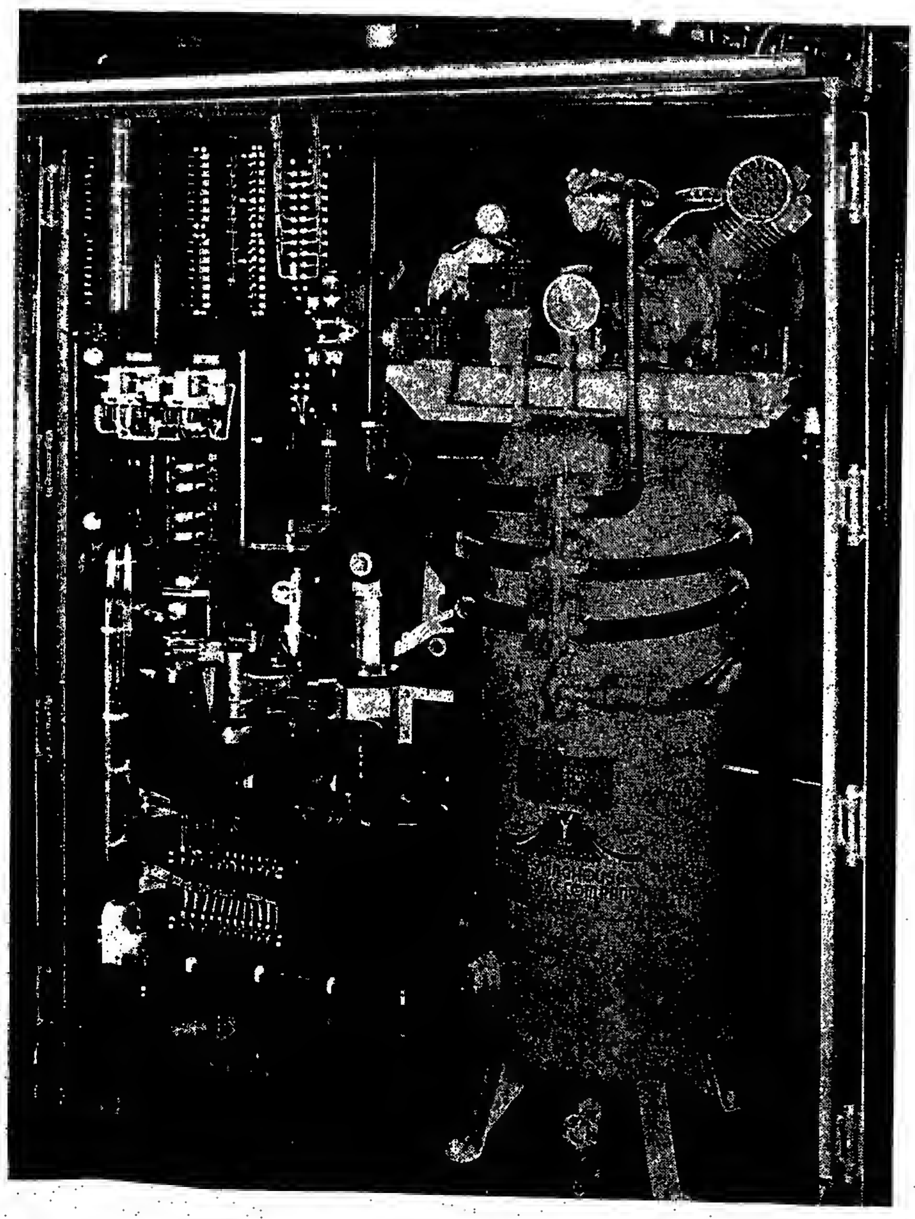

Figure 2. An outdoor-type compressed-air mechanism with trip-free hand-closing lever

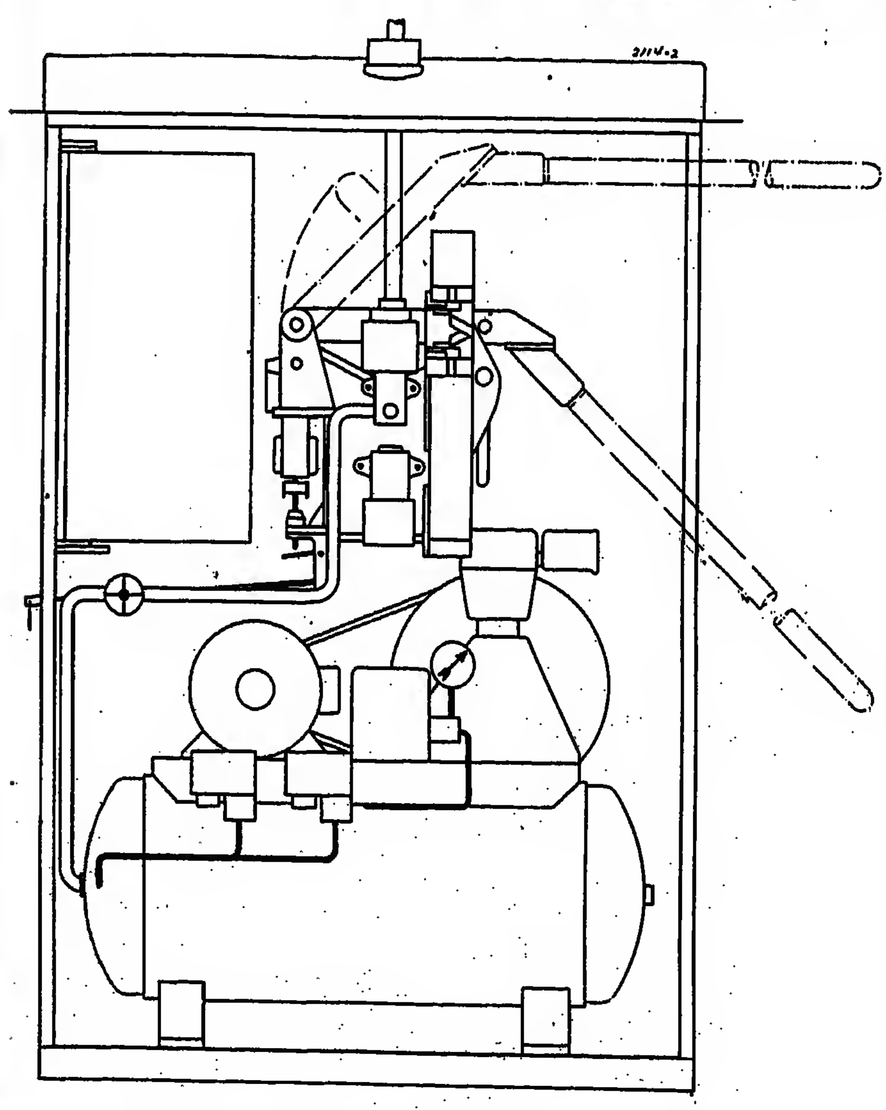

goes into speed and, of course, is eventually lost, as breaker strikes its stops in the closed position, but the general shape of the pull curve of the solenoid usually falls just above the load curve of the breaker, so that there are no large instantaneous surpluses or deficiencies. With the same breaker and a simple air-operated mecha-

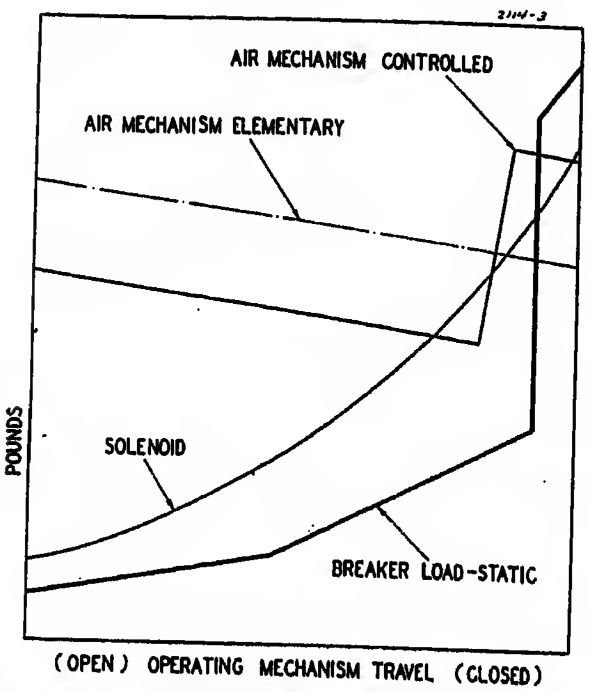

Figure 3. Typical curve of a breaker load and mechanism pull

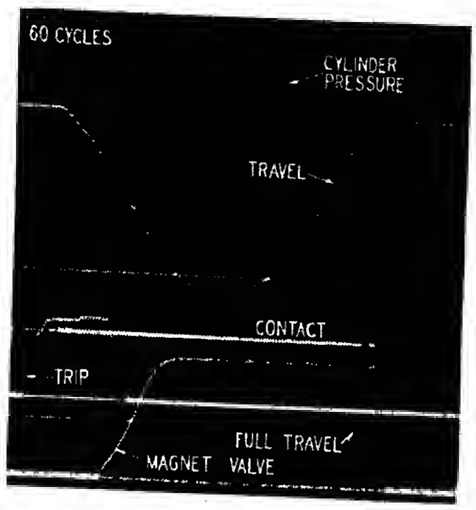
nism, "Elementary," the pull characteristic would be largely flat, drooping slightly toward the closed position, as the air was expanded into the operating cylinder or dropped in pressure, because of resistance to flow in the connecting passages between the reservoir and the cylinder. Rather than change the breaker levers to co-ordinate the simple air-mechanism pull and the conventional breaker load, a scheme has been worked out to throttle or control the flow of air, and the air-mechanism pull curve takes the general shape of that shown in Figure 3, "Air Mechanism—Controlled."

The principle of the throttle is that when the load is light the air passage is kept small. When the load is about to rise, the throttle is opened by a mechanical linkage, and with the augmented air supply, the stroke is completed with just the right amount of pull to insure positive latching and yet not with excessive slam. Since the throttle is adjustable both as to amount of opening and to position at which it becomes effective, it makes possible the use of one size of mechanism on several types and ratings of breaker.

The throttle is operated through a slotted link, since it is found that full air pressure is required over a greater part of the stroke when fast reclosure is attempted, as compared to that required to complete a simple closing and latching. Under this condition of fast reclosure greater power must be available, first to arrest the opening motion, and then to bring the contacts back to the closed position. The use of a throttled air system of course means the choice of an air pressure and piston area such that the required maximum pull will be secured, but this does not mean that it takes more air than an unthrottled system—rather, that through control, the power availa-



(a). Reclosing in less than 20 cycles

Figure 4. Oscillograms of breaker timing

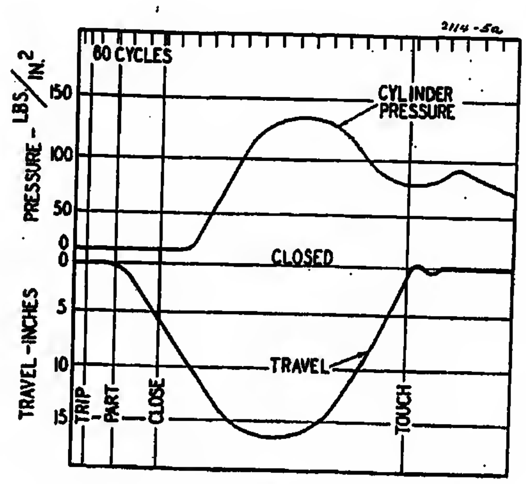
ble is released as demanded by the load, with proper provision made for those operations particularly requiring high speed.

Result of Tests

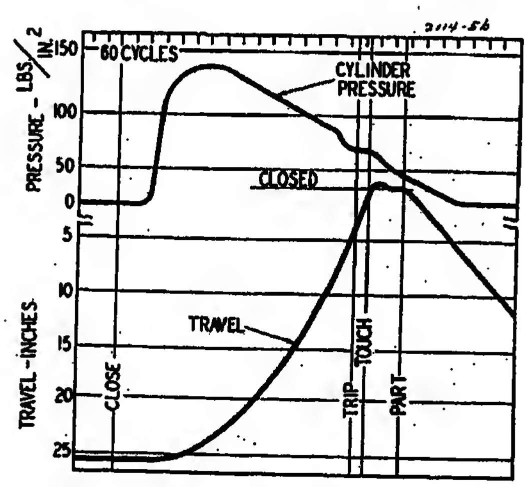
A timing test setup was made on a typical 138-kv oil circuit breaker equipped with an eight-inch compressed-air mechanism of the type described above. Oscillographic records, shown in Figures 4a and 4b show the variation in cylinder pressure, the motion, or travel, of the movable contacts, the motion of the exhaust valve, a battery indication of contact engagement, and the trip-coil and magnet-valve-coil currents. For the sake of clarity the essential data have been traced from these oscillograms and are shown in Figures 5a and 5b.

Figure 5a shows an *OC* operation for which the time from energizing the trip coil to retouching the contact was 19.3 cycles. It will be noted that the magnet valve was energized $4^1/_2$ cycles after the trip coil, and that the contacts had traveled approximately 36 per cent of the entire stroke at the instant the air valve was opened. The contacts continue opening with reducing speed until there is a cushioned reversal of motion at 57 per cent of the full stroke. The cylinder pressure falls as the contacts travel toward the closed position, due to expansion and throttling. The result is a quick reclosure without excessive strain on the mechanism or pole unit parts, and without excessive slam as the breaker reaches the closed position.

Figure 5b illustrates a *CO* operation using the same breaker and mechanism.



(a). Reclosing in less than 20 cycles



(b). A close-open operation

Figure 5. Clarified speed and pressure records from Figure 4

This test was set up for pretripping, as soon as the auxiliary switch contacts in the trip circuit were made up. Even under this condition the "air-trip-free" action of the mechanism is demonstrated by the fact that there is no back pressure on the operating piston after the first few cycles of travel. A comparison of the opening portion of Figures 5a and 5b shows that at the end of eight cycles after energizing the trip coil, the contact separations exceed that required to interrupt normal short-circuit currents.

Field service throughout a full range of seasonal changes in weather verifies the

Current- and Potential-Transformer Standardization

AIEE COMMITTEE ON PROTECTIVE DEVICES
Current Transformer Subcommittee*

Synopsis: This report has been written to summarize the work of the AIEE current transformer subcommittee and to discuss the considerations which led to the adoption of the material in the revision of section 4, "Instrument Transformers," of the Proposed American Standard for Transformers, *C*-57. Special attention is given to the principles underlying the establishment of the overcurrent requirements of current transformers for relaying service and the revision of the method of specifying the accuracy of instrument transformers for metering service. Mention is also made of the reasons for making other changes, such as in the preferred primary current ratings, potential-transformer ratios, and so forth.

DURING the past two years the current transformer subcommittee of the relay subcommittee revised the section on instrument transformers of the American Standard, *C*-57. When this group was appointed, its assignment was to formulate specifications for current-transformer performance in the overcurrent range for relay application. During the progress of the work, however, the activities of the group were enlarged until they covered the complete revision of section 4 of the Proposed Standard for Transformers. This was the result of a desire to correlate the new material with the old material and to save time and duplication of effort by having the work done by one group. Contacts however were made with the other interested groups so that the work proceeded smoothly with the support and co-operation of these groups. This paper has been written to present the reasons why the material in section 4 is there in its present form.*

Paper 42-116, recommended by the AIEE committee on protective devices, for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 13, 1942; made available for printing May 19, 1942.

* Report prepared by J. E. Clem, central station engineering department, General Electric Company, Schenectady, N. Y.; J. H. Neher, senior engineer in charge of relay design, engineering department, Philadelphia Electric Company, Philadelphia, Pa., and E. L. Harder, central station engineer, Middle Atlantic district, industry engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Personnel of AIEE current transformer subcommittee: J. E. Clem, *chairman;* G. Camilli, F. E. Davis, Jr., G. B. Dodds, T. R. Halman, D. R. Laib, P. O. Langguth, C. V. Morey, J. H. Neher, A. T. Sinks, D. W. Taylor, E. C. Wentz, C. O. Werres.

Primary Current Rating of Current Transformers (4.021)

The original proposal in the printed draft of *C*-57 contains 29 values of primary current ratings divided into four groups. It was generally felt that this represented an excessive number of ratings and that the number of primary current ratings could be drastically reduced and still adequately cover the field.

The first step was to set up a list of ratings based on one of the sequences in the system of preferred numbers. This gave a list of approximately 16 ratings which covered the range adequately. However, no agreement could be reached upon the values obtained by this simplified method of approach, because certain active ratings were not included and, accordingly, a different method of approach had to be used.

Primary current ratings of 10, 25, 50, 100, 200, 400, and 800 had been established by the joint AEIC-EEI metering group of the association of Edison Illuminating Companies and the Edison Electric Institute, and these ratings were used as a nucleus around which the list now appearing in the standards was established. It was necessary to effect a compromise among the requirements of the groups interested in applying relays, meters, and instruments. Because of the whole-hearted co-operation among the interested groups in reaching a solution which would afford a saving to the industry, the number of preferred primary ratings has been substantially reduced, the reduction being from 29 to 21 ratings.

* Numbers following subheads refer to paragraphs of the currently proposed revision of section 4 of the Proposed American Standard for Transformers *C*-57 which are given in appendix 3 of this paper.

The preferred primary current ratings are now in one table in paragraph 4.021. It is not the intent that all the values be made available for each circuit voltage; rather, it is the intent that the ratings used for any circuit voltage be limited to as few of values appearing in the table as possible.

It was also felt that there were too many preferred ratings for double-ratio current transformers, and the reduction in the number of values required was a simple matter after the problem had been solved for single-ratio current transformers.

Standard Burdens for Rating Purposes (4.030)

Section 4.030 of the revised standard concerns standard burdens for current transformers, combining and taking the place of the former two sections 4.030 and 4.031 dealing respectively with "Burdens for Current Transformers for Metering Service" and "Burdens for Current Transformers for Relay Service."

Formerly, burdens designated as *X*, *Y*, and *Z*, or 2.5 and 15 volt-amperes at 0.9 power factor, and 50 volt-amperes at 0.5 power factor, respectively, at five amperes and 60 cycles were set as standard metering burdens; then a separate series was set up for relay service as 12.5, 25, 50, 100, and 200 volt-amperes at 0.5 power factor at five amperes and 60 cycles, these burdens to be used for rating purposes.

These two groups have now been combined into one list of standard burdens designated as *B*-0.1, *B*-0.2, *B*-0.5, *B*-1, *B*-2, *B*-4, and *B*-8 corresponding to the ohmic values at 60 cycles of the burden of 0.1 ohm, 0.5 ohm, and so forth. The first three have a burden power factor of 0.9, and the last four have a power factor of 0.5 at 60 cycles. The old meter burden *Y* of 0.6 ohm at 0.9 power factor and the relay burden 0.5 at 0.5 power factor have been replaced by a single burden *B* 0.5, corresponding to 0.5 ohm at 0.9 power factor or 12.5 volt-amperes at 0.9 power factor. There is no essential difference in these three values as far as performance is concerned, but the new value fits into the list of burdens in more orderly fashion.

It was also found necessary to add an additional value of burden; namely, that

high degree of reliability obtained in laboratory testing. The flexibility in design and the compactness of the unit obtained by the use of compressed air, and the encouragement gotten from commercial contacts, indicate an increasing demand for this type of mechanism.

designated as B-0.2, or five volt-amperes at 0.9 power factor for metering service. This burden is now required for certain current transformers used on low-voltage circuits.

In the revised table then, burdens B-0.1, B-0.2, B-0.5, and B-2 are standard burdens for metering service for rating purposes, and burdens B-0.5, B-1, B-2, B-4, and B-8 are standard burdens for relay service for rating purposes. It should be noted that these burdens also may be designated by the volt-amperes and power factor at five amperes and 60 cycles of each, if the longer designation is preferred. The new designations are different from the old ones in order to avoid confusion with former designations. The proposed values are as shown in paragraph 4.030.

Burdens for Potential Transformers (4.036)

Former section 4.032 concerned standard burdens for potential transformers for rating purposes in all classes of service. This is now included in the revised standard in 4.036. Only one change was made; namely, the volt-amperes of burden W was changed from 13 to 12.5 merely so that it would be one half of the value of the X burden, which is 25.

Classification of Current Transformers for Accuracy Metering Service (4.031)

Former section 4.033 concerned standard accuracies of current transformers and section 4.035 concerned standard accuracies of potential transformers for metering service. In the revised standard these are included as sections 4.031 for current transformers and 4.037 for potential transformers. Accuracy classes have been specified on a different basis from that previously used. Formerly, fixed limits were assigned separately to ratio error and phase angle for each accuracy class, but on this basis the class designation did not in itself indicate the probable effect of the transformer on the accuracy of measurement of watts or watt-hours.

Since the primary concern with respect to ratio and phase angle of an instrument transformer is the effect on the accuracy of measurement of watts or watt-hours, it is more consistent to use this effect as a criterion of performance, rather than merely the arbitrary ratio error and phase-angle limits which might be chosen. A measure of this effect is the ratio of what a wattmeter would read in a circuit with an instrument transformer having no ratio error or phase angle to what it would read in the same circuit with an instrument transformer having the usual errors. This ratio has been called "transformer correction factor" or TCF, and the standard defines it as "the factor by which the watt-hour meter registration or the wattmeter indication must be multiplied to correct for the error introduced by the transformer through the combined effect of the ratio correction factor (RCF), phase angle (β),* and power factor angle (θ) of the metered load.

Thus for a current transformer (see appendix 1):

$$\text{TCF} = \text{RCF}\frac{\cos\theta}{\cos(\theta-\beta)}$$

At the same time it was also decided to use RCF instead of per cent ratio error.

$$\text{RCF} = \frac{\text{true ratio}}{\text{marked ratio}}$$

The values of TCF for a transformer are dependent upon the power factor of the circuit being measured and the RCF and phase angle of the transformer. Where the transformer angle is small, the relation between these various factors can be expressed in a rather simple manner within accuracy limits sufficiently good for the purpose. By choosing limits for θ and TCF, the limiting values of phase angle and RCF are set. The range of power-factor angle chosen is from 0 to 53 degrees 08 minutes, corresponding to circuit power factor of 1.0 and 0.6 lagging respectively, which covers the usual range of power factors encountered in practice. For these conditions the relation between the limiting values becomes:

For CTs, $\beta = 2{,}600\,(\text{RCF}-\text{TCF})$, in minutes

For PTs, $\gamma = 2{,}600\,(\text{TCF}-\text{RCF})$, in minutes

If e represents the permissible per-unit error in the measurement, it may be positive or negative, and the corresponding limiting values of TCF will be $(1 - e)$ and $(1 + e)$. See Figure 1.

The limiting values of TCF as set up in the standard have been chosen entirely from the practical viewpoint of transformer accuracies which are required and those attainable with transformers either of modern or earlier design. The new accuracy classes and, consequently, the limiting values of TCF correspond very closely to the former accuracy classes at circuit power factors at or near 1.0. A new class of wider limits than before has been added to permit an accuracy rating for current transformers with ratio errors in the order of two per cent at 100 per cent rated current such as for certain bushing and similar types.

* β is defined as the angle by which the secondary current leads the primary current.

It will be noted on investigation, for example, that the former 1/4 class results in the limiting TCFs for current transformers at 100 per cent rated current of 0.99365 and 1.00635 in the range of line power factors from 0.6 to 1.0, which produces maximum meter errors of about ±0.635 per cent. This is more than double the 0.25 per cent error sometimes assumed to be indicated by the former 1/4 class designation, which corresponded to the maximum ratio error only without consideration of phase angle and over-all metering error.

For the new 3/10 class at 100 per cent rated current β varies from +15.6 to −15.6 minutes (see Figure 1), the limits of which are 50 per cent greater than formerly for the 1/4 class but which result in only half the maximum possible meter error for that class. It should be noted that this method is the equivalent of that used for the former class M only which has been continued as the class 5/10.

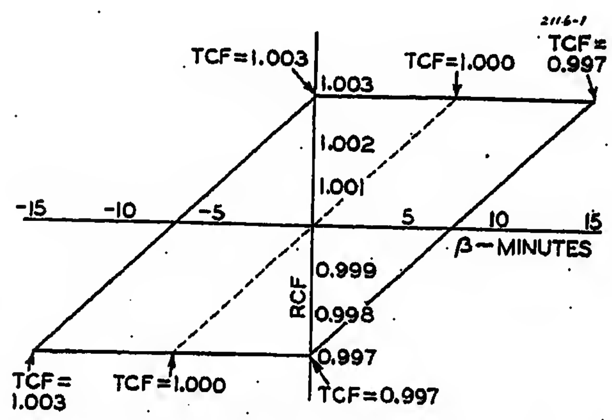

Figure 1. Parallelogram showing limits of ratio correction factor, RCF, and phase angle, β, for a current transformer having a 3/10 accuracy class rating

There accordingly results a means of accuracy rating of instrument transformers for metering service that is of more significance than formerly to the average meterman, since the accuracy class rating is associated directly with the effect of transformer characteristics on the accuracy of measurement. The limits set appear to be practical and adequate for all ordinary purposes, and the method utilized is not involved but provides the necessary rigidity in a simple manner for specification purposes.

Standard Accuracy Classes for Current Transformers for Relaying Service (4.032)

This section, not previously included in the proposed American Standard for

Transformers is the result of an intensive effort to establish standard classes of overcurrent performance. It provides a much needed benchmark for comparison of the performance of various current transformers and for specifying their accuracy at the high currents involved in protective-relay applications. It also establishes in a general way the limits within which a given transformer does not exceed specified errors under overcurrent conditions.

It is important to note that the terms "accuracy" and "performance" as covered by this standard refer to steady-state conditions only. The performance of current transformers under transient conditions is far too complicated to permit of standardization at the present time. While the generalization may be made that the better the steady-state performance, the better the performance will be under transients, nevertheless, it must be realized that adequate performance within the limits of these standards is not necessarily indicative of adequate performance under transient conditions. Reference should be made to the various items of the bibliography.

Current transformers are classified primarily on the basis of the standard burden which each can carry with a specified secondary current without exceeding a specified per cent error. To standardize ratings five amperes has been selected as the standard rated secondary current, and for overcurrent performance the transformers are classified primarily on the basis of their ability at secondary currents of the same value, namely 20 times rated.

Since all the transformers are standardized on the secondary current, the current need not be part of the necessary designation. The designation proposed to identify or express the accuracy classification is, for example, 2.5*H*400 or 10*L*-200. The first number identifies the accuracy class and the limiting per cent error. The letter identifies the type of accuracy classification. The second number identifies the terminal voltage which can be developed on one of the standard burdens at 20 times rated secondary current without exceeding the specified per cent error. This scheme of designation was adopted, because it was expected to give the most useful information.

In the application of relays it is essential that the operating engineer have a knowledge of the performance of the current transformer under overcurrent conditions. While considerable error can frequently be tolerated, it is essential to know the amount of the error or a limiting value which will not be exceeded. This point of view led to the establishment of two accuracy classes for current transformers for relaying service.

In general, the change in the phase angle need not be considered in relaying applications because often it is of no consequence and is relatively small as long as the ratio error is not excessive. Therefore, most attention is focused upon the ratio error. The standard limiting ratio errors are 10 per cent and $2^1/_2$ per cent, the particular one applicable being indicated by the first figure in the accuracy designation. The figure of 10 per cent has been chosen, both because errors not in excess of this figure can be disregarded in most relay applications, and because for errors in excess of this figure the accuracy of most current transformers falls off very rapidly. The second accuracy class with $2^1/_2$ per cent as the limit in ratio error has been set up to cover those cases where 10 per cent cannot be tolerated. The error is expressed in per cent of the secondary current.

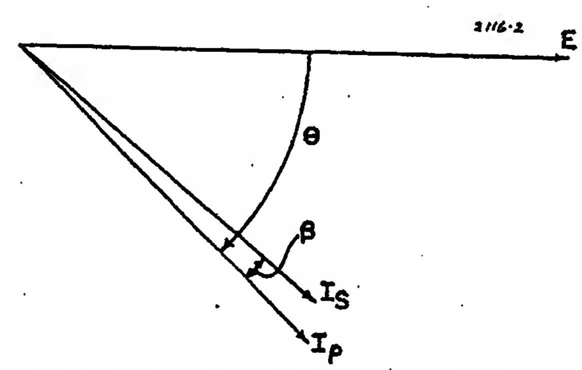

Figure 2. Actual and indicated currents

The overcurrent requirements for current transformers are based upon an overcurrent of 20 times rated in the secondary winding. With a five-ampere rated secondary current, the choice of 20 times rated secondary current is preferable to 20 times rated primary current, because the former results in a secondary current of 100 amperes, which is a convenient number for such purposes.

While the current transformers are classified primarily on the basis of the burden which can be carried at 20 times rated with the rated accuracy, it is desirable to specify, if possible, the burden which can be carried at lesser overcurrents than equal accuracy. An analysis showed that this could be done very simply for transformers of relatively high internal impedance,* such as wound types. Transformers having relatively low internal impedance can be standardized at only one point. Therefore, any method conceived of standardizing the performance at reduced overcurrents for the transformers of relatively low internal impedance, such as bushing type, had serious disadvantages. It was either too complicated or, if simple, necessitated in many cases transformers much larger than would be required to meet only the accuracy requirement at the basic standardizing point of 20 times rated.

In order to capitalize on the ability to standardize the accuracy of the high-internal-impedance types over the range of 5 to 20 times rated secondary current, without penalizing the relatively low-internal-impedance types, two separate classifications have been set up, designated as *H* and *L*. The letter *H* or *L* indicates whether the transformer is classified as a "high-internal-impedance" or a "low-internal-impedance" type. The reason for this distinction is as follows:

The excitation voltage upon which exciting current and consequent ratio error depend is the sum of the secondary terminal voltage plus the internal-impedance drop caused by the secondary current. If the secondary current is reduced from 20 times rated to 5 times rated, but the burden increased inversely, so as to keep the secondary terminal voltage constant, the excitation voltage will decrease due to the reduced internal-impedance drop. The exciting current decreases quite rapidly with a decrease in excitation voltage and for the high-internal-impedance-drop types this effect is great enough that the per cent error tends to remain constant. Thus, for the designs of high-internal-impedance drop, the requirement can be imposed that rated accuracy must be maintained for currents from 5 to 20 times rated with such burdens as to give a terminal voltage no greater than that obtained at 20 times rated current with rated burden. In only relatively few cases will this further requirement increase the size.

Two examples will clarify the meaning of the accuracy designations.

1. A 10*L*400 current transformer is of low internal impedance (as a bushing type). It can carry a *B*-4 burden from one to 20 times rated secondary current, or 5 to 100 amperes, with not over 10 per cent error. It can induce 400 volts with not over ten amperes exciting current.

2. A 2.5*H*200 current transformer is of high internal impedance (as a wound type) capable of supplying a *B*-2 burden at from one to 20 times rated secondary current with not over 2.5 per cent error. It can also supply any standard burden which will not require over 200 volts with secondary currents from 5 to 20 times rated, without exceeding 2.5 per cent error. At 2.5 am-

* The term "internal impedance" is used to identify that elusive characteristic of current transformers through which the exciting current required for a specified secondary induced voltage becomes different for different values of secondary current.

peres on the open-circuit saturation curve the transformer will induce over 200 volts.

Application Data for Current Transformers (4.033)

There is a growing appreciation of the fact that where applicable the saturation-curve method of calculating the performance of current transformers presents a distinct advantage over other methods involving the use of ratio and phase-angle curves. Transformers of the low-internal-secondary-impedance type are susceptible to such treatment. Accordingly, it was thought desirable to establish in the standard application data which shall be available from the manufacturers for use in this connection.

These data should include curves showing the excitation current as a function of the excitation voltage, or volts per turn, together with sufficient data to determine the inphase (watt) component and out-of-phase (magnetizing) component, or the phase angle. The data should also include the resistance of the secondary winding and such information in reference to the internal impedance as may be usable.

Calculations for transformers having low internal impedance may be rather simply made. The initial step is to determine required excitation voltage as based upon the secondary current and the sum of the burden ohms and the secondary resistance.

The exciting current is the maximum error current and may be read directly from the curve, and usually this is all that is required. If the phase angle or a more precise ratio error is required, it may be determined by one of the methods discussed in some of the references in the bibliography. All of these methods use the exciting current in magnitude and position with respect to the excitation voltage, although the mechanics may be different, and they are all essentially a solution of the vector diagram, Figure 3.

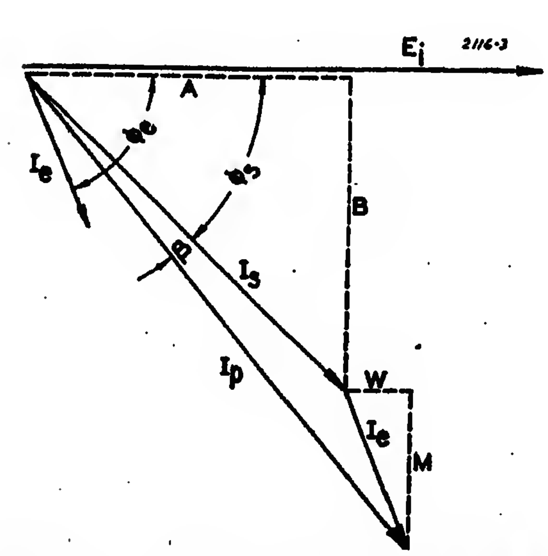

Figure 3. Vector diagram of transformer—low internal secondary impedance type

A few of the methods are given in appendix 2, and it is hoped that experience will indicate a preference for one or the other of these methods.

It is very unfortunate that transformers of the high-internal-impedance type are not directly susceptible to the simple method of calculation, although a somewhat similar method has been proposed. The Standards, therefore, continue the use of the familiar ratio and phase-angle curves for expressing the performance of this type of transformer.

Mechanical Limit for Current Transformers (4.046)

Because the mechanical strength specifications (paragraph 3.050, American Standard *C*-57) of power and distribution transformers is stated in a manner which involves a time element ranging from two to five seconds, it was suggested that the mechanical limit for current transformers should also involve a time element, and one second was suggested. However, the situation is quite different for the two types of transformers; the power or distribution transformer limits the short-circuit current to a definite value, while a current transformer has no appreciable effect in limiting the fault current. Actually, the time element for power and distribution transformers has more concern with the thermal requirement than with the mechanical. If the transformer does not fail within the first few cycles of a fault it will not fail at all mechanically.

There is some opinion that a current transformer may fail mechanically after the crest of the first maximum half cycle has passed, and this has apparently been confirmed to some extent by tests. Also it was quite strongly felt that one second was entirely too long a time in view of the fairly rapid decrement in the fault current. To facilitate testing the current is specified on a symmetrical basis, and it is permitted to cover the time range in successive applications. The proposed requirements are shown in paragraph 4.046.

This paragraph as written includes material which properly belongs in the test code. Due to the lack of a test code at the present time, this material is placed in the standard, because it involves the demonstration of the specifications of mechanical limit. The rated mechanical limit is specified in rms symmetrical amperes, coupled with the stipulation that the transformer must withstand the forces produced by this value of current when the current wave is completely offset. In testing this may be demonstrated by a symmetrical wave of twice the value of the rated mechanical limit maintained for the specified time of six cycles; or it may be demonstrated by successive applications of current with no intentional delay between applications, in which case the crest current may be measured for the final significant cycle of each application and must not be less than twice the crest corresponding to the crest of the rated mechanical limit.

Open Secondary Circuit of Current Transformers (4.047)

The original *C*-57 simply required that current transformers operate with the secondary circuit open "without damage to the transformer." In many cases the strict interpretation of this rule resulted in an abnormal design without any compensating features. Accordingly it was thought better to correlate the requirement for this condition with the test on the secondary windings. The proposed requirements are shown in paragraph 4.047.

Preferred Ratios for Potential Transformers (4.020) and Standard Insulation Classes and Tests for Potential Transformers (4.050)—Table IX

The question of what insulation test was standard for a potential transformer of a given ratio for circuits below 15 kv was the cause of many misunderstandings. The solution of this problem consisted of combining the tabulation of preferred ratios with the tabulation of insulation classes and tests.

When the preparation of *C*-57 was first begun, it was recognized that certain instrument transformers had impulse levels one step lower than those being considered for the circuit voltages with which the transformers were being used, although they could withstand the proposed low-frequency test required for these same circuit voltages. The circuit voltages in question were in the 5.0-, 8.7-, and 15-kv classes, and to take care of this situation note *c*, reading as follows, was proposed:

> "(*c*) Indoor instrument transformers are available in the 2.5-, 5-, 8.66-, and 15-kv classes insulated one level lower than the values of this tabulation."

This note was the cause of great confusion, because its wording permitted misinterpretation, and in the printed draft of *C*-57 it was interpreted as applying to the lower-frequency test also. It resulted in a line of potential transformers having ratios 20:1, 40:1, and 60:1,

which had impulse insulation levels corresponding to the present insulation classes 2.5, 5.0, and 8.66, respectively. These transformers, according to the present standard, cannot however be connected in wye for use between line and neutral at their rated excitation voltage, because they are not insulated for this service. Because of this, there has been considerable effort to eliminate them entirely from the standard. However, these transformers represent existing practice and are used extensively, particularly for metering applications. Placing them in the table and associating their ratios with their proper insulation class permits their continued use and eliminates the possibility of confusing them with the trans-

[a] Intermediate voltage ratings are placed in the next higher insulation class unless otherwise specified.

[b] Two types of potential transformers are available in insulation classes 25 kv and above. One type is for primary line-to-neutral connection and is provided with a tapped secondary winding, or with two secondary windings, to make available nominal 115 or 120 secondary volts when connected Y or Δ. These transformers are designated in Col. 2 by the double ratio, for example 200/115:1. The other type is for primary line-to-line connection to make available 115 or 120 secondary volts from each transformer. These transformers are designated in Col. 2 by the single ratio, for example 200:1.

[c] When transformer apparatus is used on a Δ-connected system which operates with one phase grounded, special consideration should be given to the selection of the insulation class.

[d] Y-connected transformers for operation with neutral solidly grounded, or grounded through an impedance, may have reduced insulation at the neutral as specified in 2.031.

[e] All potential transformers for Y connection on a three-phase three-wire ungrounded or impedance-grounded system (or on a four-wire system where the ground may be disconnected during a line-to-ground fault) should be designed to have magnetic induction low enough to enable them to operate continuously at line-to-line voltage.

The secondary windings of instrument transformers shall withstand a low-frequency test of 2,500 volts to ground and normally grounded core and other metal parts but no impulse tests are required. See notes (*g*) and (*i*) of Table II.

formers of the same ratio having the higher test which may be connected in wye at their rated excitation voltage.

In the proposed initial draft of American Standard *C*-57, the ratios of potential transformers intended for line-to-neutral connection did not give 115 volts line-to-neutral in all cases when connected wye at the rated voltages indicated. This was felt to be an undesirable situation, and these ratios were adjusted slightly to correct this condition. A double-ratio rating was also given to provide for 115-volt line-to-line as well as line-to-neutral connection.

The new proposal in Table IX is given here under the same table number. The third column, "Secondary Volts," has been added to make clear which transformers have two secondary voltages available. In the fourth column the item, "Name-Plate Rating," has been added to the heading, together with the proper entries in the column, to eliminate the previous confusion which existed as to which transformers were suitable only for line-to-neutral connection. The fifth and sixth columns were added to indicate the circuit voltage for which the transformers were intended. The seventh column was added to point out the limit voltages between line terminal and ground for steady-state operation.

Standard Insulation Classes and Tests for Current Transformers (4.051)

In the initial proposed draft of *C*-57, the insulation tests for current transformers were included in the same table as tests for potential transformers. This obviously led to much confusion and misunderstanding which has been overcome by the use of a separate table for the insulation tests for current transformers. The proposal is given as Table X.

Bushing-Type Current Transformers

The printed draft of *C*-57 did not include any material on bushing-type current transformers. It was felt that this should be done, and wherever practicable, bushing-type current transformers have been covered, but not as completely as could be desired.

Name Plates (4.075)

A new item, "Data Sheet Number," has been added to the required information on name plates. This was done, because in many cases the name plate will not be large enough to include all the information which might be thought desirable. It is the intent that the manufacturer shall have such material available under this number and will be able to furnish it upon request by reference to the proper design number.

It is expected that the "Data Sheet Number" will serve the same general purpose as the instruction book or sheet referred to in 3.090 (16). The "Data Sheet" will be the means whereby the user may obtain such information as thermal and mechanical limits, accuracy classifications, application data, or any other information of general use in the application of instrument transformers.

Appendix I. Development of Expression of Limiting Phase Angle β

In Figure 2 are shown the actual and indicated currents in a current transformer on a 1-1 turn basis. The relationship among the transformer correction factor, TCF, the ratio correction factor, RCF, and the phase angle, β, is developed as follows on the assumption that there is no error in the potential circuit:

$$\text{Actual power} = EI \cos\theta$$

$$\text{Indicated power} = EI_s \cos(\theta-\beta)$$

$$\frac{\text{Actual power}}{\text{Indicated power}} = \frac{I_p}{I_s}\,\frac{\cos\theta}{\cos(\theta-\beta)}$$

But

$$\frac{\text{Actual power}}{\text{Indicated power}} = \text{TCF by definition}$$

$$\frac{I_p}{I_s} = \text{RCF by definition}$$

so that

$$\text{TCF} = \text{RCF}\,\frac{\cos\theta}{\cos(\theta-\beta)}$$

$$= \text{RCF}\,\frac{\cos\theta}{\cos\theta\cos\beta + \sin\theta\sin\beta}$$

A positive angle β indicates in this development that the secondary current is

* Maximum.

ahead of the primary current, from which the following close approximation is obtained:

$$RCF = TCF(1 + \beta \tan \theta) \quad (\beta \text{ in radians})$$

and then

$$\beta = (RCF - TCF) \cot \theta \quad (\beta \text{ in radians})$$

The value of the phase angle β in minutes is given by

$$\beta = 3{,}438 \cot \theta \, (RCF - TCF)$$

For a given power-factor angle θ, phase angle β and ratio correction factor RCF, the value of the transformer correction factor TCF at this condition will not be exceeded for angles less than this value of θ.

Since the maximum angle θ in the transformer accuracy limits is taken as $\cos^{-1}0.6$, then these TCF limits will not be exceeded for any value of θ from $\cos^{-1}0.6$ to $\cos^{-1}1.0$.

With $\cos^{-1} 0.6$

$$\beta = 2{,}600 \, (RCF - TCF) \text{ very nearly}$$

in which both the maximum and minimum values of β, RCF, and TCF are taken for the purpose of specifying their limits.

Table B

Designation of Burden*	Burden Characteristics: Resistance (Ohms)	Burden Characteristics: Inductance (Millihenrys)	Secondary Burden at 60 Cycles and Five Amperes Secondary Current: Impedance (Ohms)	Volt-Amperes*	Power Factor
B-0.1 (*X*)	0.09	0.116	0.1	2.5	0.9
B-0.2	0.18	0.232	0.2	5.0	0.9
B-0.5 (*Y*)	0.45	0.580	0.5	12.5	0.9
B-1	0.5	2.3	1.0	25	0.5

B-4	2.0	9.2	4.0	100	0.5
B-8	4.0	18.4	8.0	200	0.5

* In accordance with 1.130 the burden may also be designated by means of the volt-ampere characteristic: that is, va 2.5, or va 50.

Table C

Accuracy Class	Limits of Transformer Correction Factor: 100 Per Cent Rated Current, Minimum	100 Per Cent Rated Current, Maximum	10 Per Cent Rated Current, Minimum	10 Per Cent Rated Current, Maximum	Limits of Power Factor (Lagging) of Metered Power Load
2.4	0.976	1.024	0.952	1.048	0.6–1.0
1.2	0.988	1.012	0.976	1.024	0.6–1.0
6/10	0.994	1.006	0.988	1.012	0.6–1.0
3/10	0.997	1.003	0.994	1.006	0.6–1.0
5/10	0.995**	1.005**	0.995	1.005	0.6–1.0

** These values also apply to 150 per cent of rated current.

Appendix 2. Calculation of Current-Transformer Ratio-Correction Factor and Phase Angle

Method 1

Starting with a given value of secondary current I_s, determine the internal voltage E_t necessary to force the secondary current I_s through the secondary resistance R_s in series with the external burden Z_b, and the angle ϕ_s by which I_s lags E_t. Express the secondary current vectorially with respect to E_t as a reference.

$$I_s = A - jB$$

From the curve such as Figure 4, determine the exciting current as a vector with respect to same reference voltage E_t.

$$I_e = W - jM$$

Determine the primary current, on the same turn base, by adding vectorially the secondary and exciting currents.

$$I_p = \sqrt{(A+W)^2 + (B+M)^2}$$

$$RCF = I_p / I_s$$

Phase angle β is the angle by which I^s leads I_p

$$\beta = \left(\tan^{-1}\frac{B+M}{A+W}\right) - \phi_s, \text{ in degrees}$$

Table D

Accuracy Class	Limits of Transformer Correction Factor	Limits of Power Factor (Lagging) of Metered Power Load
1.2	1.012–0.988	0.6–1.0
6/10	1.006–0.994	0.6–1.0
3/10	1.003–0.997	0.6–1.0

Table E

Maximum Per Cent Ratio Error	Accuracy Class	Maximum Per Cent Ratio Error	Accuracy Class	Maximum Secondary Terminal Volts*	Maximum Secondary Burden Ohms**
10	10 *H*50	2.5	2.5 *H*50	50	2
10	10 *H*100	2.5	2.5 *H*100	100	4
10	10 *H*200	2.5	2.5 *H*200	200	8
10	10 *H*400	2.5	2.5 *H*400	400	16
10	10 *H*800	2.5	2.5 *H*800	800	32

* Secondary voltage and current limitation—in any accuracy class the specified per cent ratio error shall not be exceeded for the specified secondary terminal voltage at current values from 5 to 20 times rated secondary current.

** Secondary burden and current limitation—in any accuracy class the specified per cent ratio error shall not be exceeded for the specified secondary burden ohms at current values from one to five times rated secondary current.

Method 2

Express the secondary current as

$$I_s = I_s \epsilon^{j\phi_s}$$

and the excitation current as

$$I_e = I_e \epsilon^{j\phi_e}$$

From these the RCF is

$$RCF = \sqrt{1 + 2\frac{I_e}{I_s}\cos(\phi_e - \phi_s) + \left(\frac{I_e}{I_s}\right)^2}$$

And β, the angle by which I_s leads I_p is, providing ϕ_s and ϕ_e are looked upon as being positive angles

$$\tan \beta = \frac{I_e \sin(\phi_e - \phi_s)}{I_s + I_e \cos(\phi_e - \phi_s)}$$

RCF and β may be determined directly from the chart given in Figure 5.

Method 3

Let I_s, I_e, ϕ_s, and ϕ_e be the same as in method 2 and let

$$a = \frac{I_e}{I_s} \text{ and } p = a\cos(\phi_s - \phi_e) + \frac{a^2}{2}$$

Then the ratio correction factor

$$RCF = 1 + p - \frac{p^2}{2} + \frac{p^3}{2} - + \text{etc.}$$

And the phase angle β, by which I_s leads I_p is, providing ϕ_s and ϕ_e are looked upon as positive angles

$$\tan \beta = \frac{a \sin(\phi_e - \phi_s)}{1 + a\cos(\phi_e - \phi_s)}$$

Appendix 3. Excerpts From Proposed American Standard for Transformers C-57 (Currently Proposed Revision of Section 4)

4.021 Preferred Primary Current Ratings and Ratios of Current Transformers

The preferred primary current ratings and ratios of current transformers shall be as shown in Table A.

Standard Burdens and Standard Accuracy Classes for Current Transformers

4.030 Standard Burdens for Rating Purposes

(*a*). Standard burdens for rating purposes shall have constant-impedance ohms and linear-reactance characteristics over the entire current range on which they are used and shall have resistance and inductance values, together with impedance and volt-ampere values, at 60 cycles as shown in Table B.

(*b*). Burden *B*-0.1, *B*-0.5, and *B*-2 are standard burdens for current transformers used for metering service and correspond to the *X*, *Y*, and *Z* designation previously used. Burdens *B*-0.2 and *B*-0.5 are new standard burdens for metering service.

Burdens *B*-5, *B*-1, *B*-2, *B*-4, and *B*-8 are standard burdens for current transformer used for relaying service.

4.031 Standard Accuracy Classes of Current Transformers for Metering Service

(*a*). The accuracy classification of current tranformers for metering service shall be based on the requirement that the transformer correction factor (TCF) shall be within specified limits over a specified range of power factor of the load being metered.

For the purpose of these standards the term "Transformer Correction Factor" (TCF) is used instead of the more complete term "Instrument Transformer Correction Factor" defined in 1.134 to designate the factor by which the watt-hour meter registration or the wattmeter indication must be multiplied to correct for the error introduced by the transformer through the combined effect of the ratio correction factor (RCF) and phase angle *B*.

(*b*). For purposes of standardization the limits of transformer correction factor shall be specified at 100 per cent of rated primary current and at 10 per cent of rated primary current.

(*c*). For the purposes of accuracy classification, the rated secondary current shall be five amperes.

(*d*). The standard accuracy classes and corresponding limits of transformer correction factor (TCF) shall be as shown in Table C.

(*e*). For any known ratio correction factor (RCF) of a given transformer, the positive and negative limiting values of the phase angle β in minutes may be expressed as follows:

$$\beta = 2{,}600(\mathrm{RCF} - \mathrm{TCF})$$

in which TCF is taken as the minimum and maximum transformer correction factor specified in (*d*) above.

The limiting values of the ratio correction factor are the same as the limits of transformer correction factor given in (*d*) above since the phase angle of the current transformer does not introduce a significant error when it is small and when the load power factor is 1.0. These limits of ratio correction factor, together with the corresponding limits of phase angle, keep the transformer correction factor within the specified limits for all values of power factor (lagging) of the measured power load between 0.60 and 1.00.

(*f*). A current transformer shall be given an accuracy rating in accordance with the accuracy class (or classes) in which it falls for the specified standard burden (or burdens). Double-ratio transformers shall be given accuracy ratings for each ratio.

(*g*). In practice, current transformers shall be designated in reference to accuracy rating by the accuracy class number followed by the burden number. For example 6/10 *B*-2 and/or 5/10 *B*-0.1 and so forth.

Table F

Maximum Per Cent Ratio Error	Accuracy Class	Maximum Exciting Current	Maximum Per Cent Ratio Error	Accuracy Class	Maximum Exciting Current	Maximum Secondary Terminal Volts*	Maximum Secondary Burden**
10	10*L*50	10	2.5	2.5*L*50	2.5	50	*B*-0.5
10	10*L*100	10	2.5	2.5*L*100	2.5	100	*B*-1
10	10*L*200	10	2.5	2.5*L*200	2.5	200	*B*-2
10	10*L*400	10	2.5	2.5*L*400	2.5	400	*B*-4
10	10*L*800	10	2.5	2.5*L*800	2.5	800	*B*-8

* Secondary voltage and current limitation—in any accuracy class the specified per cent ratio error shall not be exceeded for the specified secondary terminal voltage at 20 times rated secondary current.

** Secondary burden and current limitation—in any accuracy class the specified per cent ratio error shall not be exceeded for the specified secondary burden ohms at current values from 1 to 20 times rated secondary current.

4.037 Standard Accuracy Classes for Potential Transformers for Metering Service

(*a*). The accuracy classification of potential transformers for metering service shall be based on the requirement that the transformer correction factor (TCF) shall be within specified limits over a specified range of power factor of the load being metered [see paragraph 4.031 (*d*)].

(*b*). Standard output and accuracy ratings of potential transformers shall be on the basis of their standard rated secondary voltage.

(*c*). The standard accuracy classes and corresponding limits of transformer correction factor for potential transformers shall be as shown in Table D.

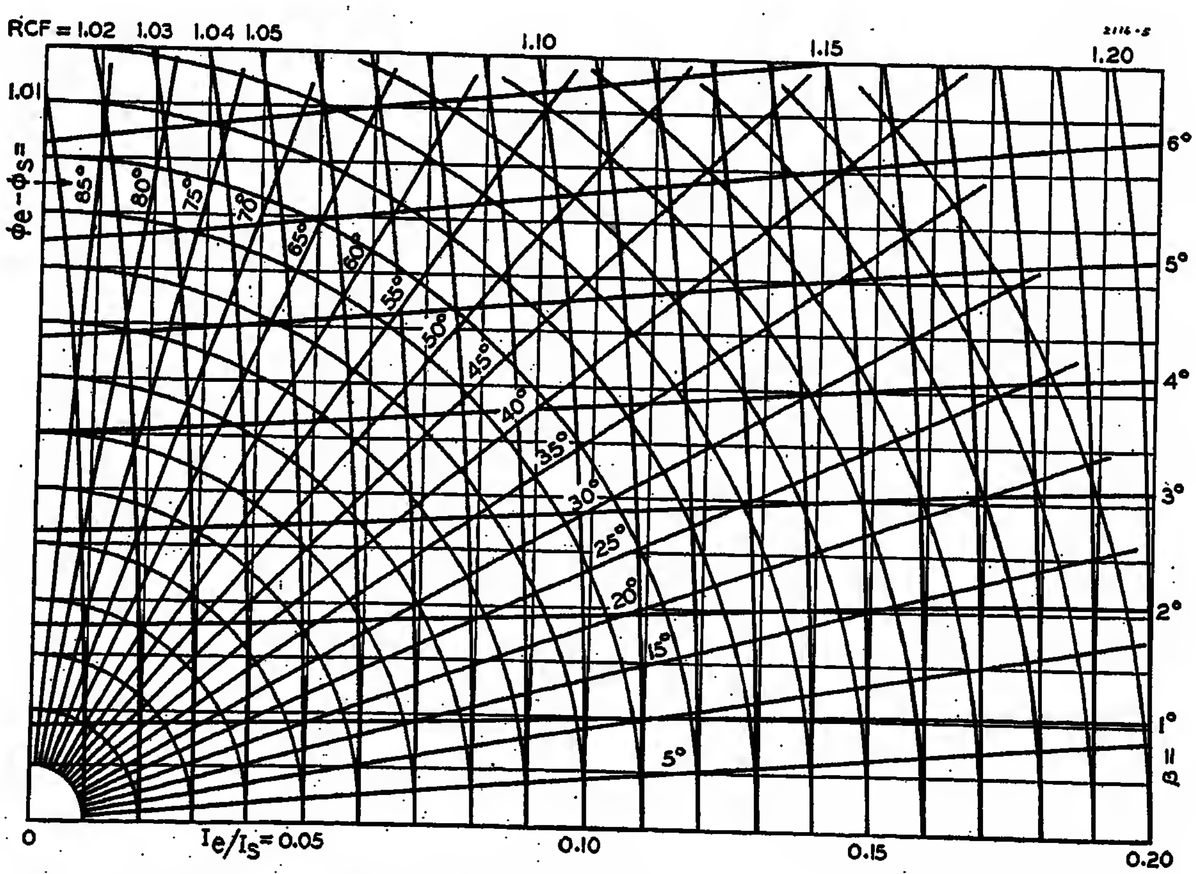
(*d*). For any known ratio correction factor (RCF) of a given transformer, the positive and negative limiting values of the phase angle "β" in minutes may be expressed as follows:

$$\gamma = 2{,}600(\mathrm{TCF} - \mathrm{RCF})$$

in which TCF is taken as the maximum and minimum transformer correction factor specified in (*c*).

The limiting values of the ratio correction factor are the same as the limits of the transformer correction factor, since the phase angle of the potential transformer does not introduce a significant error when it is small and when the load power factor is 1.0. These limits of ratio correction factor, to-

Figure 5. Chart for calculating RCF and β



gether with the corresponding limits of phase angle, keep the transformer correction factor within the specified limits for all values of power factor (lagging) of the measured power load between 0.6 and 1.0.

(*e*). These limits shall apply from 10 per cent above rated voltage to 10 per cent below rated voltage, at rated frequency, and from no burden on the potential transformer to the specified burden (see paragraph 4.002).

(*f*). In practice, a potential transformer shall be designated as 6/10 *W* if its ratio and phase-angle characteristics conform with the requirements of accuracy class 6/10 when used with any secondary burden not exceeding *W* with the power factor specified for *W* burden.

(*g*). In plotting curves of potential transformer accuracy, power factors shall be chosen to conform with the power factors of the standard burdens.

4.032 Standard Accuracy Classes for Current Transformers for Relaying Service

(*a*). 1. The overcurrent performance of current transformers for relaying service shall be specified on the basis of a standard per cent ratio error at 20 times rated secondary current, the standard relaying burdens, and the secondary terminal voltages established by the specified secondary current (20 times rated) operating into these burdens.

In these standards the term "per cent ratio error" is defined as 100(RCF−1), RCF = ratio correction factor.

2. A current transformer shall be given an accuracy rating in accordance with the maximum secondary terminal voltage at which the specified error will not be exceeded on the basis of 20 times normal secondary current operating into a standard relaying burden.

3. Accuracy classification for multiratio current transformers shall be given for the maximum secondary winding, and for double-ratio transformers shall be given for each ratio.

(*b*). Unless otherwise specified the rated secondary current shall be five amperes.

(*c*). For the purposes of standardization the standard specified per cent ratio errors shall be 10 per cent and $2^1/_2$ per cent.

(*d*). The accuracy classes of those transformers having a high internal secondary impedance (wound-type) shall be as shown in Table E.

(*e*). The accuracy classes of those transformers having a low internal secondary impedance (bushing-type) shall be as shown in Table F.

(*f*). The induced secondary voltage and corresponding value of exciting current form a good criterion of transformer performance and burden capacity. The induced secondary voltage is the vector sum of the secondary terminal voltage and the voltage drop due to the internal impedance of the secondary winding. The internal impedance may be negligible in certain designs, such as the bushing type, and quite large in others, such as the wound type.

Transformers having a relatively high internal impedance can maintain constant secondary terminal voltage under load for a range of 5 to 20 times rated secondary current, due to the fact that the internal voltage drop decreases more rapidly with reduction in secondary load current than the induced secondary voltage decreases with lower values of exciting current.

Transformers having relatively low internal impedance do not as a rule have this compensating internal voltage drop and can be standardized at one point only.

Recognition of this fact has resulted in the establishment of separate accuracy specifications for the two forms of current transformers.

(*g*). In practice, current transformers shall be designated by the accuracy class number.

The first number indicates the per cent ratio error. The letter *H* or *L* indicates which type of accuracy is specified. The second number gives the maximum secondary voltage at which the specified accuracy is obtained, with a secondary current of 20 times rated.

For example, a transformer of the 10*H*400 accuracies class has high internal impedance and the ratio error is not more than ten per cent at a secondary terminal voltage not exceeding 400 volts for secondary current values from 25 amperes to 100 amperes, or from 5 times to 20 times rated current.

4.046 Mechanical Limit for Current Transformers

(*a*). The mechanical limit of a current transformer is defined by specifying the maximum rms symmetrical primary current which the transformer is capable of withstanding with its secondary winding short-circuited for six cycles (0.1 second) and which may be in successive applications with no intentional time delay between applications. Transformers shall not be required to withstand a test for the mechanical limit exceeding one-half the thermal limit at six cycles (0.1 second) as calculated from the thermal limit at one second [see section 4.045 (*d*)].

(*b*). The transformer shall be capable of withstanding the mechanical forces produced by this value of current when the current wave is initially completely offset.

4.047 Open Secondary Circuit of Current Transformers

Current transformers conforming to these standards shall be capable of carrying rated primary current continuously with the secondary circuit open, without damage to the transformers, except when the open-circuit voltage exceeds 3,500 volts crest, which usually will occur when the ratio exceeds 300–1. When the secondary peak voltage exceeds 3,500 volts, the secondary of such a transformer shall be insulated so that it can operate continuously with current in the primary to produce 3,500 volts peak across the secondary terminals. (However, the operation of current transformers under such conditions should be guarded against to prevent excessive voltage in the secondary winding.)

Insulation Tests

THE subject of nondestructive tests on insulation has received much attention. Since a function of insulation in a given application is to provide a certain minimum dielectric strength, tests at their greatest usefulness would give a measure of dielectric strength without requiring a dielectric breakdown. Additional indications like proneness to loss of dielectric strength if subjected to certain hazards of service are valuable, and information on the deterioration or aging of insulation with service may follow from periodic tests.

Current Practices

Although an ideal test has yet to be devised, the insulation resistance and power-factor methods are widely used for nondestructive tests on insulation. Insulation-resistance measurements are recognized in many test codes and standards.[1,2] A formula is given for the insulation resistance to be expected in a clean dry machine at 75 degrees centigrade. In some cases the same formula is given for a minimum safe value. In 1934 Wieseman[3] pointed out inadequacies of this formula and suggested improvements, and his work seems to deserve more recognition. Dielectric absorption has appreciable influence upon indicated values of insulation resistance but is not mentioned in recent standards like the Test Code for Single-Phase Motors, November 1941. This absorption effect is appreciable and may be taken into account by establishing a definite time of voltage application for making observations. Actually, many of the deductions made by an experienced Megger operator are hard to formulate or standardize.

Capacitance and power-factor measurements have proved valuable for field testing of high-voltage insulation as in bushings or transformers. These measurements are largely detectors of moisture in sealed or oil-insulated types of apparatus.[4,5] For rotating apparatus perfect sealing is difficult, and a varnish film protects the insulation. Appreciable moisture can be tolerated, at least to the extent that power-factor measurements seem less significant.

An extensive and prolonged study of nondestructive tests leading to many improvements in technique has been conducted on very large machines by an Edison Electric Institute committee.[6] Field tests provide convincing evidence of any conclusions or limits established. Laboratory investigations however permit accelerated tests with one variable under study at a time, and dielectric strength tests leading to correlation with the nondestructive indicators are possible. In the belief that a study of testing methods under extreme conditions might prove helpful in interpreting field data and permit suggesting limits based on dielectric strength, some motors of the five-horsepower 440-volt class or smaller have been subjected to severe temperature or moisture conditions.

Laboratory Tests

Two similar five-horsepower three-phase 220–440-volt induction motors have been operated more than two years on an overload cycle. Each working day one motor has been brought to a temperature of 125 degrees centigrade by winding resistance, the other to 100 degrees centigrade. Insulation resistances have been observed before starting and immediately after shutdown each day. The motors have been started across the 230-volt line with 15-kw d-c generators connected. Operation thus has been similar to actual service conditions with one unit delivering about 7.2 horsepower and the other 6.4 horsepower.

Several fractional-horsepower motors have been subjected to high humidity conditions. After several trials with various cooling cycles by refrigeration, the simple arrangement of exposing the samples at room temperature in a closed metal chamber with water in the bottom (appendix I) was adopted. Insulation resistances, dissipation factors* and capacitances on samples so conditioned have been recorded periodically. Dielectric breakdown tests have been made on a number of the samples.

Motors are not suitable samples on which to secure extensive data on dielectric breakdown voltages. Accordingly, small wax-dipped paper-insulated capacitors, which could be conditioned readily, have been used to observe the relation between dielectric strength, insulation resistance, and dissipation factor under exposure to high humidity.

Insulation-Resistance Measurements

Careful technique and analysis show promise of increasing the significance of insulation-resistance measurements. The following considerations should be given attention:

(*a*). The influence of external leads should be eliminated.

(*b*). The effect of time of voltage application should be taken into account by making observations at a definite time such as one minute after test voltage is applied, or by exploring the dielectric-absorption curve.

(*c*). A definite trend in insulation resistance for weeks or months may be of significance where individual values are not.

Paper 42-124, recommended by the AIEE committee on electrical machinery and standards coordinating committee 4 for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 6, 1942; made available for printing May 13, 1942.

P. H. McAuley is with the engineering laboratories and standards department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The encouragement and assistance of R. E. Hellmund are gratefully acknowledged.

* Dissipation factor is the cotangent of the angle of which power factor is the cosine. It is often multiplied by 100 and given in per cent.

(*d*). Measurements at room temperature are attractive for practical reasons.

In both the high-temperature and the moisture tests on motors, leads influenced resistance readings. About ten feet of rubber-insulated cable lying on a wooden floor was connected to each of the five-horsepower motors. The cables were isolated and checked for insulation resistance at the start of the test which happened to be in the winter time. Later it was found, under summer humidity conditions, that the cable resistances were less than those of the motors. Similarly, on the small motors subjected to high humidity, leakage between the leads and frame in the terminal boxes determined observed insulation-resistance values at times. Hence, an essential precaution to obtaining significant values on motor

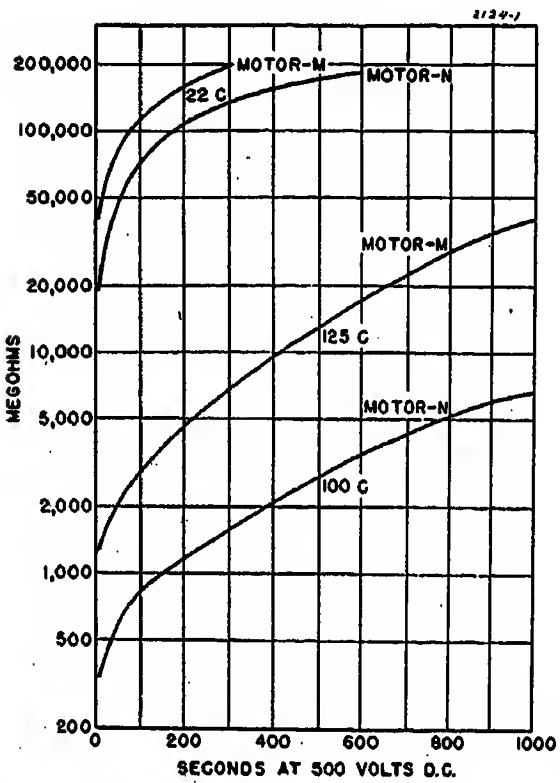

Figure 1. Insulation resistances hot and at room temperature on two five-horsepower motors on daily load cycle

insulation is to make sure that leads[7] are not influencing the results.

The effect of time of voltage application is shown in Figure 1 which gives insulation resistance values before and after one of the daily runs for each of the five-horsepower motors. For the curves while hot, the machines were cooling rapidly from the high temperatures of operation. Thus, cooling as well as dielectric absorption contributed to the increase of apparent insulation resistance with time. The 125 degrees centigrade motor, for instance, in 15 minutes has reached a resistance higher than the five-second value at room temperature. Times longer than 15 minutes appear necessary to arrive at steady-state conditions. These are not practical for small apparatus, but the rapid changes with time indicate the desirability of selecting a definite time arbitrarily for comparative values. For data in this paper insulation resistance values are for one minute after application of 500 volts d-c. Bridges with electronic balance indicators were used.

An enclosed d-c motor operated daily at 165 degrees centigrade has shown a reversal of the trend of change in insulation resistance. With the test started in August, the hot insulation resistance of the armature increased gradually from 2.2 to 1,000 megohms with drying and curing of the insulation. However, after several months operation enclosed and overloaded, the effect of brush dust reversed this trend. It was even more apparent in room-temperature-resistance values. In one case, these dropped from 7,500 megohms to 50 megohms over a period of six months. Simply cleaning the armature with compressed air raised the resistance to 30,000 megohms.

Electrical standards usually suggest a temperature of 75 degrees centigrade for insulation-resistance measurements. This temperature tends to minimize the effects of moisture, but a machine may require many hours or days at 75 degrees centigrade to reach a steady state of insulation resistance. On large generators the pertinent question often is whether continued operation is safe. On small machines the information may be required to determine the advisability of applying voltage and starting operation without drying. Therefore, the usefulness of tests would be enhanced by making measurements and establishing limits for a temperature in the ambient range.

Aging of Insulation

The temperature aging of insulation is difficult to detect from insulation-resistance measurements. It does not seem possible to draw conclusions on the relative insulation condition of the motors operated at 125 degrees centigrade and 100 degrees centigrade, although further experience may disclose significant relations. A physical examination shows that the 125 degrees centigrade insulation is somewhat brittle. Probably, it would be much more vulnerable to long or severe exposure to vibration or moisture. But where the operating schedule is regular, standard temperature limits appear conservative for many conditions of operation. From these tests the following observations were made, applying of course to thoroughly baked insulation:

(*a*). At room temperature the induction motors clean and dry had insulation resistances of from 100 to 100,000 megohms. In summer the values were below 1,000 megohms. In winter in a heated room 10,000 to over 100,000 megohms were obtained.

(*b*). A heated motor showed insulation resistance upon cooling of 10,000 to 1,000,000 megohms or an increase of 10 to 100 times.

(*c*). The 125 degrees centigrade motor had hot resistances of 1,200 to 2,500 megohms after 18 months operation, while the 100 degrees centigrade motor varied between 500 and 1,200 megohms. These values appear to have increased with aging of the insulation, but this point is submerged by the effects of the leads in the early part of the tests. The daily changes with temperature correspond fairly well with temperature correction curves[8] given by Rylander.

(*d*). One feature in comparing results on the two motors is the relative consistency of the resistance values. The day-to-day variations seem closely related.

(Table I shows values for one week. When one motor changed up or down, the other tended to do likewise. Many exceptions occurred, but there seemed to be a definite consistent relation, which suggests the influence of external conditions affecting both motors alike. Possibly it was simply temperature variations resulting from changes in line voltage or ambient temperature. The evidence is good that certain influences were functioning consistently and, that wide variations in insulation resistance may appear more logical with a better understanding of all the variables involved.)

(*e*). During weekends or occasional longer periods of shutdown, insulation resistance values tended to fall. This suggests that the room temperature reading at any given time is influenced by the integrated effect of moisture absorption since the previous heating period. It follows that a single humidity reading at the time of a test is not likely to be significant.

Moisture

Insulation is affected by exposure to moisture in spite of varnish treatments and usual methods of enclosure. These

Table I. Insulation Resistances in Megohms on Two Five-Horsepower Motors Following Daily Load Runs

Motor	Mon	Tues	Wed	Thurs	Fri
125 C	1,100	750	1,300	2,000	1,500
100 C	700	650	700	800	750

Table A

Operating Voltage	Minimum Megohms 20 C–30 C	AIEE Formula Megohms 75 C
110	0.1	0.11
220	0.5	0.22
440	3	0.44
550	5	0.55

factors influence the rate of moisture absorption and drying. On motors standing idle, the absorption is cumulative and appears to be readily reversible.

Four $^1/_4$-horsepower three-phase 440-volt enclosed motors were used as test samples. Measurements were made under the following conditions:

(*a*). As received from the factory.

(*b*). After five hours at 48 degrees centigrade.

(*c*). After 25 hours at 74.5 degrees centigrade.

(*d*). After 44 hours at 95 degrees centigrade.

(*e*). During 18 days standing at room temperature.

(*f*). After 15 hours at five degrees centigrade and seven hours at room temperature.

These test conditions were consecutive and represent a drying cycle, an idle period, and a cooling cycle conducive to condensation. Figure 2 gives capacitances and dissipation factors observed with a 115-volt 60-cycle bridge for conditions (*a*) to (*e*) inclusive on one motor, and the others were quite consistent. The record of moisture absorption is definite. The 30 per cent dissipation factor at the start and the decrease in capacitance and dissipation factor with drying are characteristic of moisture. The later increase in dissipation factor and capacitance when exposed to prevailing summer humidities indicates a slow but definite reabsorption of moisture. The rate varies appreciably and the trend reverses at times. In 18 days the original condition was not yet attained again.

Table II gives insulation-resistance data on the four motors for conditions (*a*) to (*f*) except that only one set of values was recorded during the 18-day idle period. The consistency in performance of the four motors is noteworthy. In all cases values on the different motors are of the same order of magnitude under given conditions. Columns 2, 6, and 7, however, are all for room-temperature measurements at different stages of moisture absorption. Drying increased insulation resistances about 100 times. A cooling cycle conducive to condensation later caused a 1,000 to 1 decrease. In analyzing measurements made at room temperature these variations must be recognized.

Table II. Insulation Resistance in Megohms for Four Small 440-Volt Motors at Controlled Temperatures

1 Motor	2 28 C	3 48 C 5 Hrs	4 75 C 20 Hrs	5 95 C 19 Hrs	6 22 C 23 Hrs	7 25 C (18 Days) 5 C (15 Hrs) 25 C (7 Hrs)
A	460	125	430	415	22,000	27
B	475	119	400	445	65,000	16
C	455	99	340	360	42,000	25
D	495	106	310	340	38,000	31

Accelerated test data for motor *A* without rotor or end bells in the 100 per cent humidity test chamber are given in Table III. After a few days dissipation factor and capacitance increased to the point where readings could not be obtained. The insulation resistance decreased steadily with time of exposure to well below one megohm, and the process seems to be an extension of the rate and the degree observed at ambient humidity.

A number of used motors which had been in storage for years were tested. The dissipation factors were between 30 and 45 per cent. Motor insulation appears to absorb moisture to this extent under normal conditions of storage in summer, and this effect has been observed on idle generators.[6] New and used motors do not appear greatly different unless in the time element involved following a drying treatment.

Further moisture-exposure tests were made on the four motors after redrying. Figure 3 shows the insulation-resistance data.

Curve *A*—Stator only as in Table III.

Cuve *B*—Retreated stator with a different varnish.

Curve *C*—Same as *A*, but enclosed and with synthetic tubing leads to eliminate lead leakage.

Curve *D*—Retreated stator with a different varnish immediately after drying.

The motors were exposed at high humidity for 71 days, and insulation resistances decreased steadily and consistently. Dissipation factors also indicated similar absorption with time, but readings were less consistent in the later stages of the test.

Curve *A*, Figure 3, duplicates the similar test of Table III rather well. By comparison, *C* shows that enclosure retarded absorption materially. Better varnish treatment in cases *B* and *D* did likewise and this result agrees with statistical service data. Improved results have been obtained under some service conditions with additional and special varnishes. These protective measures influence the insulation state reached in a given time.

For part of the test, a voltage of 115 and later 230 volts, 60-cycle, was applied between the windings and iron of stator *A*, Figure 3. When this voltage was removed, the insulation resistance dropped from a 0.4-megohm level to 0.08 megohm. No improvement occurred on application of the voltage, but further depreciation was prevented. The evidence is meager, but further study of

Figure 2. Effect of drying and exposure at summer humidity conditions on capacitance and dissipation factor of small motor insulation

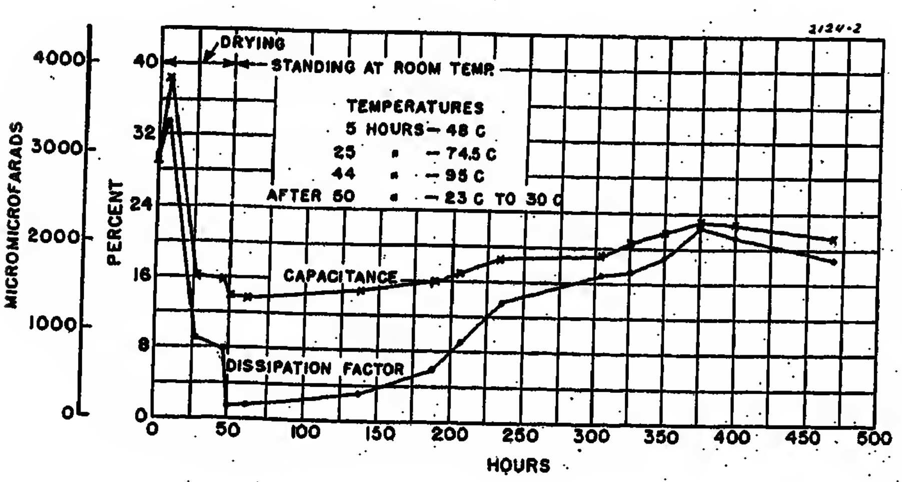

Figure 3 (right). Insulation resistances of small motors in humidity-conditioning chamber

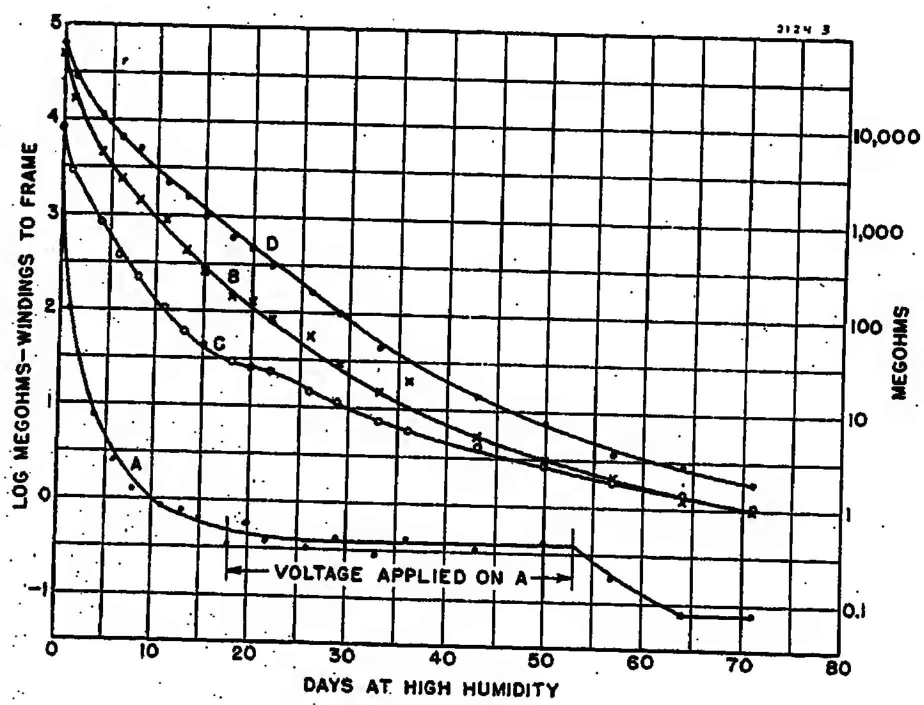

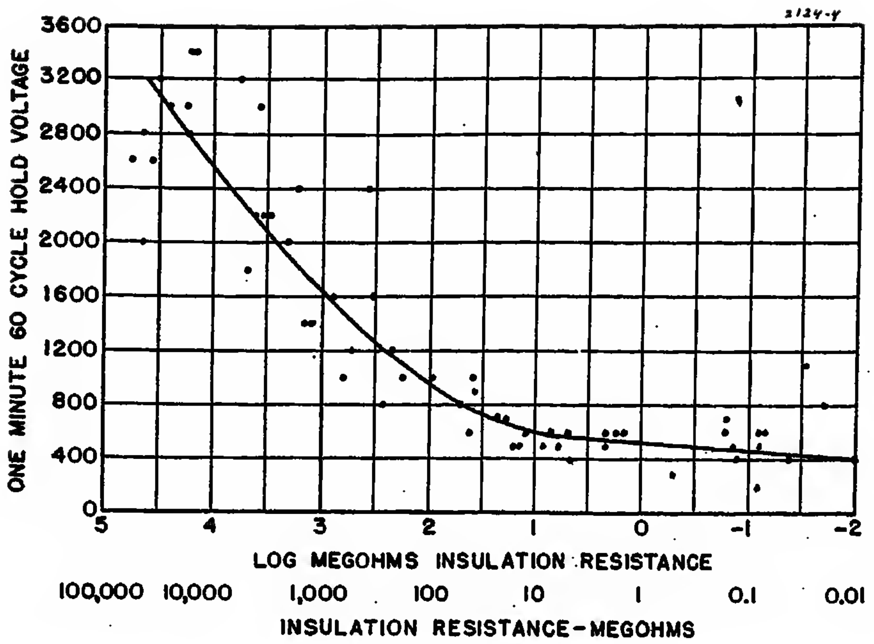

Figure 4. Relation between dielectric strength and insulation resistance on capacitors in moisture-exposure tests

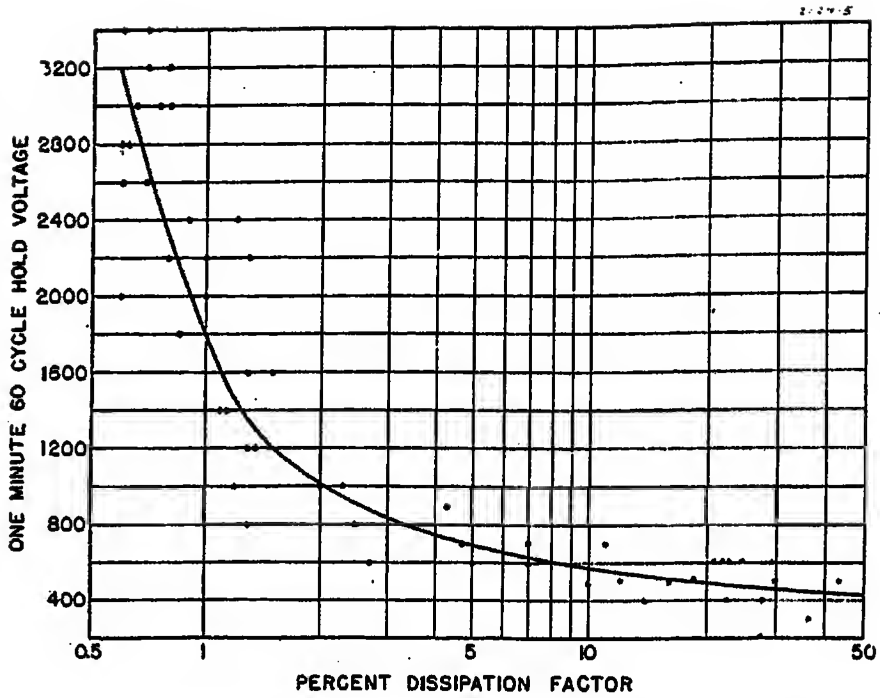

Figure 5. Relation between dielectric strength and dissipation factor on capacitors in moisture-exposure tests

the value of keeping some voltage on insulation to ground under adverse moisture conditions seems warranted. Unfortunately, this measure is not readily applicable to intercoil insulation.

The process of moisture absorption appears to be reversible. If the insulation is dried or even stored in a heated room, recovery is appreciable and rather rapid. The motors were dried between the tests of Table III and Figure 3 apparently without affecting later performance. Table IV gives readings on the stators three days after completion of the tests of Figure 3. Insulation resistances and dissipation factors, in spite of dielectric breakdown tests in the meantime, indicate appreciable drying has occurred at room temperature. The rate depends again upon the varnish treatment. The problem resolves into avoiding the application of voltage when the insulation is in a weakened condition.

Dielectric Strength

The real criterion of suitability for service is the dielectric strength of the insulation. Moisture reduces dielectric strength appreciably.

Following the exposure tests of Figure 3, dielectric breakdown tests were made on the four motors as in Table IV. The dielectric test for new motors of this class is twice normal plus 1,000 volts for one minute. Two of the stators, *A* and *C*, were below this value following the moisture exposure tests. However, the poorer one held 1,000 volts for one minute, which leaves a little margin over operating voltage in spite of severe test conditions. The motors operated at 100 degrees centigrade and 125 degrees centigrade for two years stood a 2,000-volt momentary test after each year of operation.

Maximum 60-cycle test voltages held for one minute between motor windings and frame for different values of insulation resistance are given in Figure 7. The points at or above 4,000 volts are for new stators, and other points are following different times of exposure to moisture. The curve is drawn near the lower limit of the points. Since the points are the highest voltages held for one minute, and failures occurred at the next highest 200-volt step, the curve is of the nature of a minimum breakdown voltage curve, although a larger number of tests probably would modify it some. There is a fairly definite relation between insulation resistance and dielectric strength for these fractional-horsepower motors.

The capacitors used for dielectric breakdown tests have three layers of about 0.0005-inch paper insulation and are rated at 220 volts alternating current. Operating volts per mil are much higher than in motors, and very little moisture can be tolerated. Samples were exposed at high humidity, and a few were removed periodically and tested for insulation resistance, dissipation factor, and dielectric breakdown strength, as shown in Figures 4 and 5. There seems to be reasonably good correlation between the electrical test values and dielectric strength. For insulation resistances below 100 megohms or dissipation factors over two per cent, the dielectric strength is reduced appreciably to rapidly approach a minimum value.

These capacitors also illustrate another phenomenon on the insulation-resistance test. Figure 6 shows the variation of insulation resistance with time for a sample after 24 days exposure. The insulation resistance first increased with time as in the usual dielectric-absorption curve. After about 20 seconds the trend reversed, and after 40 seconds insulation resistance decreased rapidly with time, possibly because of a partial breakdown at 500 volts direct current. Recovery was rapid and fairly complete, however, as the sample immediately afterwards held 600 volts 60-cycle for one minute and failed at 700 volts. The same action has been observed on motors after appreciable exposure. Davis and Leftwich[9] have reported the decreasing resistance section of the curve due to defective auxiliary apparatus on generators. These effects accent the desirability of observing insulation resistance at one minute or more after voltage is applied. A 10- or 15-second Megger reading would not have disclosed the situation. Also, in this

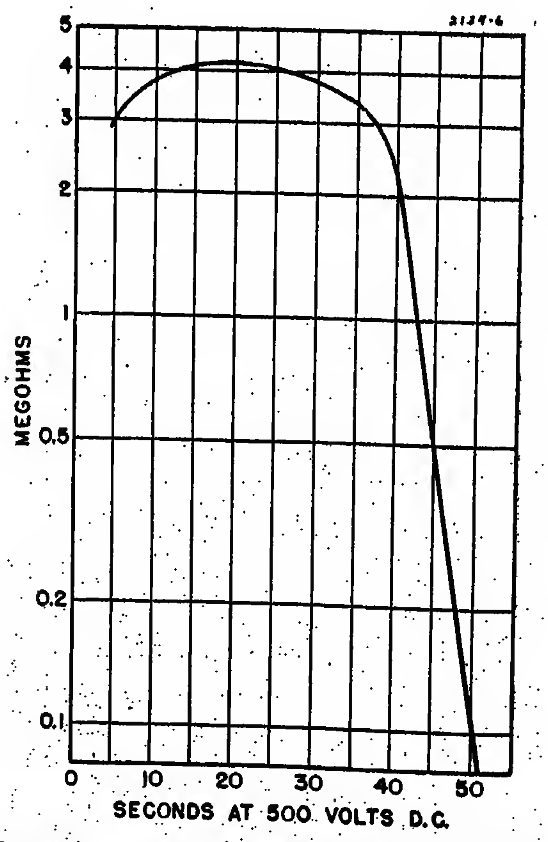

Figure 6. Insulation resistance on capacitor after considerable exposure to moisture

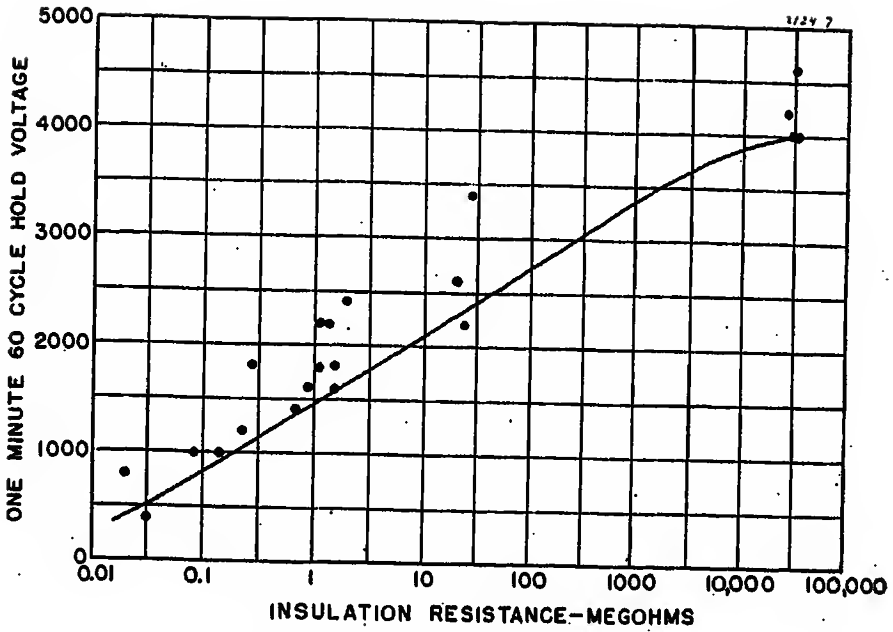

Figure 7. Relation between dielectric strength and insulation resistance for fractional-horsepower 110- to 440-volt motors

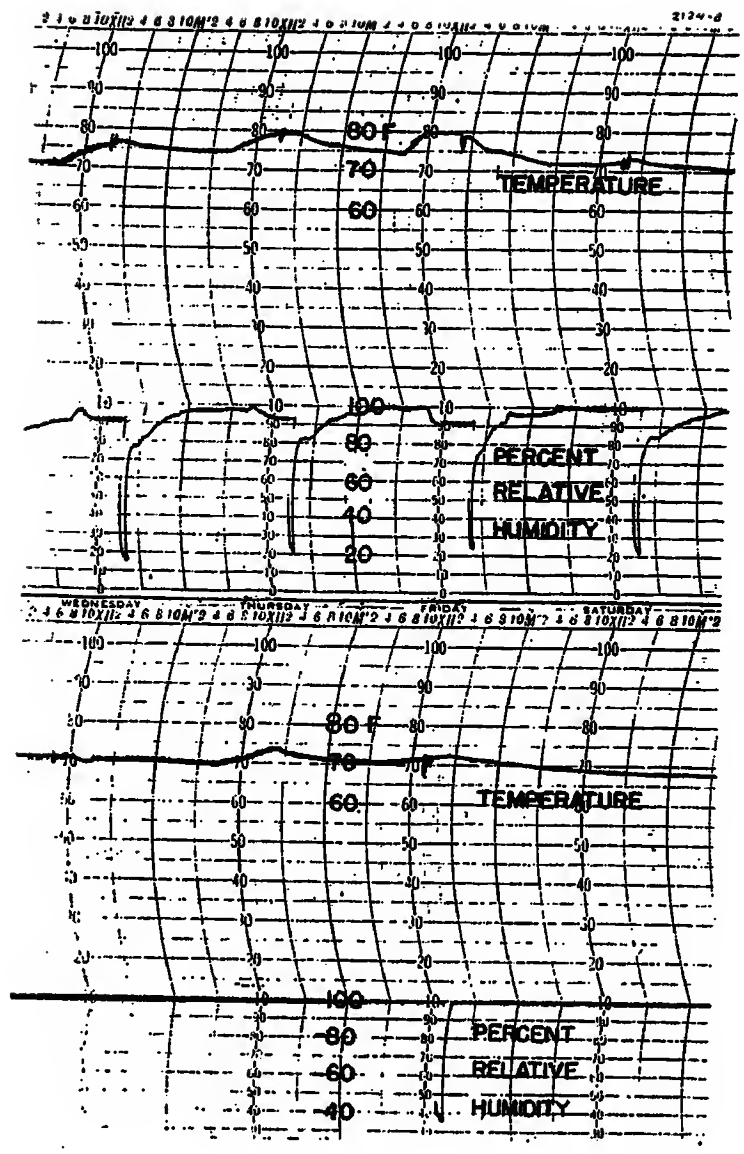

Figure 8 (right). Temperature and humidity chart from metal test chamber with water in the bottom

case at least, a weakened condition of the insulation was detected at a d-c voltage of one-half the 60-cycle crest breakdown value. These capacitor samples are small, however, and results may have been affected by heating or drying at test voltages.

Nondestructive Tests Versus Dielectric Strength

The purpose of these investigations is, of course, to determine if nondestructive insulation tests can be relied upon to indicate the suitability of apparatus for service.

1. There is some possibility of establishing for some devices minimum insulation-resistance values which will assure satisfactory operation in spite of appreciable moisture absorption.

2. The test methods studied do not appear dependable for revealing insulation defects other than moisture absorption, with the possible exception of dirt.

To establish satisfactory limits for motors considerable dielectric-strength data and field experience should be available. Table IV and Figure 7 indicate, however, that insulation strength decreases with insulation resistance. This is recognized in the standards formula for expected values at 75 degrees centigrade. However, the 75 degrees centigrade temperature implies some drying. Also, no time of voltage application is specified, which leaves to chance the inclusion of such effects as in Figure 6. Recognizing the greater usefulness of tests at room temperature, it may be reasonable to suggest from Figure 7 the following tentative limits above which small motors can be safely connected to the line for starting. The values in column 2 are for room temperature at one minute after the d-c test voltage is applied. A ratio of about 60 has been given[8] for values taken at 25 degrees centigrade and 75 degrees centigrade.

These limits allow some margin of safety at operating voltages, but wide variations in practice are to be expected. Appreciably lower values may not prove fatal in many cases. Also, where moisture is not involved, these limits may give no assurance of a satisfactory condition. In fact much higher values often may be associated with poor insulation. Additional experience on many sizes, types, and makes of motors under service conditions will be necessary for proper determination of the best values, but the possibility of establishing useful limits seems good.

The detection of defects under dry conditions is very uncertain for low-voltage apparatus. The roasted condition of the motor operated at 125 degrees centigrade was not apparent from the electrical tests. Columns 5 and 6 of Table IV also are significant. The motors had been tested to failure, but insulation resistances of 1,950, 2.1, and 3.2 megohms were later recorded for three of the windings. Motor *C* did show evidence of the previous breakdown by its zero insulation resistance. It is quite likely that higher insulation test voltages would reveal the condition in all cases. There is always danger, however, in testing at voltages much above operating voltage, or the nondestructive feature of the test may be sacrificed. The failure of insulation-resistance test voltages to disclose punctures or breaks in insulation is readily understandable. The smallest air gap will not sparkover much below 1,000 volts in short-time tests. The separation between conductor and core in small motors may be approximately 0.05 inch, and the dielectric breakdown of air for this distance usually exceeds 4,000 volts with creepage strengths somewhat lower. Consequently, if the puncture or fault is clean and reasonably dry, the insulation resistance may be affected to a small extent. The strength of the insulation between turns, coils, and phases in motors also is important. However, under

Table III. Measurements Between Windings and Frame on Stator *A* Exposed to 100 Per Cent Humidity

Days Exposed	Megohms	$\mu\mu f$	Per Cent Dissipation Factor
0	200,000	1,275	1.2
1	5,100	1,420	5.1
5		7,100	38
6	3.1	8,200*	> 50*
7	1.5	11,100	> 50
8	0.85	14,800	> 50
11	0.42	24,200	> 50
12	0.31	30,000	> 50
13	0.21	30,000	> 50

* These and later readings are very approximate as the bridge could not be balanced for dissipation factors greater than 50 per cent.

Table IV. Tests on Stators After 71 Days at 100 Per Cent Humidity as in Figure 4

1	2	3	4	5	6
	As Removed			After 3 Days in a Heated Room	
Motor	Megohms	Per Cent Dissipation Factor	Volts Held for 1 Minute	Megohms	Per Cent Dissipation Factor
A	0.083	> 50	1,000	1,950	17.5
B	0.88	40	1,600	2.1	31
C	1.08	> 50	2,200	0	15
D	1.95	37	2,400	3.2	34.5

service conditions, the testing of this insulation becomes rather elaborate. In a well-proportioned machine test results on the ground insulation should be indicative of general machine condition.

Conclusions

1. Test codes and standards should recognize the effect of dielectric absorption on insulation resistance and suggest a time such as one minute after voltage application for observing resistance.

2. For industrial apparatus rated below 600 volts room-temperature measurements of insulation resistance seem more practical than 75 degrees centigrade values.

3. Aging of insulation due to temperature is difficult to detect from electrical measurements. These indicators are sensitive to moisture absorption and possibly to dirt.

4. There appears to be a very good correlation between insulation resistance as affected by moisture and dielectric strength for fractional-horsepower motors.

5. Minimum room-temperature values of insulation resistance for starting small motors are suggested.

Appendix I. Humidity-Conditioning Chamber

In seeking a convenient testing cycle at high humidity, several combinations of cooling and exposure to moist atmospheres were tried. It was difficult to reproduce conditions, and considerable handling of the samples was required. The simple expedient of a closed metal can with water in the bottom finally was adopted. For most of these tests the chamber consisted of a can about 30 inches in diameter by 36 inches high with a deep lid about 34 inches in diameter. The assembly was turned upside down from the usual position, and the lid filled with water. Thus, the water provided both a seal and a source of moisture. A pinhole permitted entrapped air to escape. No temperature or humidity controls were provided other than the laboratory heating system which determined ambient conditions. Both temperature and humidity in the chamber were recorded with a Friez Hythergraph, Figure 8. These records indicate a saturated atmosphere most of the time, but this depended to a certain extent upon the condition of the samples and the frequency of opening the chamber. The time to return to maximum humidity after opening the chamber varied with ambient humidity and the duration of the open condition. Times from 0.5 to 20 hours were observed. This might be a handicap in short-time tests, but a fan should speed evaporation appreciably. For insulation tests of this kind, this type of chamber provides a simple, convenient, and easily reproducible conditioning atmosphere. The correlation to actual service conditions with wide temperature and humidity changes and moving air is problematical, but that, relatively, it is a very severe moisture-exposure test seems certain. One possible case which it does simulate closely occurs where water penetrates and remains inside an idle enclosed machine for some time.

Ignitron Rectifiers in Industry

J. H. COX
ASSOCIATE AIEE

G. F. JONES
NONMEMBER AIEE

WHEN a new device is developed, it is usually adopted and proved by a particular industry. In the case of the ignitron rectifier, the first applications were in transportation service in mines and railways. The apparatus and its performance in these early installations were discussed by the present authors in an earlier Institute paper.[1]

Since that time, as superior operating results became known, the ignitron has been taken up by other industries, most notably the electrochemical. In excess of 2,000,000 kw of ignitron-rectifier units have been purchased by that industry alone.

This paper will discuss primarily installations for large power concentrations.

Rectifier Description

Continuously pumped ignitrons have been applied to date in four sizes which, in six tube assemblies, have continuous ratings at 600 volts of 1,250, 1,667, 2,500, and 4,000 amperes. The 2,500-ampere size has been applied in greatest numbers. However, larger-capacity sections are desired for the larger installations, and so the majority of applications have been made using 12-tube assemblies. One design will be described.

The ignitron consists of a drawn steel tank with a removable cover plate into which is mounted the main anode bushing and anode shield terminal. Graphite continues to be the best material for rectifier anodes. The deionizing shield surrounding the anode and the baffle between anode and cathode pool, are also of graphite. This latter is insulated from the cathode to avoid the transfer of the cathode spot from cathode to baffle when high overloads are applied. The tank itself constitutes the cathode connection, since the ignitron does not require an insulated cathode and is bolted to the cathode copper bars on the assembly frame. The ignitor is mounted on a rod which passes through the side of the tank, insulated with a glass-kovar seal, on a flexible steel diaphragm. The mounting is provided with adjusting screws to enable adjustment of the ignitor from outside the tank. Solder-to-porcelain vacuum-tight seals are used for the main anode bushing. A small solid radiator terminal holds this seal within safe temperatures. The low-current potential connection to the anode shield is made through an aviation spark-plug-type bushing with a soft copper gasket. The vacuum-sealing gaskets in the separable joints of the ignitron proper, are enameled aluminum wire rings. Such gaskets operate satisfactorily at 100 degrees centigrade, and the rectifier operating temperature is objectionably close to the maximum safe temperature of rubber. However, rubber constitutes a most convenient, and semiflexible vacuum-tight gasket which requires relatively low flange pressures. Therefore, the external connections to the vacuum pumping system, which operate at low temperatures, are gasketed with iron-band-protected rubber. The ignitron tanks are cooled by water passed through copper tubing, which is wrapped around the tank and coiled on the bottom, and attached to the steel with high-temperature solder. Additional cooling in high-current units is provided by an internal steel coil. This latter is copper-lined to keep all water-cooled surfaces nonferrous. Figure 2 shows a cross-section view and Figure 3 an external view of the ignitron described.

A rectifier unit consists of a transformer and the rectifier assembly or assemblies to which it is connected. In large-capacity units two or more rectifier assemblies may be connected to one transformer.

Rectifier circuits which efficiently utilize the circuit elements are arranged for three-phase operation and require multiples of three anodes. (Smaller installations are sometimes made with four anodes.) Where the power required can be supplied with six anodes, or where the small number of units suggests sectionalization to insure continuity of service, ignitrons are assembled in groups of six on one frame with one cooling system and one vacuum pumping and measuring system. However, in large stations where ample reserve is maintained with one unit out of service, simplicity dictates assembly in units of 12. Such assemblies have proved most convenient, and one vacuum system of any established type has proved adequate. The individual tanks are connected to the vacuum pumps through a vacuum manifold with water-cooled pumping connections which condense the mercury vapor and prevent transfer of mercury between tanks and pump. On these large-size tubes an individual vacuum valve on each facilitates both manufacture and repair, since vacuum tightness can be checked more easily by isolating smaller elements. Also, one ignitron tube can be treated as an entity and interchanged with a spare in less than one hour if necessary.

Figure 4 shows an assembly of 12 ignitrons rated at 5,000 amperes d-c in the 600-volt class.

All high-power rectifiers have been water-cooled. Since cooling water which is pure enough to pass through the rectifier jackets or tubes directly without trouble due to corrosion or scale is rarely available, practically all installations are provided with heat exchangers which permit the recirculation of pure or treated

water. Where ample raw water is available, water-to-water exchangers are used, otherwise water-to-air. Water-to-air exchangers are nearly always used in mining installations where cooling water is either not available or of very low quality.

Unit Excitation and Control

The earlier types of ignitron excitation which utilized thyratron tubes have mostly been superseded by circuits which generate impulse voltages by means of saturating reactors.[2] These circuits utilize static devices throughout: that is, simple transformers, reactors, capacitors, and Rectox rectifiers. The excitation-circuit devices, together with the vacuum- and cooling-system control, are mounted in a cabinet located on or near the rectifier. Two types of phase control of rectifier voltage have been used. One is a mechanical phase shifter, which consists of a wound-rotor induction machine. The excitation power is passed through this phase shifter, and the phase position of the excitation impulses is determined by the position of the phase-shifter rotor in its stator. This position is controlled by a fractional-horsepower motor through a gear box. The other type of phase control utilizes some form of phase-shifting network in which the phase position of the excitation impulses is determined by the value of direct current in a saturable reactor. This latter is a less simple circuit than the mechanical phase shifter, but is more flexible where automatic control is required, and speed of response is important. Particularly, the phase-shifting network is suitable for use with a simple type of voltage regulator such as the Silverstat. Also, such a network may be designed to include voltage-compensating characteristics which will maintain full energy excitation through supply-line voltage fluctuations as great as 50 per cent.

Station Layout

The simplest and most economical arrangement of apparatus in a rectifier substation is to effect a straight line run of power from the a-c supply source to the d-c bus. Figures 5 and 6 show a typical multiunit station layout having this arrangement. Incoming power is delivered to the a-c bus, from which it is distributed to the ignitron units through a-c switchgear, the transformers, ignitrons, and d-c switchgear to the d-c bus.

For the layout shown, the a-c switchgear is in a small masonry house separated from the main building. This can be modified to supply conventional outdoor switchgear, outdoor metal-enclosed gear, or the switchgear can be located in the substation building.

All transformer equipment is outdoor. It can be supplied with conventional bushings and an overhead bus structure or with potheads and an underground system as shown.

The substation building is designed with two levels, the ignitrons and all necessary operator control devices being located on the operating floor with some accessories and low-voltage switchgear in the basement. All of the equipment in the basement is operated electrically from the operating floor and is completely supervised by indicating devices. The operator need go to the basement only for routine inspection and maintenance. In many installations the low-voltage switchgear is also located on the operating floor.

Some detail equipment which is required for station operation and which can be located as convenient is not shown. This includes the station battery with charging equipment, the degassing equipment, air-cleaning apparatus if required, storage space for spare parts, and equipment for supplying power to plant auxiliaries which are not associated with the substation equipment.

Building appurtenances such as stairways, lavatory facilities, and operators' office must be included. A repair bay should be provided and is usually at the end of the substation building. Crane facilities and sufficient head room for untanking the largest transformer will determine its construction. An enclosed clean room for working on interior parts of rectifiers is desirable.

Rectifier-Switching Arrangements

Figure 7 shows the several switching arrangements which are in use for ignitron units, rated at 8,000 to 10,000 amperes in the 600 d-c voltage class, in multiunit substations.

Circuit *A* is used when the concentration of power supply to the a-c bus is heavy, a condition which would require large rupturing capacity and costly oil circuit breakers in the rectifier-unit circuits. Circuit breakers are not used, the primary switching consisting of a disconnecting switch which is capable of opening the transformer magnetizing current. For this arrangement, primary faults must be opened by the switchgear in the supply circuit or circuits to the plant. This involves a plant shutdown until the faulty circuit is isolated by operation of the disconnecting switches.

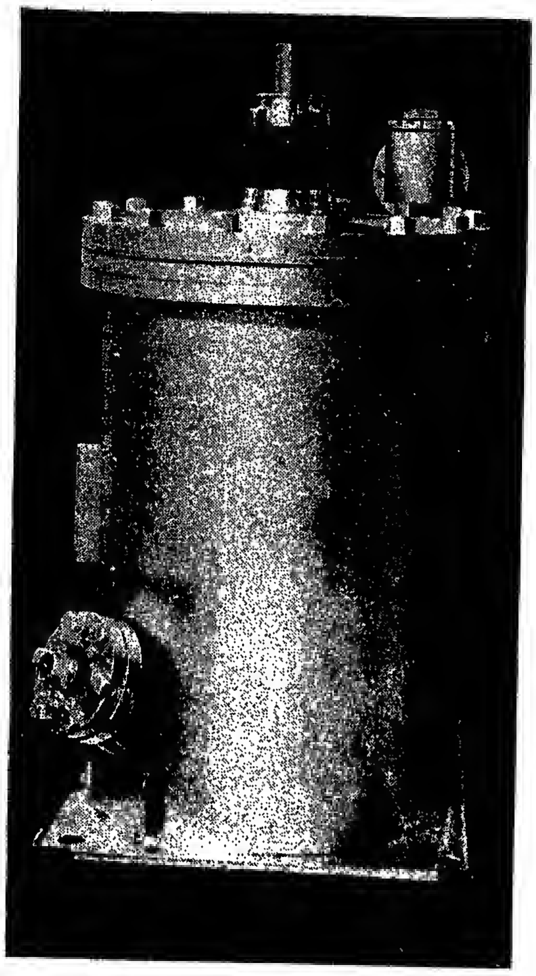

Figure 3. A single ignitron

The secondary switching consists of high-speed anode switchgear with one pole for each phase of the transformer secondary.

High-speed switching, which will limit the d-c rise in the average circuit in the order of one-third cycle, on a 60-cycle basis, is essential for large multiunit substations. At the time of arc back, all normal units will contribute direct current to the arc back in the form of reverse current. This current increases rapidly, depending upon the inductance of the circuit, and must be limited by the switchgear to a value which the switchgear can open successfully and without undue maintenance. It is also advantageous to limit the stresses on the other equipment involved in the circuit, particularly the transformer.

When an arc back occurs, the sound anodes of the ignitron assembly in which the arc back has occurred will supply current to the faulty anode. This feed to the arc back is in addition to the back feed from other ignitron units and is a short circuit, through the arcs involved, on the transformer secondary. This fault must be suppressed by opening the a-c supply to the transformer or by opening the faulty circuit between the transformer and the ignitron.

For arrangement A, the a-c supply to the transformer cannot be opened except by operation of the circuit breakers in the station supply. High-speed anode switching is therefore essential for this circuit.

The anode circuit breakers are supplemented by semihigh-speed cathode circuit breakers. These are used for normal switching operations. Disconnecting switches permit maintenance of the circuit breakers with a minimum of equipment out of service.

Circuit B is quite similar to circuit A except that an oil circuit breaker is used in the circuit to the rectifier transformer. Its use can be justified if the rupturing capacity required is 500,000 kva or less. The circuit breaker is then relatively inexpensive, and each ignitron circuit is completely independent of the others. Circuit faults are isolated without plant shutdown. Complete flexibility of control is afforded.

The use of high-speed anode switching makes it unnecessary to open the oil circuit breaker at the time of arc back. When two ignitron assemblies with independent low-voltage switching are connected to one transformer, the anode switching can be opened for one assembly without affecting operation of the other. This is of advantage in keeping maximum conversion equipment in service. The importance of this feature is in inverse ratio to the number of conversion units normally connected to the common d-c bus.

Circuit C is similar to circuit B except that the high-speed anode switches are omitted, and a high-speed cathode circuit breaker is substituted for the semihigh-speed switch. With this arrangement reverse current to the ignitron assembly which has arced back is opened with high-speed action by the cathode circuit breaker. Arc quenching may be used to suppress the alternating fault current by preventing the normal anodes of the assembly from firing to the faulty anode. This latter operation is effective in approximately one cycle.

Circuits B and C are therefore comparable except for two features. Arc quenching sometimes fails in its operation. It is about 90 per cent effective. When it fails in operation, the oil circuit breaker must be opened by overload relay action to remove the fault. Anode switching is fully operative, but there are six poles of switchgear to maintain, compared to a single larger pole of cathode switching. The choice between the two circuits is therefore dictated by consideration of maintenance, as compared with an occasional failure to segregate the fault in a half-rectifier unit.

If arc quenching is not used in connection with circuit C, the primary oil switch unit must be interlocked with the cathode switch so that the entire unit is removed from service in the event of arc back, and the a-c short circuit endures for the opening time of the oil switch, which is usually of the order of six cycles.

Circuit C makes use of anode disconnecting switches in the anode circuits to each ignitron section, one assembly making up one half of the unit. These are used so that each assembly can be isolated for maintenance and continue with normal operation of its associated assembly. They are also of use during the degassing process.

For those installations, where a complete unit outage is permitted because of spare capacity available, the anode disconnecting switches can be omitted. This applies equally to circuits A, B, or C. Circuit D shows a circuit similar to circuit C except with the anode disconnecting switches omitted.

For single rectifier units connected to an isolated d-c bus, the switching can be simplified. The unit may consist of one or more ignitron assemblies. For either condition, the amount of current in-

Figure 4. An assembly of 12 ignitrons rated at 5,000-amperes d-c in the 600-volt class

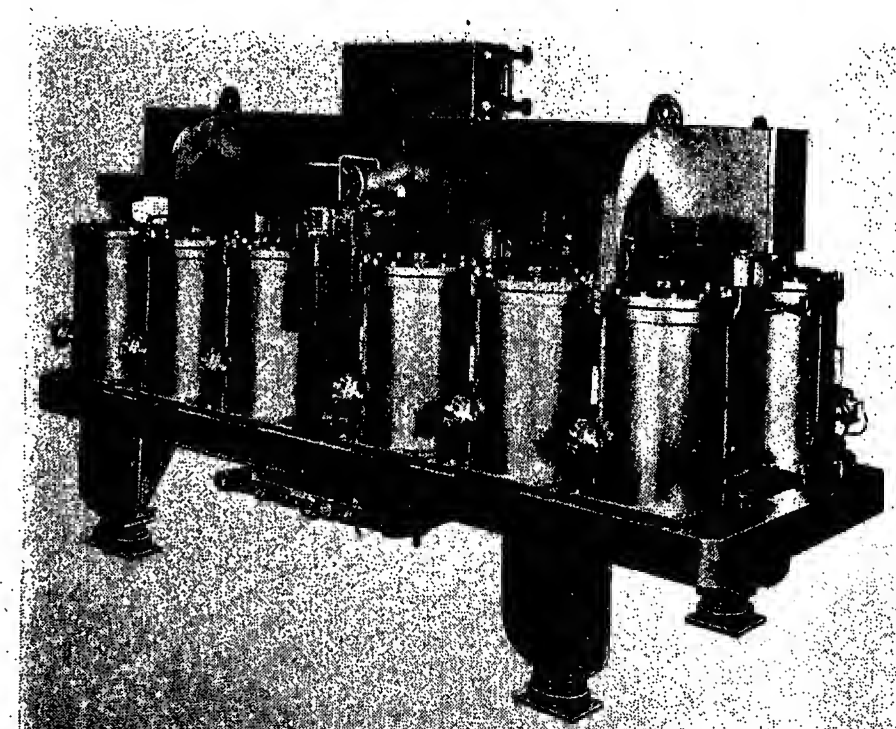

Figure 5. Plan view of a typical multiunit ignitron substation

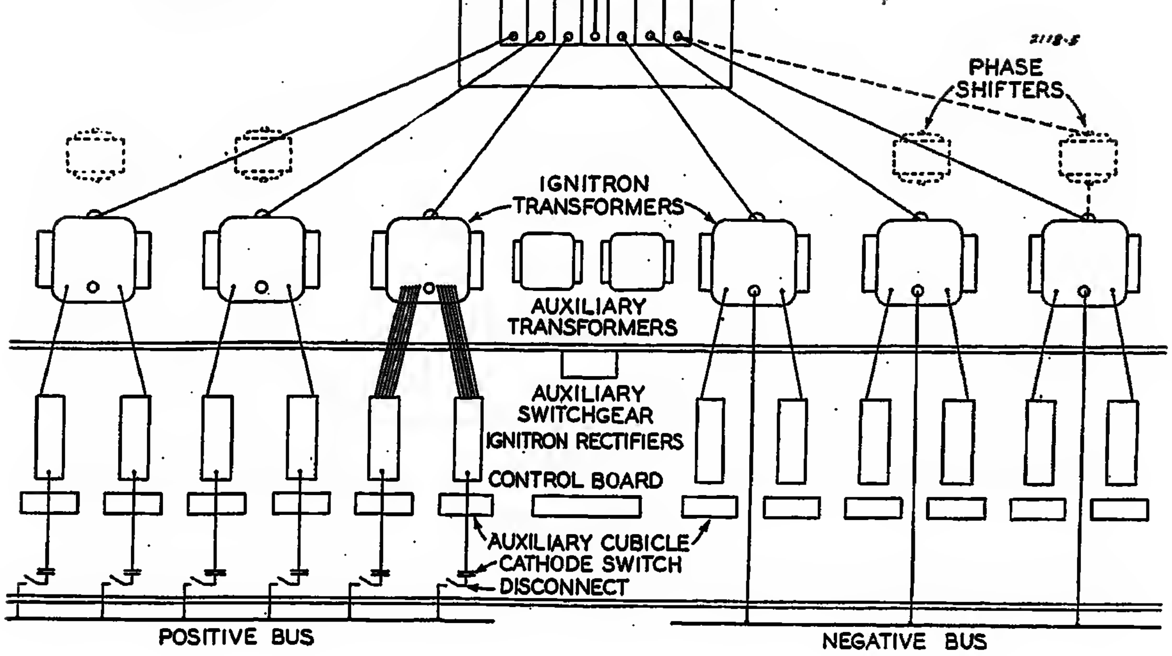


volved in an arc back is relatively small and semihigh-speed switchgear, having a speed of $1^1/_2$ to 2 cycles to current limitation, is adequate for the service. This may be arranged, as in the case of high-speed switching, either with anode breakers with suitable cathode switching to provide the type of operation desired, or with a cathode breaker and an oil switch in the primary of the transformer. Reverse current for a single assembly is applied from the electrolytic cells. Where a cathode switch is used, an arc back is cleared by the opening of the cathode circuit breaker, followed by the opening of the oil circuit breaker.

For double assembly units, arc quenching can be used in combination with the semihigh-speed cathode switches to secure continuous half-unit operation. Anode disconnecting switches can be used for half-unit isolation. Circuit *E* illustrates the use of semihigh-speed cathode switching with a single rectifier unit supplying an isolated d-c bus.

A special use can be made of high-speed anode switching for a single rectifier unit supplying an isolated load where continuous service is an absolute essential. The switch can be arranged to trip individual poles and on reverse current only. At the time of arc back only the pole of the circuit involved in the fault will open, the other anodes continuing in service.

Station Voltage Control

The great majority of industrial loads requiring one- or two-unit stations, particularly including electric railways, are adapted to the normal five to eight per cent shunt characteristic of noncontrolled rectifiers, and phase control of voltage is not necessary. For applications requiring flatter voltage regulation one of the phase-control systems is used, and there is a wide choice of control method ranging from manual to fully automatic. Provision can be made for flat compounding and cross compounding where more than one unit on a bus is involved. Where small units are located at the end of a low power feeder, which frequently occurs in mines, and the a-c supply to the rectifier transformer varies widely, some form of compensator is used which by phase control reduces the voltage at the lighter loads and provides a nearly flat voltage regulation from light load to full load. Above full load the uncompensated voltage regulation prevails.

In large stations containing many units on one bus, phase control is always used, primarily to compensate for minor differences in impedances and equalize the currents in the several units, and to provide small variations in voltages as desired for the load. However, since large phase-control angles adversely affect power factor and increase harmonics, the minimum feasible transformer tap is used in order to keep the phase control angles at a minimum.

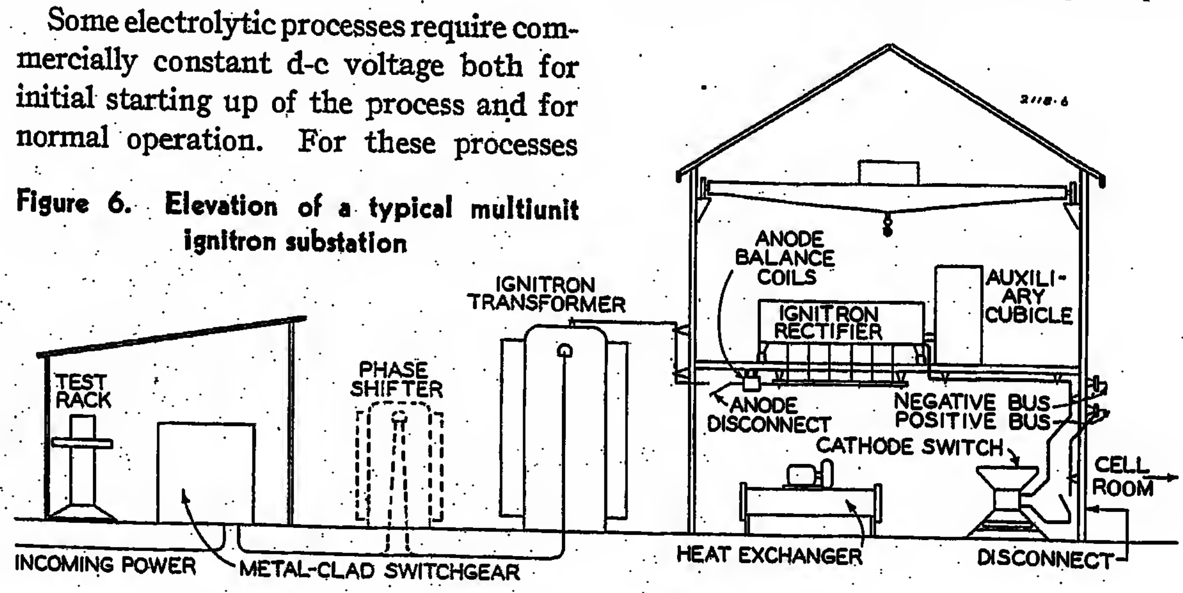
Some electrolytic processes require commercially constant d-c voltage both for initial starting up of the process and for normal operation. For these processes no-load voltage taps can be provided in the rectifier transformers to compensate for seasonal voltage changes and for electrolytic cell aging.

Ignitor or phase control of d-c voltage can be used for short times in the range required to pick up and drop load due to switching requirements. It can also be used for small voltage adjustments over long-time periods of operation.

Some processes require a wide voltage range for initial starting up in order to condition new cells in small blocks, but require essentially constant voltage for normal operation. For these processes an autotransformer of sufficient capacity to supply all rectifiers connected to one or several cell strings in parallel can be supplied. No-load taps are supplied in sufficient number and range to accomplish the desired results. Phase voltage control can be used for d-c voltage adjustment between taps. It is not however recommended for long-time wide-range voltage adjustment, because of its adverse effect on power factor and the increase in harmonics. The autotransformer can also be used for permanent adjustment of d-c voltage when required by a change in production schedule.

Some processes require that constant current be maintained through the electrolytic cells, even though the cell characteristics change frequently and rapidly. For these processes an autotransformer having a combination of no-load taps and tap changer under load can be supplied. The no-load taps cover the extreme voltage range required. The tap changer under load is arranged to boost or buck the d-c voltage from any no-load tap and in the range required. The tap points of the tap changer under load equipment can usually be made sufficiently fine so that phase control of voltage is not required between taps or, if used, will be limited to a few per cent in range. In many processes the fluctuations in voltage required to maintain constant current are so great and frequent as to require pro-

Figure 6. Elevation of a typical multiunit ignitron substation



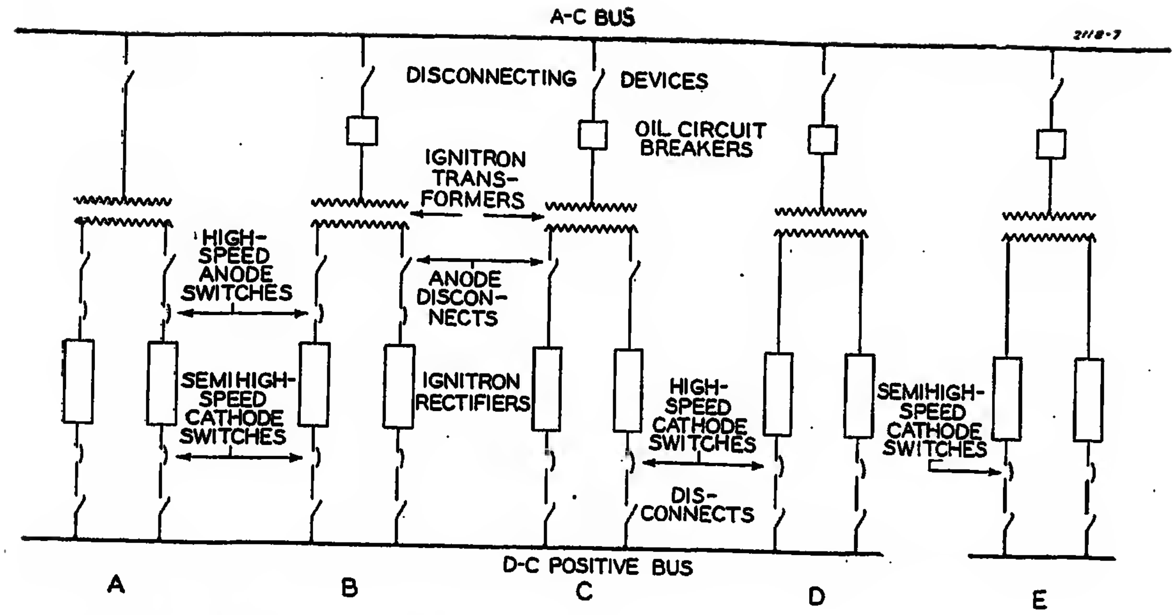


Figure 7. Schematic diagrams showing various arrangements of rectifier switching

hibitive frequency of tap changing or large phase-control angles. In these processes attempts to maintain constant current have been abandoned.

At some locations the demand clause in power contracts is such that high power rates must be paid over a year, because of a short-time swing over the demand ceiling. For processes where load conditions fluctuate rapidly and over considerable range, autotransformers with tap changer under load equipment can be used to secure constant kilowatt input to the cells. This will insure maximum production at the normal power rate, or at minimum power cost. Where more than one station is supplied from the same source, the averaging effect of the several stations proves most advantageous in reducing the number of tap changes required.

Regulation for either constant direct current or for constant kilowatt input can be made full automatic.

Figure 8 shows an autotransformer connected to the rectifier a-c bus, the voltage of which can be varied according to the electrolytic process requirements.

Since the loads on the large station busses constitute practically a short circuit for a single rectifier unit, it is not possible to place units on the bus individually at full voltage following a station outage. Where the power-supply system is large with respect to a single station, it has been general practice to connect all units to the power supply and the a-c bus without excitation, and then to close the excitation contactors to all units simultaneously with a master control switch. Where the supply system is not adequate for this procedure, station phase control of voltage is used. In this method of starting a station following an outage, all units are connected to the bus, either simultaneously as above or individually, but with phase-delay angles set uniformly to limit the station current to a value satisfactory to the supply system or to the rectifier unit, depending on the procedure. The phase-control angles are then advanced uniformly on all rectifier units to increase load to normal at a rate satisfactory to the supply system.

Telephone Interference

A rectifier of any type creates harmonics which are present in the a-c and d-c systems to which it is connected. Harmonics may be induced in telephone lines, which are adjacent to the power systems, under certain conditions of exposure. The telephone-interference problem becomes of increasing importance when the rectifier load is a large percentage of the system load in the exposure areas.

For electrolytic plants, the d-c load is concentrated, and exposures between the d-c circuits and telephone lines are easily controlled. When the a-c power is transmitted a considerable distance, or is supplied from a power network system, exposures are probable, and the telephone interference problem must be considered.

The number of phases at which any rectifier unit can operate cannot be greater than the number of anodes of the unit. Small units having only six anodes are therefore limited to six-phase operation, which operation is used as a base for rectifier harmonic consideration. Since the power involved in a six-anode unit is usually small, the influence on exposed telephone lines is usually too small to be important. As the number of phases in multiples of six are increased, some of the base harmonics of six-phase operation are cancelled, the cancelling increasing as the number of phases is increased. Operation of rectifier units in the higher multiphase relationships, therefore, decreases the telephone-interference problem.

A single rectifier unit of 12 anodes can be supplied from a transformer which is wound to give 12-phase operation. It is not economical to build a transformer for a higher number of phases in a single unit. For those installations which have a large number of rectifier units, multiphase operation can best be secured by operating the units out of phase with respect to each other, and in symmetrical relationship.

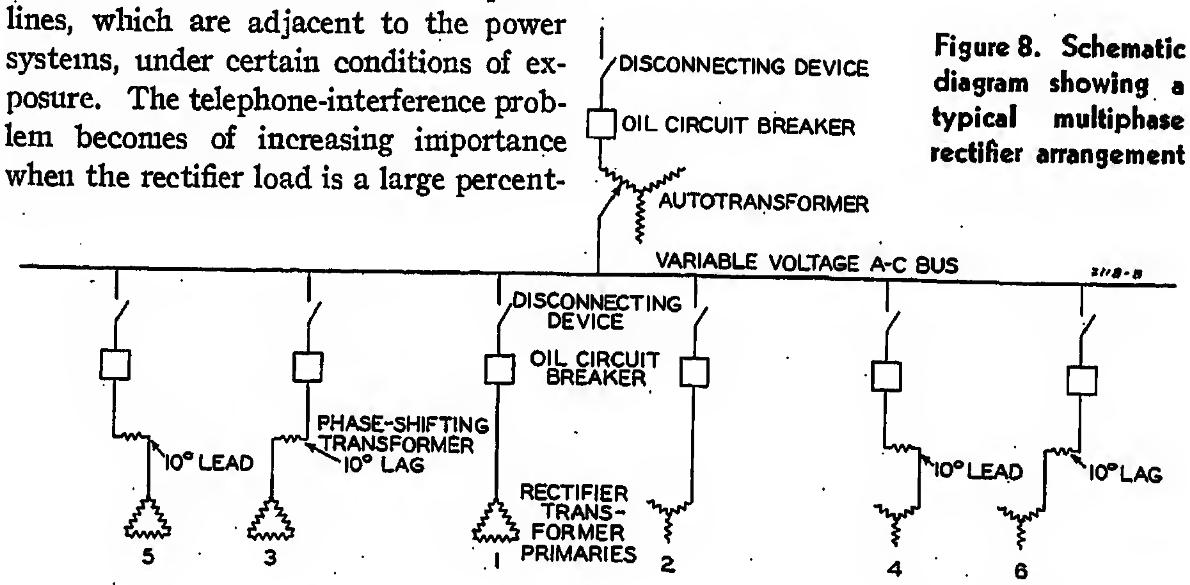

Figure 8. Schematic diagram showing a typical multiphase rectifier arrangement

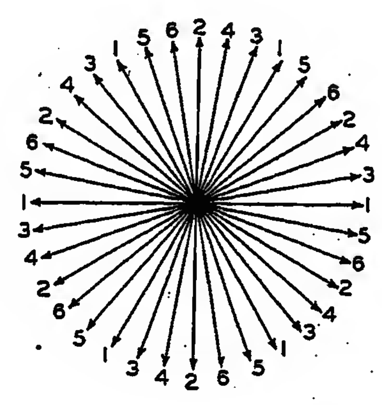

The combination of two six-phase rectifier units having a delta and a star-connected transformer primary respectively will result in over-all 12-phase operation, since the delta and star are inherently 30 degrees out of phase. The supply voltage to a transformer can be shifted any number of degrees desired by the use of a phase-shifting transformer.[4–6] A combination of delta and star-connected transformers together with phase-shifting transformers can be used to effect any degree of multiphase relationship, the only limit being the number of rectifier units available. For phase arrangements greater than 12, the usual inductances in the circuits are sufficient to provide interphase action.

Table I

Number of Units in Substation	Anodes Per Unit	Base Unit Phases	Maximum Over-All Phase Operation Per Station
1	6	6	6
1	12 or 24	12	12
1	18	6	6
2	6 or 12 or 24	6	12
2	18	6	12
2	12 or 24	12	24
3	6 or 12 or 24	6	18
3	12 or 24	12	36
4	12 or 24	6	24
4	12 or 24	12	48
5	12 or 24	6	30
5	12 or 24	12	60
6	12 or 24	6	36
7	12 or 24	6	42
8	12 or 24	6	48

Figure 8 shows the circuits to the primaries of six rectifier units to secure 36-phase over-all plant operation.

To secure maximum benefit from multiphase operation, the units should be of equal rating, and their loads should be balanced. The impedance of the phase-shifting transformer will result in some unbalance in load between duplicate phase-shifted and unshifted rectifier units, unless some compensation is used. Compensating reactors can be connected in the circuits of the unshifted units, or transformer action can be built into the phase-shifting transformer which will compensate for its voltage drop at any given load.

The benefits secured from multiphase operation are not in direct proportion to the increase in the number of phases. The proportionate benefit from each succeeding increase in number of phases drops off sharply beyond 30- to 36-phase operation. Experience to date has demonstrated that 36-phase operation gives satisfactory operation from the telephone interference standpoint in most cases.

Recently the rectifier load on some power systems has become quite large and concentrated. Spot loading of three or more 36-phase operating groups may be encountered. For these special cases the sheer magnitude of the higher harmonies may be sufficient to warrant an increase in multiphase operation. Also a resonant condition for one or more of the higher harmonics may exist. For these installations operation at 72 or 108 phases may be of advantage.

If one rectifier unit, in a multiphase set-up, is taken out of service, an unsymmetrical phase relationship will result. Under this condition, a 36-phase arrangement gives just as good results as any higher-numbered phase arrangement. Operation with one unit out of service gives reasonably satisfactory results.

By the use of base units connected 6 or 12 phase, as required, and by phase shifting of associated units, the combinations shown in Table I can be secured.

Low-, Medium-, and High-Pressure Gas-Filled Cable

G. B. SHANKLIN
MEMBER AIEE

Synopsis: After preliminary development work systematic laboratory tests, closely simulating service conditions, were started in 1934 leading towards final development and improvement of gas-filled cable. The first full-size field installation of gas-filled cable was placed in service in 1938. The results of this work up to that time were summarized in an AIEE paper presented at the winter convention, January 1939. The present paper will deal with progress made since then, covering the whole range of voltage ratings from 10 kv to 138 kv, divided as follows: low-pressure gas-filled cable systems 10 kv to 40 kv, operating at gas pressures from 10 to 15 pounds per square inch; medium-pressure systems 40 kv to 69 kv, operating at gas pressures from 24 to 40 pounds per square inch; high-pressure systems 69 kv to 138 kv, operating at gas pressures from 150 to 200 pounds per square inch.

AFTER preliminary development work on gas-filled cable a systematic series of long-time load-cycle endurance tests closely simulating service conditions were started in our laboratories the early part of 1934, and this work is still being continued. These laboratory studies have proved a most useful guide in perfecting gas-filled cable design. They have allowed the best selection of materials and the most effective methods of construction and treatment in the factory.

The first full-sized field installation of gas-filled cable was placed in service during the summer of 1938, and since then quite a number of 15-kv and 27-kv installations have been added. Our first and only published report on gas-filled cable was in the form of an AIEE paper presented at the winter convention, January 1939.[1] It seems an appropriate time to summarize advancements made since then and co-ordinate with field experience.

Gas-filled cable has, we believe, technical merit and advantages that more than warrant its full development. It is simple, economical and of small size. Pressure control means uniform control of both insulation and sheath behavior with a lesser chance of trouble with either. The self-supervising feature is also important in view of the fact that most cable troubles come from sheath defects or damage. Finally, compound migration troubles are eliminated and there is no concern about the contour of the cable run within tensile strength limits of the cable itself. Three-conductor, 27-kv low-pressure cable has been in operation for several years past in vertical tunnel shafts from 200 to 250 feet in depth without trouble of any kind, nor has bleeding of compound from the insulation been any more than experienced in ordinary runs.

Three-Conductor Cable

The theory, characteristics, and design of gas-filled cable were dealt with in some detail in the previous paper and will not be repeated here. Briefly, this cable is similar in materials and construction to ordinary solid-type paper-insulated cable, with the exception that longitudinal gas feed channels are provided for uniform gas-pressure maintenance and control.

For low- and medium-pressure use at voltages up to 69 kv the three-conductor shielded type represents the most practical and economical form, since the gas feed channels can be conveniently located in the three triangular filler spaces that are otherwise merely waste space. Figure 1 gives a good idea of the cross-sectional construction. Two of these gas channels are of open steel spiral construction, giving free access to the insulated and shielded conductors. The third is a solid-wall metal tube filled with dry nitrogen gas and sealed off at each end before treatment of the cable length. The function of this tube after installation will be described later. Vacuum drying and impregnation treatment in a large tank before leading is exactly like that for solid-type cable. After impregnation and while still hot, the compound is drained from the tank, being displaced by dry nitrogen gas. The reel of cable is left in the heated tank until all surplus compound drains off, and only that compound held by capillary attraction in the dense cross section remains. The channels and outer surfaces present a clean appearance, but it is surprising how much of the heavy compound is held in the cable cross section by capillary balance, the finished cable being almost as well filled as a solid-type cable.

The treated reel length is then removed to a nitrogen-filled chamber directly behind the lead press, and the lead sheath is applied under a flow of nitrogen. After end sealing the gas pressure is raised to approximately ten pounds per square inch and the cable length is maintained at this pressure until ready for splicing in the field. Before the shipping reels leave the factory, the whole cable cross section is saturated with nitrogen to the same pressure as that in the gas feed channels. This assists greatly in maintaining uniform cross-sectional pressure in service.

Joints

Figure 2 shows a typical three-conductor joint. With exception of the tube insert connections and the fact that the lead casing is filled with nitrogen gas instead of compound, the joint is the same in construction and size as an ordinary solid-type cable joint, the same method of con-

Cut-away view showing details of construction

Paper 42-102, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 2, 1942; made available for printing April 27, 1942.

G. B. SHANKLIN is engineer of the cable division, central station department, General Electric Company, Schenectady, N. Y.

A number of engineers associated with the author have contributed to this work. The author wishes especially to acknowledge the help of J. A. Scott and J. B. Felter who carried out the laboratory tests, and of W. C. Hayman, V. A. Sheals, L. Wetherill, L. L. Phillips, L. Zickrick, F. H. Buller, and A. R. Lee.

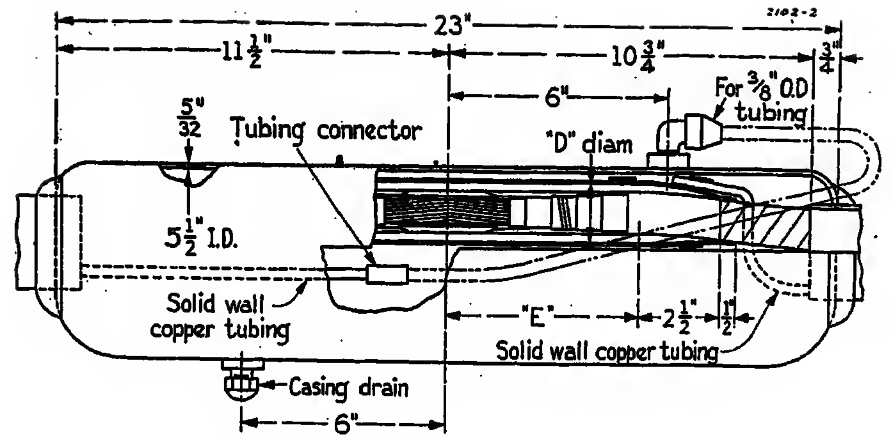

Figure 2. Normal joint

For 27-kv three-conductor gas-filled cable

necting, stepping, reinforcement taping, and shielding being followed. In preparation for splicing, the cable pressure is lowered to about two pounds, the ends are cut, conductors are spread, and temporary sponge rubber seals are applied in the crotch to prevent appreciable loss of gas during the remaining operations. The total time is the same as that required for constructing a corresponding solid-type joint, because of the fact that the time required for the special operations is compensated for by the absence of compound filling operations.

Pressure Control

The primary function of the solid-wall metal-tube insert in the cable is to furnish a by-pass path for gas flow at low points or dips in the cable run, where slugs or surplus compound might gradually form in the open channel spaces during initial periods of heavy load, or during hot summer weather. The method of interconnecting the tube ends and the joint casing, as shown in Figure 2, traps any compound that might enter the casing and assures a free gas path and uniform pressure control over the entire length of the cable line. The lead sleeve casing in Figure 2 is shown eccentric, the bottom part acting as a sump for collection of surplus compound. It has since been found that an ordinary concentric casing gives sufficient capacity for this purpose.

Field tests have shown that, with the help of this tube insert, pressure can be controlled at one terminal end only of lines up to about ten miles in length. A pressure relay at this one location will give an indication of gas leakage at any point in the line, and when loss of pressure occurs, additional gas can be injected from an emergency storage cylinder until the leak can be located and repaired. Where feasible, pressure control and relaying at both ends of long lines is desirable but not necessary.

The first installations of gas-filled cable, as described in the previous paper did not have the metal-tube insert. They are operating successfully, and there has not been any special trouble in maintaining and controlling pressure. It is necessary, however, or at least advisable, to "blow out" the cable line periodically with nitrogen gas and make sure the channels are sufficiently clear of compound to transmit gas pressure. The metal-tube by-pass insert has completely eliminated this need, and there is no question but that it simplifies and facilitates operation of three-conductor gas-filled cable.

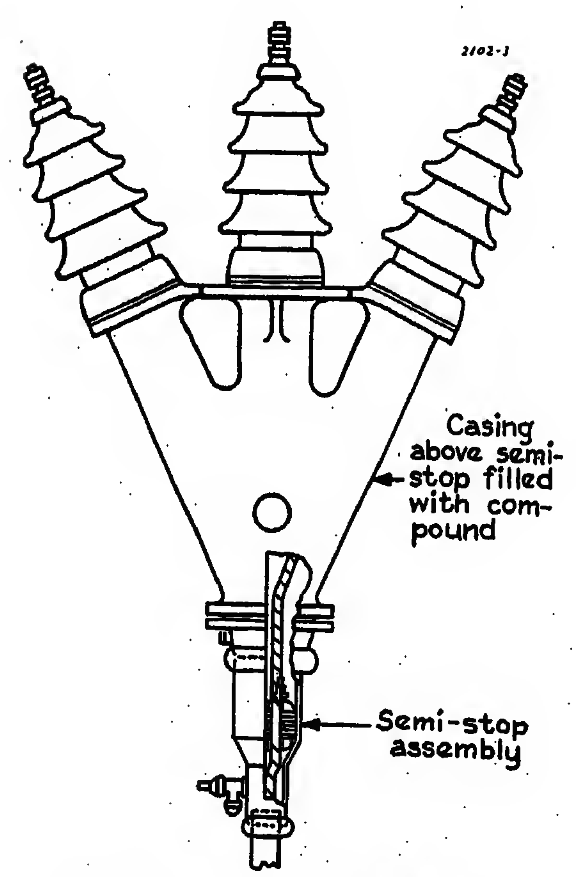

Figure 3. Compound-filled terminal

For 34.5-kv three-conductor gas-filled cable

Terminals

A typical soft compound-filled, three-conductor terminal for gas-filled cable is shown in Figure 3. The only departure from terminals used with solid-type cable is the semistop gasket assembly in the base to prevent the soft compound from draining into the cable channels. A simpler all-gas-filled terminal without the semistop has been developed for use at 15 kv and is also being made available for higher voltages. Both kinds of terminals are also designed as single-conductor and spreader three-conductor types. The only difference between terminals for low-pressure cable (10 to 15 pounds per square inch) and medium-pressure cable (25 to 40 pounds) is that heavier porcelains are required to withstand the higher gas pressure.

Single-Conductor Cable

The gas feed channel for single-conductor cable is in the form of an annular space directly under the lead sheath as shown in Figure 4. Copper tape with stamped button spacers centers the insulated shielded conductor and gives support to the lead sheath. In comparison, the single-conductor cable is less economical than the three-conductor type, because of the increased over-all diameter and cost this channel construction represents. In the three-conductor cable decreased insulation thickness and smaller diameter compensate for the extra gas operations in the factory and field, and the costs of low-pressure gas-filled cable and of solid types are practically the same. Single-conductor gas-filled cable, however, is of higher cost than equivalent solid type, because of the channel requirements mentioned.

This handicap is not very serious and in large sizes the low-pressure single-conductor type has found a useful place as primary station tie cable where numerous vertical runs are encountered. Absence of compound migration troubles and the self-supervision obtained from gas pressure control justify the extra cost. Another promising field for single-conductor gas-filled cable is for power transmission at 46 kv and above, when the load per circuit is too large or the ducts too small for three-conductor cable. In this voltage range medium-gas-pressure operation is more economical than low

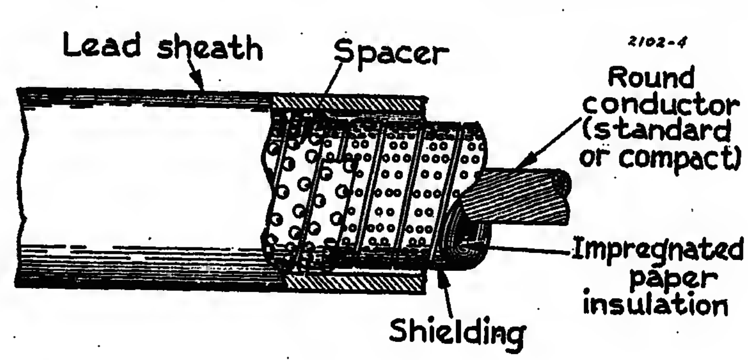

Figure 4. Single-conductor gas-filled cable

Cut-away view showing details of construction

pressure, as will be discussed later, and the further reduction in insulation thickness gained thereby offsets the added cost of the gas channel construction.

The solid-wall tube insert for by-passing compound slugs, such as used in three-conductor cable, is not well adapted to single-conductor construction. This is largely overcome by paralleling the gas connections at each manhole of the three cables making up one circuit, assuring three separate paths for gas flow. The possibility of slug formation in all three cables at one time, in one location, and of sufficient number to materially interfere with pressure control, is remote.

Ionization as a Function of Gas Pressure

A fundamental and important characteristic of gas-filled cable is clearly brought out by a study of Figure 5, which shows ionization starting voltage as a function of gas pressure. A similar curve was given in the previous paper. At that time we had only limited test data above 15-pound pressure and little operating experience to confirm test results. Additional data obtained since allow a more accurate construction of this curve. It closely simulates operating conditions, in that it shows ionization voltage after capillary balance has been reached from load-cycle bleeding of compound, but before appreciable wax formation from test overvoltage has started.

The earlier paper described the self-extinguishing and self-healing properties of wax formation in voids of gas-filled cable. Further work has fully confirmed this important characteristic. It offers an additional factor of safety at those locations along a cable line where ionization might get started. Expressed in another way, gas pressure and ionization control automatically eliminate weak spots and result in more uniformity along the cable length. This in turn allows working voltage stress to more safely approach the critical voltage stress at which cumulative ionization deterioration occurs.

The whole question is whether the measured ionization starting voltage curve in Figure 5 represents this critical voltage stress or something less. From all of the evidence we have obtained it is the writer's opinion that the curve in Figure 5 is something less than critical stress and is actually a goal representing an upper limit of safe working stress in service to be approached as more experience is gained. There are sound reasons for believing this.

First, it has already been proved by numerous long-time load-cycle tests at pressures up to 30 pounds per square inch that gas-filled cable remains stable at stresses considerably higher than represented by the curve in Figure 5. Instability and ultimate breakdown on these tests occur at stresses from 40 to 70 per cent above the Figure 5 curve.

Admittedly, laboratory tests on relatively short lengths are not conclusive in establishing safe working stresses until confirmed by field experience. We have had confirming field experience of this kind with low-pressure gas-filled cable operating during recent years at an average gas pressure of 12 pounds per square inch and an average voltage stress of 65 volts per mil. Reference to Figure 5 will show that at this pressure ionization starts at 80 volts per mil. Accordingly, operating experience has been at a stress only 15 volts per mil less than this. No service failure has yet occurred in gas-filled cable systems and no signs of ionization have been detected. One length of 27-kv cable was removed for test after one year of service. It was found to be in perfect condition. This experience would indicate that there is a good margin of safety and some latitude for increasing present working voltage stress. It also indicates that uniformity in the field is under the same control as obtained in the laboratory on relatively short test lengths.

Additional proof that the initial ionization versus pressure curve in Figure 5 represents a stable and safe condition is found in the characteristic behavior of all representative lengths on long-time load-cycle tests. Typical test results of this kind are shown in Figures 6 and 7. Figure 6 is a chart of the whole test in terms of power-factor stability. Three load cycles per day from room temperature to 80 degrees centigrade were applied, and the gas pressure was maintained at ten pounds per square inch cold and not more than 14 pounds hot. It will be noted that the test was started at 85 volts per mil, only slightly above the ionization-pressure curve in Figure 5. After stabilization was assured, the voltage was increased, and these steps were repeated until final failure occurred after 16 days at 120 volts per mil.

Figure 7 gives power-factor voltage curves on this length as measured initially and at the end of each voltage step shown in Figure 6. Initial ionization at

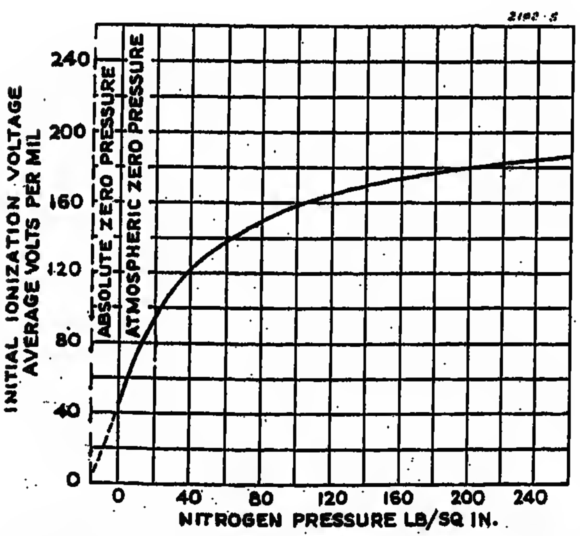

Figure 5. Ionization voltage versus gas pressure

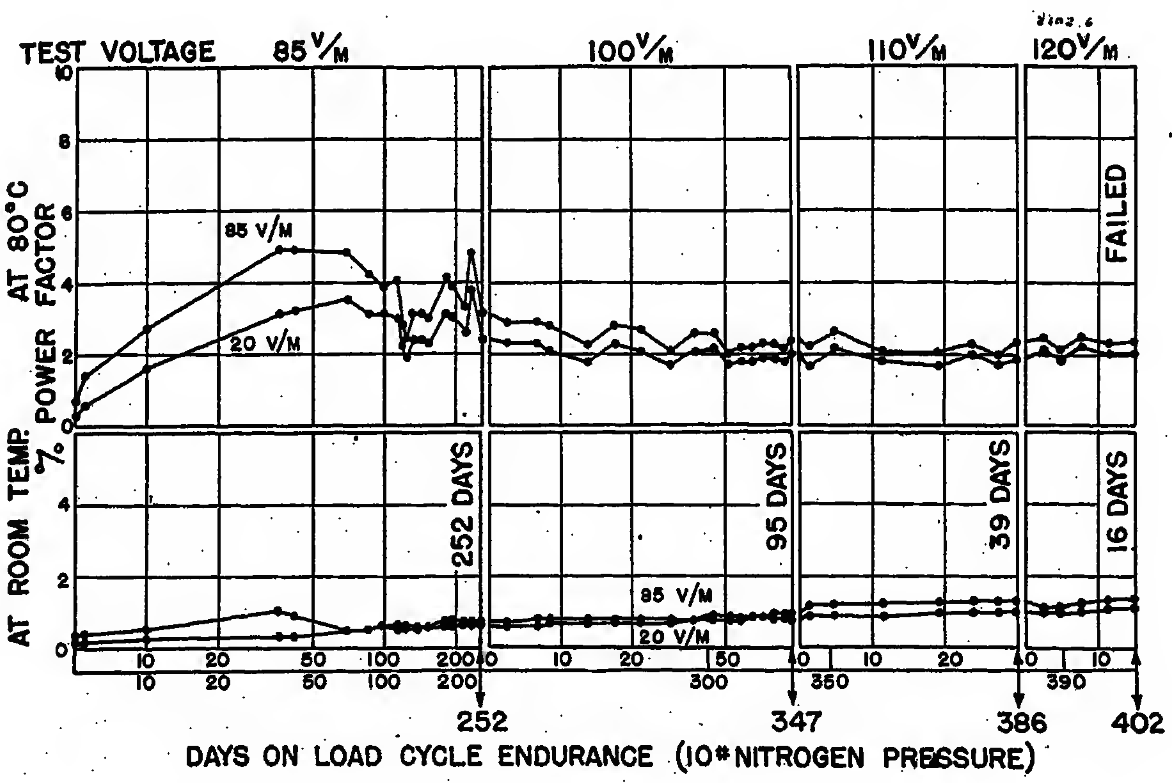
Figure 6. Load-cycle endurance at ten pounds pressure

Three-conductor gas-filled cable of standard construction, with exception that inner 50 per cent of insulation wall consists of three-mil paper tape instead of usual six-mil tape. Total insulation thickness 0.200 inch



are offset by the other savings described. All told, we consider this simplified medium-pressure gas-filled cable system an important technical and economic advancement.

High-Pressure Systems

Full advantage of high-gas-pressure operation can only be realized by drawing the cable into a welded steel pipe line. There have been proposals to use a special double lead sheath construction, reinforced for both radial and longitudinal strains, to operate at gas pressures as high as 200 pounds per square inch. This type of cable could be installed in underground ducts in the usual manner which is an advantage, but there appear to be two serious obstacles.

1. The over-all cost is too high in comparison with other available cable systems, such as oil-filled, medium-pressure gas-filled, and, finally, high-pressure gas-filled drawn into steel pipe.

2. There is serious doubt of the feasibility of safely operating reinforced sheath at such high pressures, because of mechanical strength limitations.

There is no doubt but that the steel pipe construction is the most promising, and further comments will be confined to that type.

When properly designed and installed, the high-pressure gas-filled pipe cable system is technically sound and economically attractive. It has however certain limitations that should be fully understood.

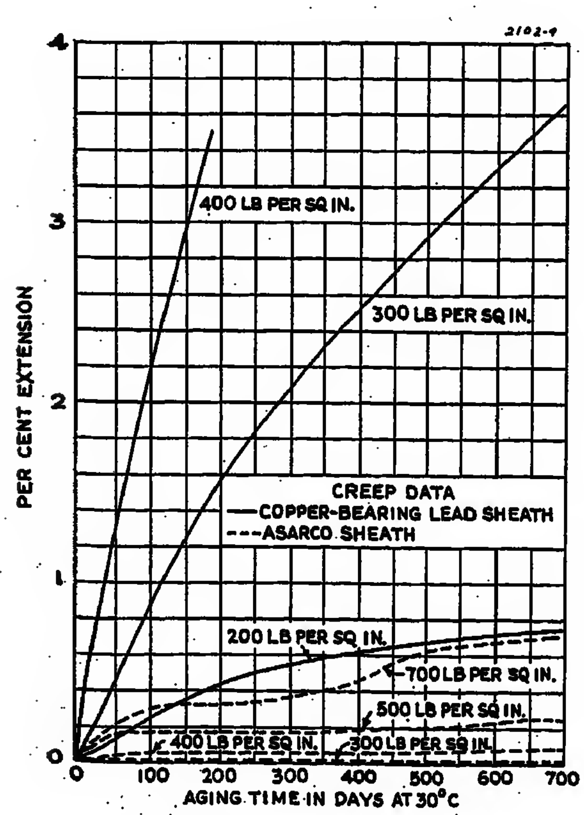


Figure 9. Creep properties of lead sheath

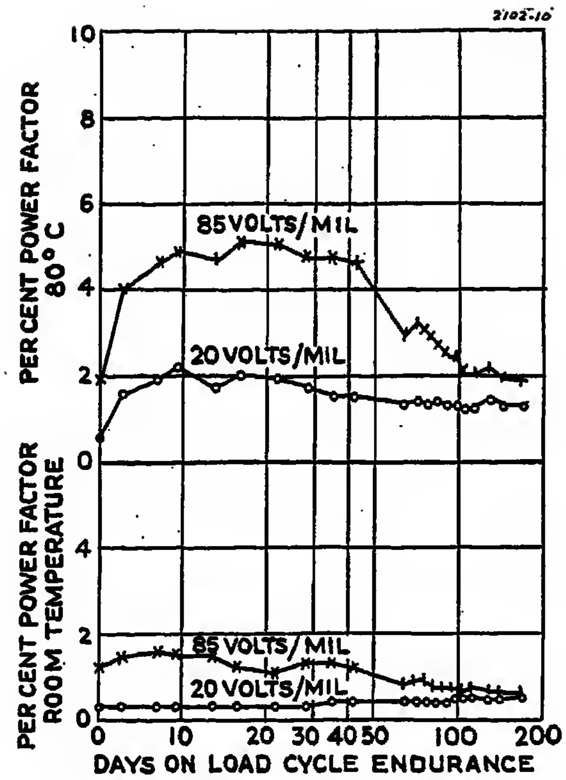

Figure 10. Load-cycle endurance at ten pounds pressure

Standard three-conductor gas-filled cable with aluminum-paper strand shielding similar to cable in Figure 8. No-load nitrogen gas pressure held at ten pounds per square inch (low pressure). Cable still on test at 100 volts per mil

1. It is best adapted to direct burial in open ground, and its use is likely to be limited in this country where most underground systems are in congested areas under paved city streets. The standard duct and manhole construction (and the flexibility it represents) has always proved superior to direct burial under these conditions.

2. Important high-voltage tie-line loads in this country are growing, and the steel pipe cable system is not well adapted to handle extra heavy loads. It is not possible to use one single-conductor cable per pipe, with three pipes spread out to better dissipate copper losses. Instead, it is necessary to draw all three cables into one congested pipe, and the losses to be dissipated are much higher. In this respect pipe cable is no different from other forms of three-conductor cable and has the same well-recognized limitations for economic loading.

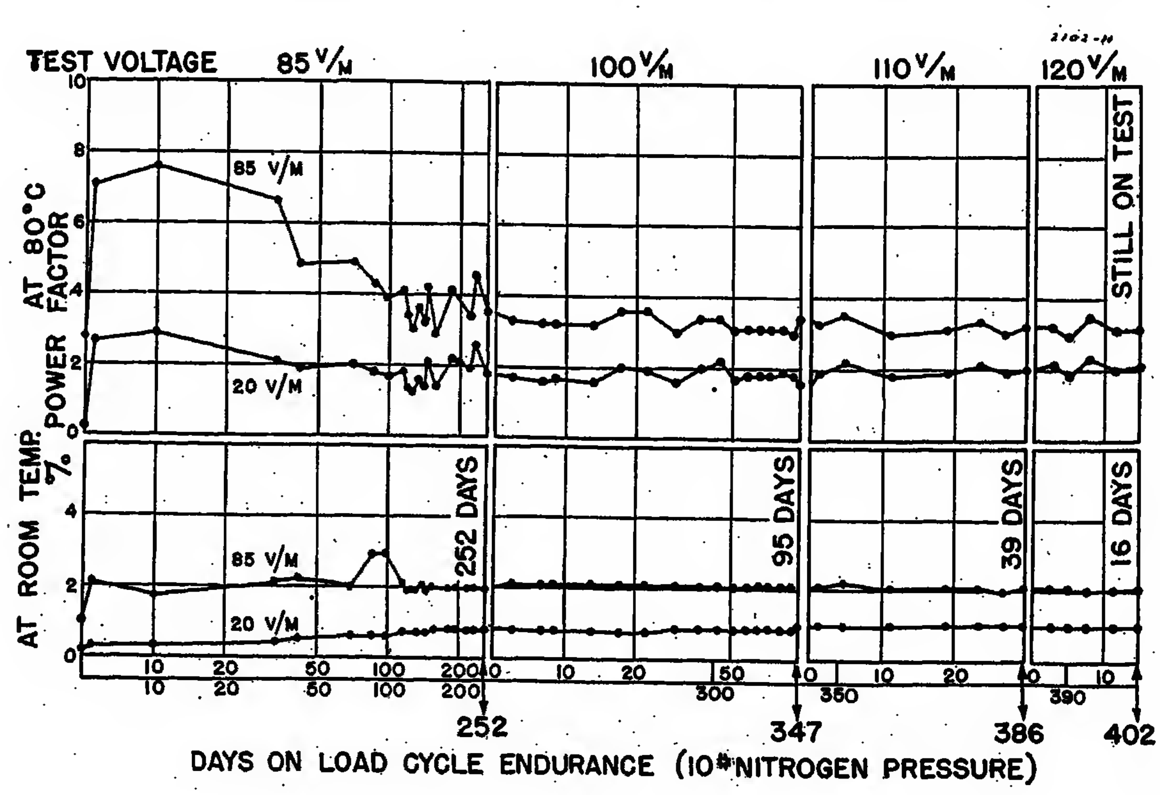
These aspects of the problem are not so important in Europe where the practice of direct burial in open ground is commonly followed, and where load requirements per circuit average considerably less than in this country.

From an insulation standpoint gas-filled pipe cable offers no difficulties. Reference to Figure 5 will show that at 200 pounds pressure initial ionization is at 180 volts per mil. In view of greater self-healing properties from wax formation at high pressures, we could probably operate with safety at an average stress not less than 160 volts per mil. In this respect high-pressure gas-filled cable, like oil-filled cable, has greater 60-cycle strength than can be utilized. Insulation thicknesses for oil-filled cables are based on transient voltage requirements rather than normal 60-cycle rated voltage stress, and the same thing should hold for high-pressure cable. Accordingly, insulation thicknesses for high-pressure gas-filled cables are the same as for oil-filled cable, the rated voltage stress varying from 126.5 volts per mil at 69 kv to 142.5 volts per mil at 138 kv.

Figure 5 shows that this range of voltage stresses is conservative at 200 pounds pressure. In fact, the gas pressure could be reduced to 125 pounds without danger. There is no particular object, however, in not taking advantage of the higher factor of safety offered by the higher pressure, since standard steel pipe will withstand

Figure 11. Load-cycle endurance at ten pounds pressure

Standard three-conductor gas-filled cable exposed to room air for eight hours before applying the lead sheath. Chart shows the effects of oxygen absorption during exposure



200 pounds pressure just about as well as 125 pounds.

Details of pipe construction, welding, covering for corrosion protection, joint sleeves, compressed air test for leakage, and so forth will not be dealt with here, since this practice is well-known and common to all of the various pipe cable systems, of which there is a number of installations in Europe and a few in this country.

Sheaths Intact

After the pipe is laid and ready to receive the gas-filled cable, the remaining operations vary, depending upon whether the sheaths on the three single-conductor cables are left intact or stripped off as the cable lengths are drawn into the pipe. Each of these two methods has advantages and disadvantages that need careful balancing. For loads involving conductor sizes above approximately 750,000 circular mils, short-circuited sheath losses become so great that there is not much choice, economy dictating removal of the sheaths. For lighter loads and smaller conductor sizes there is much to be said in favor of leaving the sheaths intact, but it is difficult to draw an exact dividing line between these two practices without studying each specific case.

With sheaths intact the methods of manufacture, shipment, installation, and splicing are exactly the same as already described for low-pressure systems in ducts, the only difference being that the gas channel between the insulated shielded conductor and the sheath is smaller and simpler than shown in Figure 4, an open spiral wrapping of fibrous tape being substituted for the metal button spacer tape. Each joint is enclosed in a wiped lead sleeve, and since splicing is done under a slow flow of nitrogen gas, the cable insulation is at no time exposed to air or moisture. It is not necessary to remove these impurities from the pipe until the whole line is completed. At that time the pipe can be dried out by short-circuit current in the conductors, or circulation of hot air, or both. Afterwards, the dry air in the pipe is washed out by nitrogen flow assisted, if desired, by drawing a rough vacuum first. These same operations can be done piecemeal on sections of the line as completed if more convenient, and the finished sections maintained at a few pounds nitrogen pressure.

After the whole line is ready, the outlet plugs in all lead joint sleeves are removed, the plugs in the outer steel sleeves replaced, and the gas pressure is brought up to 200 pounds. There is then an interconnection of gas pressure between cable and pipe at every joint sleeve. Equalized pressure throughout removes any question of stress burden on the lead sheaths.

If future repair work, involving replacement of cable lengths, is ever required, these operations are reversed. After lowering the gas pressure, outlet plugs in the lead joint sleeves are replaced, segregating the cable from the pipe. Replacement of cable can then proceed as with low-pressure cable, and at no time is the insulation exposed to moisture and air absorption.

Sheaths Stripped Off

In addition to elimination of sheath losses and reduction in conductor size obtained thereby, stripping of sheaths as the cables are drawn into the pipe has one other advantage. The removed lead can be salvaged. The disadvantages are:

(*a*). An outer tape wrapping and copper armor are necessary for protection during pulling.

(*b*). Extra cost and time for stripping the sheath and protecting cable ends from exposure.

(*c*). Pipe must be dried and filled with nitrogen gas piecemeal before the cable is pulled in, and pulling must be done under a slow flow of nitrogen.

(*d*). Absorption of air and moisture during unavoidable exposure will increase dielectric losses and require a heavier wall of insulation than when sheath is left intact.

(*e*). Future repair work without undue exposure of insulation is more difficult and complicated.

Comparative over-all installed costs and service records will be required before the relative merits of these two high-pressure gas-filled cable systems can be finally decided in those cases where sheath losses are not a dominating factor.

Summary of Recent Test Results

Space will not allow a detailed presentation of all the test data obtained on gas-filled cable since the last published report. We have carried out comparative test studies of the best available impregnating compounds, particularly as a function of viscosity, the effects of paper thickness, strand shielding, exposure to air, further tests on the effects of gas pressure, and some impulse tests. Conclusions drawn from these tests will be summarized, and pertinent results relating to these conclusions given.

Thickness of Paper Tape

The load-cycle test in Figure 6 represents a test length of cable with the inner half of the insulation composed of three-mil paper tape instead of the usual six-mil tape. In all other respects this length was of standard construction. Theoretically, thinner tape means smaller butt space voids and higher ionization voltage. Actually, Figure 7 shows that ionization voltage was no higher than usually obtained with standard six-mil tape. Standard cable retains stability up to 100 volts per mil on load-cycle test at ten pounds pressure and ultimately fails at 110 to 120 volts per mil. The thin paper length in Figure 6 lasted little if any longer, failing in 16 days at 120 volts per mil. In view of the fact that thin tape is more expensive and difficult to apply, tends to wrinkle more, and will not withstand cable bending as well, it is doubtful that there is any benefit that overbalances these disadvantages.

Strand Shielding

It has already been explained that the test length represented in Figure 8 had strand shielding, and the test results did

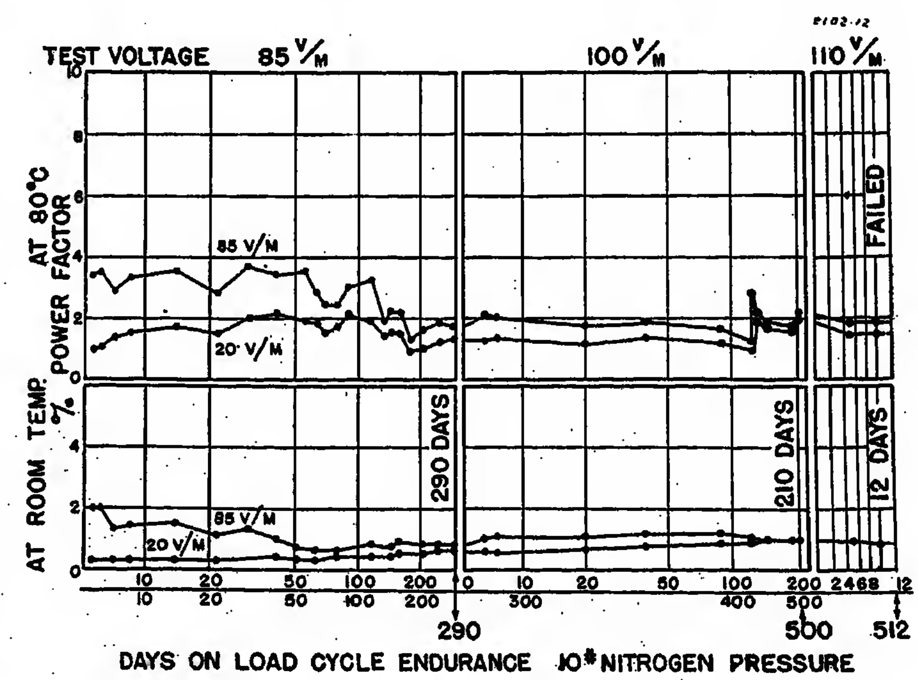


Figure 12. Load-cycle endurance at ten pounds pressure

Three-conductor gas-filled cable of standard construction, with exception that viscosity of impregnating compound was increased to 350 Saybolt at 100 degrees centigrade by addition of 1.5 per cent soluble synthetic compound

not appear to show any particular improvement in ionization characteristics over equivalent cable without strand shielding. This is confirmed by load-cycle tests on an additional strand-shielded length as given in Figure 10. Ionization starting voltage is no different, and it required about the same length of time (75 days) to stabilize at 85 volts per mil as experienced with standard lengths without strand shielding. The length in Figure 10 is still on test at increased voltage stress. Possibly ultimate results will show some benefit from strand shielding, but we haven't found it yet. The explanation seems to be that ionization and wax formation occur more or less uniformly in butt spaces throughout the insulation thickness and do not concentrate at the conductor surface alone.

Exposure to Air

To study the effects of casual exposure to air, as may happen in jointing operations or through some accidental exposure, a standard test length was exposed to room air for eight hours after removal from the treating tank and before the lead sheath was applied. The results of load-cycle testing are given in Figure 11. It will be noticed that oxidation action from the absorbed air increased dielectric power factor at both room temperature and 80 degrees centigrade, the latter increasing to about double that met with in standard cable. It will also be noticed that in spite of this the cable had good endurance and was removed from test after 16 days at 120 volts per mil without failure. The conclusion can be drawn that, within accumulative heating limits, oxygen absorption does not affect voltage endurance but does appreciably increase dielectric loss and should be avoided for this reason. This is particularly true of medium- and high-pressure systems operating at the higher voltage ratings, where liberties with impurities and dielectric loss cannot be taken without serious risk.

Effects of Compound Viscosity

The series of tests we have carried on over a period of years on gas-filled cable indicate rather definitely that there is such a thing as optimum viscosity of impregnating compound and that this is in the order of 100 Saybolt at 100 degrees centigrade, representing the standard all-mineral compound used for some time past. We invariably obtain better results with this compound than with either thinner or heavier impregnants, apparently for reasons explained in the previous paper.

Check tests, that will not be given, again show that thin oil, such as used in oil-filled cable and having a viscosity of 37 Saybolt at 100 degrees centigrade, drains too freely from the insulation and results in poor ionization and endurance characteristics. This is not surprising and would be expected from theoretical considerations. The surprising thing is that various high-viscosity compounds give from fair to very poor results, but even the best shows no advantage over the standard compound.

We have tried about all of the recognized available types of high-viscosity compounds, including rosin mixtures, soluble synthetic mixtures, and hydrogenated oil, with viscosities from 200 to more than 1,000 Saybolt at 100 degrees centigrade. All of these, with one exception, gave poor and unstable results that are hardly worth showing. The best consisted of standard compound mixed with 1.5 per cent soluble synthetic to give a viscosity of 350 Saybolt at 100 degrees centigrade. An incomplete test on a length impregnated with this compound and designated as test length 8, was reported in the previous paper. The complete test is charted in Figure 12. The results obtained from both an ionization and voltage-endurance standpoint were about an average of those obtained with standard cable.

Since extra high-viscosity compound means longer periods of impregnation treatment and drainage, and more difficulty in clearing out gas feed channels, we have, as yet, found no advantage that would justify its use. A study is also being made of preimpregnated tape and, so far, no advantages have been found that would justify its complications and greater cost. Further and more complete tests may modify this belief.

Impulse Tests

After 21 days of vertical drainage with 75-degree-centigrade load-cycles five lengths of single-conductor, 1,000,000-circular-mils gas-filled cable, without strand shielding and having 0.203-inch insulation, were subjected to standard impulse breakdown at a gas pressure of ten pounds per square inch. An average breakdown of 367 kv was obtained with a deviation of 35 kv, or 9.6 per cent. This corresponds to an average stress of 1,800 volts per mil, compared with an average of 1,680 volts per mil obtained on 33 lengths of ordinary solid and oil-filled cable. On the basis of maximum stresses, which some prefer, the gas-filled cable gives 2,130 volts per mil, and the solid and oil-filled, 2,260 volts per mil. For all practical purposes it can be said that the results on all three types are closely the same. It is reasonable to assume that the same thing would hold for medium- and high-pressure gas-filled cable, since the insulation thickness is not under compression and does not vary with pressure.

Improvements in Preventive-Coil Control for A-C Locomotives With Particular Reference to Resistor Transition

P. H. HATCH
MEMBER AIEE

H. S. OGDEN
MEMBER AIEE

SINCE the original development of the a-c locomotive there have been many attempts to improve the locomotive control over that provided on early designs.

Control problems have come under three general classifications, namely:

1. Voltage control for the acceleration of the locomotive.

2. Functional control for adjusting various fields of the series traction motor for best commutating characteristics.

3. Protective relays for protection of locomotive and traction motor circuits from grounds and faults of various kinds and for protection of the traction motor from overspeeding.[1,3]

This article will deal only with the first of these problems, namely, those incident to the voltage control as it relates to accelerating a locomotive, with particular reference to a new development in the art. The new development is the resistor transition scheme for switching preventive coils from one pair of transformer taps to the next. A résumé of service experience with a locomotive so equipped is also included.

While the search for a better method of acceleration has proceeded, there have been no revolutionary improvements made, and progress has been essentially a refinement in design.

Early locomotives made use of a switching reactor, or preventive coil, in tapping from one set of transformer taps to the next, and the scheme which developed the most favor soon grew to what was termed as the three-preventive-coil notching scheme. In this scheme two small preventive coils feed a large preventive coil which in turn feeds the traction motor circuits through its mid-tap. The two small preventive coils are connected to two sets of bus bars, which are connected by tap switches to the main transformer taps in the correct order. Each tap switch carries one quarter of the load current in the normal design where all preventive coils have their mid-tap equidistant from the two end terminals. The three-preventive-coil scheme of control has persisted and is now the scheme most generally used on a-c locomotives in the United States.

During recent years several voltage-control schemes of a somewhat different nature have been devised and in some instances have been tried out in service both in this country and abroad, but by and large the schemes have met with indifferent success. Schemes tried in this country include one that has used a relatively large buck-boost transformer, the primary of which is controlled by means of light-current relatively high-voltage switches. When the large buck-boost transformer has been notched up to its maximum voltage, balanced voltage conditions are obtained. This condition is retained through suitable transfer switches while the buck-boost transformer is reconnected to repeat its operation from higher main taps on the main transformer. Also there have been tried variations of European schemes, utilizing a motor-driven switching device which shifts taps under zero voltage conditions obtained by mechanical interlocking with arcing switches designed to handle the arcing duty.

Since the year 1937 improvements in the basic type of voltage control have been evolved which have consisted essentially of improvements in the contactors themselves, in the interlocks which are used to insure against faulty closure of switches, and further in an arrangement of auxiliary relays known as "sequence or interlocking" relays which, while having increased the number of operating coils in the system, have materially decreased the number of contacts in the control circuits and have given an overall improvement in reliability and a decrease in maintenance.[3]

One of the chief sources of trouble that arises with notching schemes using individual contactors is the failure of one of the individual contactors to open its circuit when it is called upon to do so. This may arise from purely mechanical reasons such as sticking of the operating rod or some of the mechanical portions of the contactor, or from electrical reasons, such as those which cause the tips of the contactor to weld together. Because of the relatively large number of tapping contactors used upon a modern locomotive (24 in the case of the latest New Haven and Pennsylvania Railroad locomotives), the number of interlocks required for complete protection against contactor closure when a given contactor has stuck closed for some reason was prohibitive. For this reason previous to 1937 it was considered sufficient to interlock positively against direct short circuits upon a given preventive-coil bus, and no attempt was made to prevent possibilities of overvoltage being applied to a preventive coil.

The development of the "sequence relay" made interlocking possible which would prevent the closure of any switch that might set up undesirable conditions after another had stuck closed.

To protect against an unbalanced preventive coil, caused by failure of a switch to close in sequence, differentially connected current transformers supplying a thermal-element preventive-coil relay are provided. The relay characteristics are so proportioned that on normal switching operations, in which one tap switch is opened before the next is closed, when the preventive coil is left connected with but one leg for a few cycles, the relay will not trip. Should a tap switch remain open, the heater element will cause the relay to trip after a definite time, opening the control circuits to all the tap switches. Such thermal relay connections also provide protection against internal failures of the small preventive coils, as such faults give rise to current in the same direction as exciting currents and thus are effective in tripping the thermal element.

Operating experience prior to 1937 developed the weakness of utilizing the three possible unbalanced preventive-coil combinations as the first three starting notches for a locomotive. Locomotives so connected gave rise to an abnormal number of preventive-coil failures directly traceable to operation on one of the unbalanced notches while starting heavy trains at difficult locations. Modern practice therefore prescribes the use of balanced connections for the coils for all notches—except possibly the first—

Paper 42-126, recommended by the AIEE committee on land transportation for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted April 27, 1942; made available for printing May 19, 1942.

P. H. Hatch is assistant mechanical engineer with the New York, New Haven, and Hartford Railroad Company, New Haven, Conn. H. S. Ogden is in the transportation control engineering department of General Electric Company, Erie, Pa.

where currents are low, and there is no occasion for extended operation.

The aforementioned improvements, however, do not progress greatly toward the solution of one of the first criticisms of the a-c locomotive, namely, the sag in tractive effort that occurs between notches. During the transfer from one notch to the next it is necessary that one end of a preventive coil be open-circuited completely before closing it in on the next higher voltage. During this time the total load current for the particular preventive coil is carried through one half of its winding. This winding offers a considerable impedance to the load current because of the unbalanced ampere turns in the coil. The impedance drop under these conditions becomes the impedance that will be supported by the iron plus the series-air-core impedance of the turns in the coil itself. As used here, "series-air-core impedance" refers to the reactance of the coil, assuming no iron is present, as the ampere turns available are many times in excess of those required to saturate the iron.

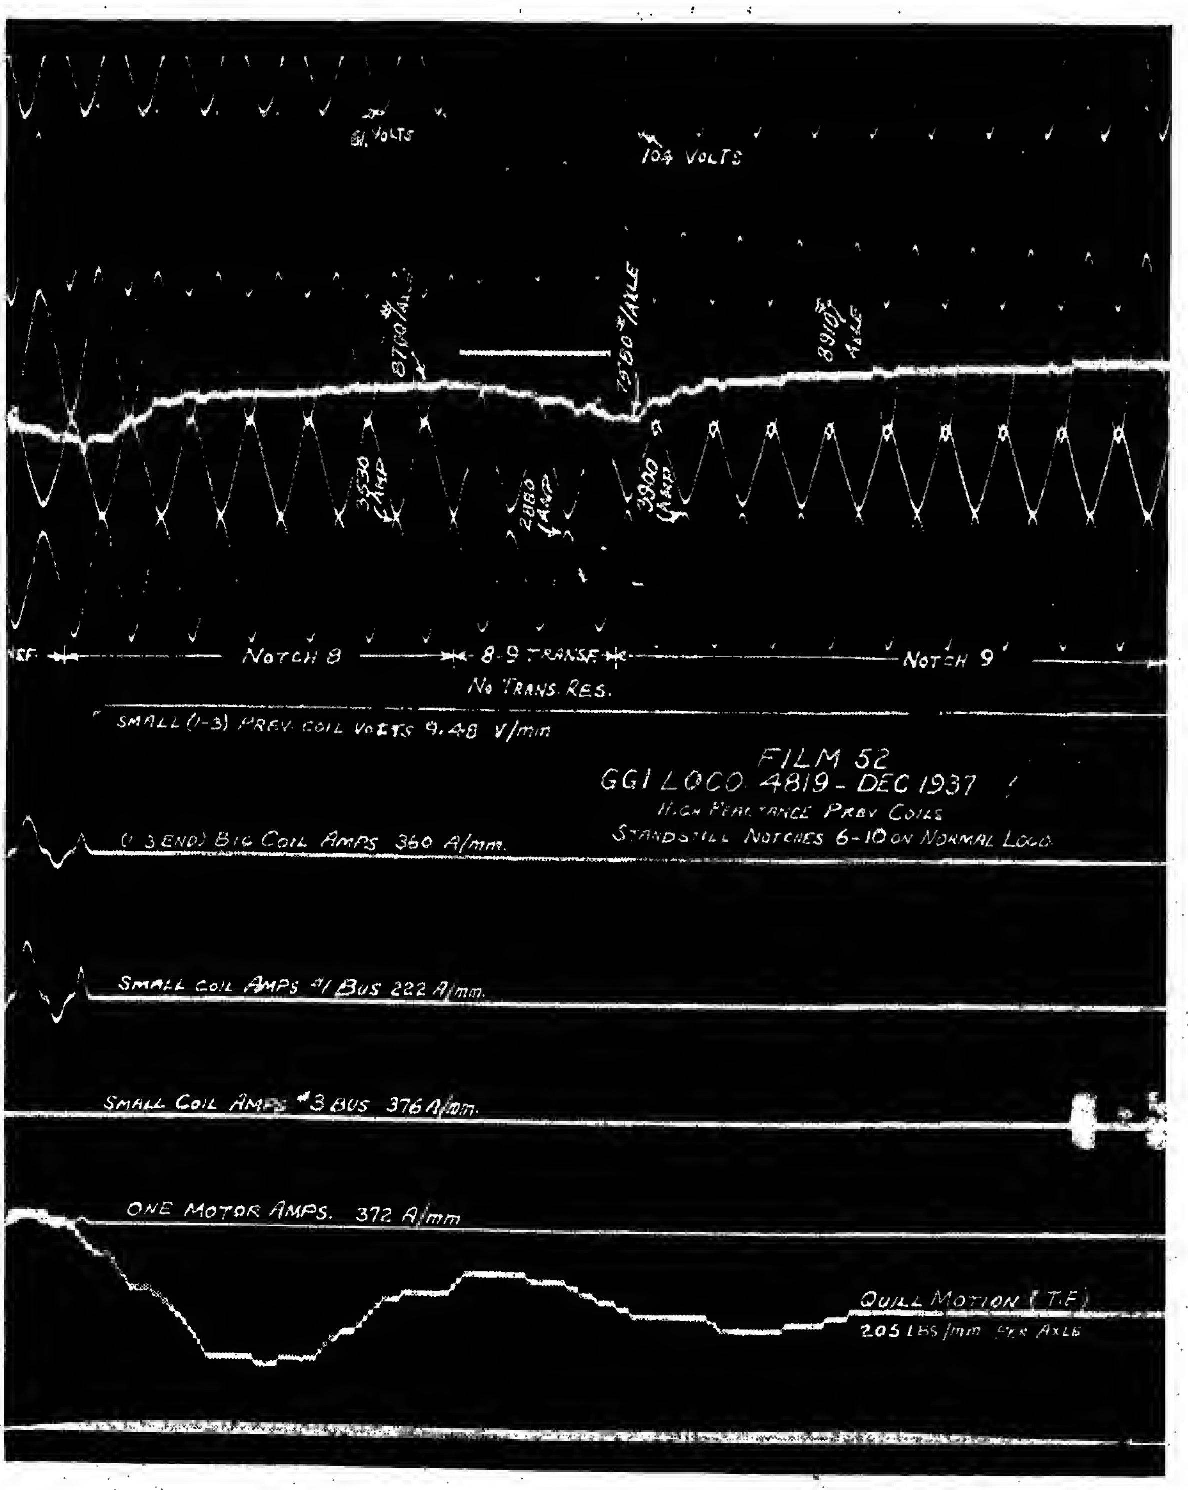

Figure 1. Film 52—transition between notches 8 and 9 without transition resistor

The insertion of the high impedance of one half of a preventive coil in the circuit causes a very marked decrease in the voltage left to be applied to the traction motors, with the result that there is a considerable falling off of traction motor current, and thus a sag occurs in the motor tractive effort. Under severe conditions of starting and running when operating at tractive efforts very close to the slipping point of the wheels, such a reaction during the notching is very undesirable. Most of the control schemes tried out or proposed have had as one of their main objectives the smoothing out of the notching characteristics between notches. Some of the schemes have been more or less successful in this, but for the most part they have introduced other undesirable features.

Another characteristic inherent in the three-preventive-coil scheme is the presence of the extremely high voltages which occur in the saturated preventive coil undergoing tap change. Such voltages are of the "peaked-wave" variety, maintaining for only a very small portion of each cycle and occurring when the current wave passes through zero. At the higher transformer voltages and motor currents the "peaked-wave" voltages have been measured which reach values of approximately twice the transformer secondary voltage. This comes about from the fact that all of the available voltage of the transformer secondary may appear across one half of the small preventive coil for an instant during each cycle, and the turn ratio of the preventive coil will give twice this voltage between its two outside terminals. When it is considered that the nominal rated voltage of a small preventive coil is of the order of 128 volts, and the secondary voltage of the main transformer may be of the order of 1,400 volts, the amount of overvoltage that is applied to a preventive coil is extreme.

The presence of peak voltages during switching operation imposes a very severe switching duty upon the tap switches, as is evidenced by the loud noise and substantial arcing that usually occurs during operation of the tap switches under load conditions.

The saturation of the preventive coil during the transition period has another effect which at times in the past has been the most important phenomenon in connection with the switching. This is the occurrence of a displaced current wave upon the closure of the next higher tap switch with the result that very high values of transient currents are obtained. If the value of air-core reactance in the preventive coil undergoing switching is not of sufficient magnitude, currents high enough to cause welding of the tap switch may occur.

These extremely high currents come from:

1. Trapped flux in the coil being switched due to the reversal of applied voltage. This phenomena is similar to that which sometimes occurs when a power transformer is energized and the switch closure comes when the instantaneous applied voltage does not correspond to the flux in the transformer iron, with the result that a distinct "bump" can be heard if one is in the immediate vicinity of the transformer.

2. A component from the trapped flux of the large preventive coil which may be saturated, and many times is, during the switching operation.

3. The proportionate share of the load current for the particular switch involved.

Such currents do not occur every time a transition is made, as their occurrence is dependent upon the instant during the

current wave that the tap switch is closed. For this reason tests designed to record the maximum values of current obtained upon contactor closure have to be made recording the results of very large numbers of closures.

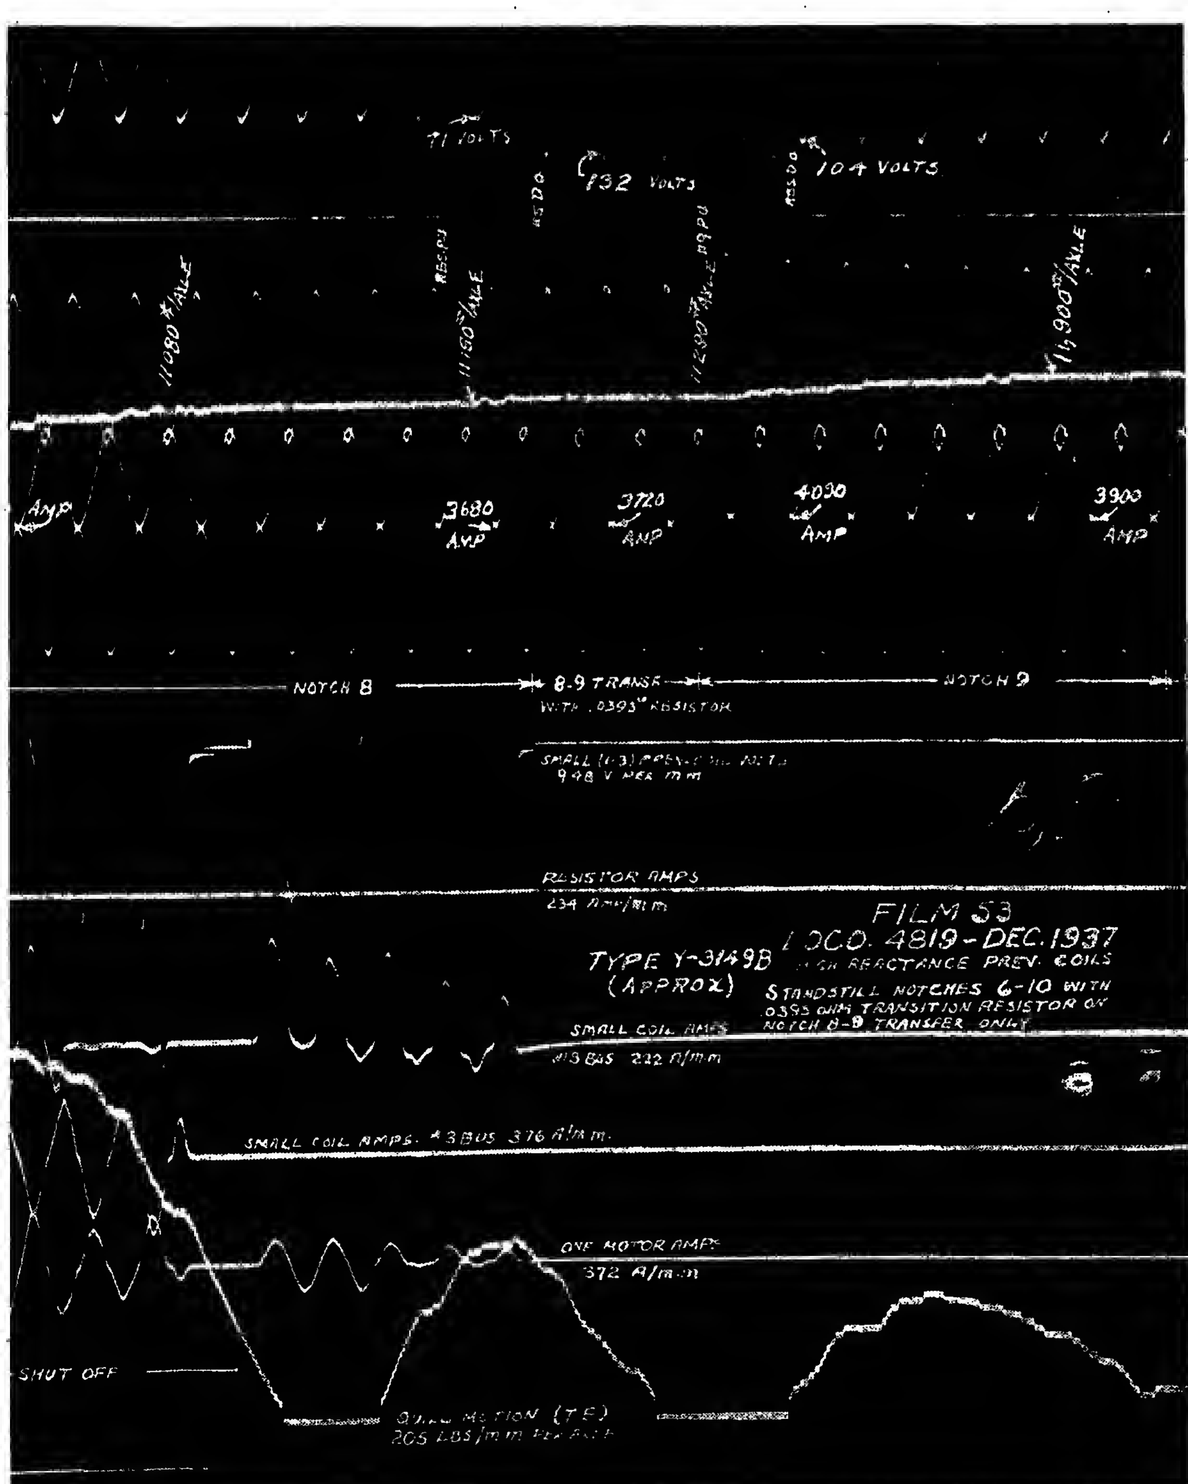
The surge current peaks have been measured as high as 23,000 amperes in a 1,250-ampere contactor, and possible values may be calculated with a reasonable degree of accuracy. Preventive-coil air-core reactances are usually figured to limit these currents to around 12,000 to 14,000 amperes, which seems to be a satisfactory value for the circuits and contactors involved.

Most of the early difficulties with the three-preventive-coil scheme of control centered around the welding of the tap-switch contacts, as then it was not known what magnitude in surge currents would be obtained, nor what steps would have to be taken to limit these currents to satisfactory values.

One of the suggestions made during the early days involved the connection of a resistor across the preventive coil to prevent the extreme amount of saturation which occurs in the coil. However, this suggestion was not followed up as it appeared simpler and more helpful to connect special air-core reactances in series with the preventive-coil bus circuit to limit the flow of exciting current through the small preventive coils. While the air-core reactance coils were so connected as to limit the flow of exciting current, the arrangement was such that the effect of load currents was to balance out the reactances of the coils. In later designs the reactance of the external coils was built into the preventive coils themselves so that the extra pieces of equipment are no longer required.

In 1937, during the search for a better scheme of control, it was suggested that a resistor of proper ohmic value be connected across the terminals of the preventive coil that was open-circuited during the transition. With this connection, while the preventive coil was operating "one-legged" the current would divide properly and flow through the resistor to the preventive coil and then to the motors. The value of resistance was determined by the maximum current to be encountered in the service of the locomotive and the designed voltage of the preventive coil. The voltage across the preventive coil at no time then would exceed its maximum designed value, and there would be no possibility of saturation of the coils.

Figure 2. Film 53—transition between notches 8 and 9 with transition resistor



Early Experiments With Transition Resistor

Such a scheme of connection was tried out upon the Pennsylvania Railroad in 1937, on locomotive 4819, at which time oscillograms were taken which showed very clearly the results to be expected from such an arrangement. In addition to the currents and voltages recorded on the films, it was also possible to measure directly the torque of the traction motors involved so that the results of the sag in tractive effort during ordinary notching and the lack of a sag in tractive effort in notching with the transition resistor were definitely recorded.

The drive from the traction motors to locomotive driving wheels is of the well-known spring cup type. In order to measure the motor torque, it was necessary only to provide an electric position-measuring device to indicate the deflection of the drive springs and record the indications on one of the oscillograph elements. When the spring constants are known, it is a simple matter thereafter to calibrate the indication of the element in pounds tractive effort.

The tests were confined to observing the effects on one transition only, namely from notch 8 to notch 9. The resistor used was of very small physical size, being capable of withstanding the currents involved for only a few cycles. The tests were all made at standstill, as it was impractical to measure the motor torque while the driving wheels of the locomotive were rotating.

The first of the oscillograph films (film 52) gives a record of the transition from notch 8 to notch 9 without the use of the resistor. Referring to film 52 (Figure 1) it will be observed that during the transition the tractive effort fell from 8,700 pounds per axle in notch 8 to 7,580 pounds per axle during the transition; the traction motor current fell from 3,530 peak amperes per motor to 2,880 peak amperes per motor and then rose again to 3,900 peak amperes per motor in notch 9 after

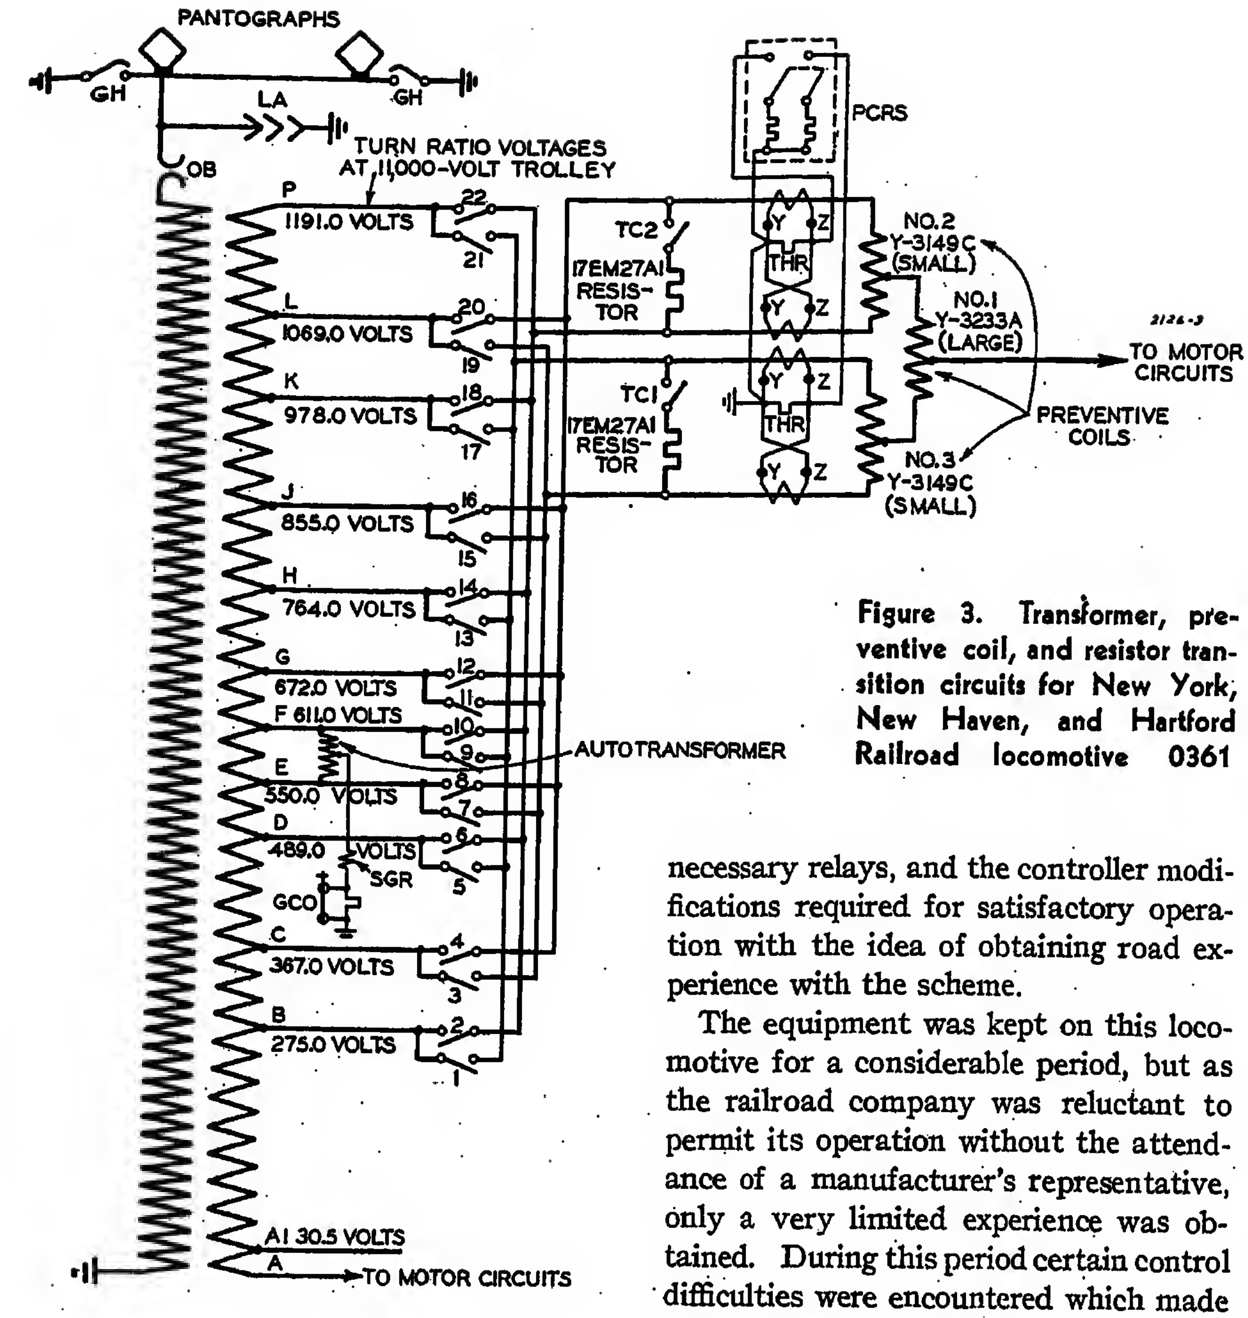


Figure 3. Transformer, preventive coil, and resistor transition circuits for New York, New Haven, and Hartford Railroad locomotive 0361

the transition was completed, this current corresponding to 8,910 pounds per axle as measured on the film. Also to be observed are the very high peaks in small preventive-coil voltage, which curve goes clear off the bottom edge of the film to a value impossible of determination. The rms value of the preventive-coil voltage for notch 8 is 43.5 volts, and for notch 9 is 49.8 volts.

Film 53 (Figure 2), taken immediately after film 52, with the transition resistor functioning, shows the very striking improvement obtained. In this case the tractive effort per axle moved gradually from 11,180 pounds per axle to 11,900 pounds per axle some time after the transition was complete. The increase in traction-motor current was also gradual, raising from 3,680 peak amperes in notch 8 to 3,820 peak amperes during the transition, and then to 4,090 peak amperes after the transition was complete. The preventive-coil voltage is kept down to its normal value; the increase during the transition is only to 91 volts rms as compared with the nominal rating of the preventive coil of 128 volts.

Pennsylvania Railroad locomotive 4819 was subsequently equipped with a pair of resistors, a pair of resistor contactors, the necessary relays, and the controller modifications required for satisfactory operation with the idea of obtaining road experience with the scheme.

The equipment was kept on this locomotive for a considerable period, but as the railroad company was reluctant to permit its operation without the attendance of a manufacturer's representative, only a very limited experience was obtained. During this period certain control difficulties were encountered which made the scheme of getting the resistor switch closed before the tap switch opened, and then opening the resistor switch after the next higher tap switch had closed, somewhat unreliable. However, there was a noticeable improvement in locomotive acceleration and a very marked reduction in the amount of arcing on the tap switches, both in noise and the amount of visible arc, during the time the resistor transition equipment was working.

The equipment was subsequently removed from Pennsylvania Railroad locomotive 4819, and returned to the manufacturer's plant for reconditioning.

Service Experience on New York, New Haven, and Hartford Railroad

Having observed the performance of Pennsylvania Railroad locomotive 4819 with the resistor transition equipment functioning, New Haven representatives expressed interest and a desire to have the equipment turned over to them for use and service experience on one of their locomotives, in order to explore fully the possibilities of improved locomotive performance and reduced tap-switch maintenance.

New Haven electric locomotive 0361 (Figure 6) was selected for the installation of the resistor transition apparatus. This locomotive is one of six built by the General Electric Company in 1938 and used in main-line passenger service between New York and New Haven. A brief description of the locomotive follows:

Class	0361–0366
Service	Passenger
Power supply	11,000 volts, 25 cycles, a-c, 660 volts, d-c
Wheel arrangement	2C+C2
Number and type of traction motor	6GEA-622
Total weight	432,000 pounds
Weight on drivers	273,000 pounds
Length between coupler pulling faces	77 feet 0 inches
Over-all width	10 feet 2 inches
Height over a-c pantographs down	14 feet 8 inches
Maximum tractive effort (25% adh.)	68,500 pounds
Continuous tractive effort	24,100 pounds
Speed at continuous tractive effort	56.0 miles per hour
Continuous rated horsepower	3,600
Photograph	Figure 6

This locomotive has 22 tapping contactors and 20 a-c controller notches without intermediate buck-boost notches. No sequence relay interlocking is provided.

The application was made while the locomotive was in the shop for its first truck overhaul and traction-motor commutator turning after making a total mileage of 263,000. It was released from the shop July 16, 1941, after making various yard tests to determine that the new apparatus was functioning properly. Before assignment to any revenue trains, however, it was given a series of light runs on the main line, still further to insure that operation was correct.

In order to find out if duty on the tapping contactors was actually lessened by reason of the elimination of severe current and voltage transients in the preventive coils, new tips and arc chutes were installed on all such contactors. On subsequent periodic inspections burning and wear of tips and arc-chute sides could be compared with conditions on similar locomotives without the resistor transition.

The transformer and preventive coil connections for this locomotive are as shown in Figure 3. The control circuits in Figure 4 show the master controller and the relay circuits associated with the operation of the resistor transition switches $TC1$ and $TC2$. Figure 5 is a sequence diagram for the operation of the relays, tap switches, and resistor transition contactors for certain representative steps. The following is a brief description of the operation of the control circuits which have as their function the closure of the resistor transition switch before the opening tap switch breaks its

contacts, and thereafter the holding of the resistor transition switch closed until the next tap switch is closed.

Upon the movement of the master controller from one notch to the next, a segment between notches gives an impulse of electric energy to an appropriate wire which is connected to the magnet valve of the resistor transition switch it is desired to close. The operating coil of the magnet valve is wound for approximately half the normal control voltage of the system so that its operation will be very fast. The coil is protected against the control voltage, should the controller be left midway between notches, by a resistor that is shorted out of the circuit by a relay (*TR*1 or *TR*2), whose circuits are made up before the transition is initiated, as described later. Should the controller remain between notches, the relay is de-energized by interlocks on the resistor switches, thereby inserting the protective resistance in series with the magnet valve coil. Attached to the armature of the magnet valve is an auxiliary normally open contact (*TC*1*V*, *TC*2*V*) which "makes" upon the initial travel of the armature before the latter starts to open the air valve. This contact forms a holding circuit from the battery to cause the magnet valve to continue to close, thus operating the air valve and supplying air to the cylinder of the contactor, regardless of the length of time the impulse remains on the wire from the controller. The transition switch closing its main contacts also opens the circuit to the transition relay by means of interlocks. Another set of transition relay contacts (*TR*1, *TR*2) are in series with the holding circuit to the magnet valve of the particular switch involved. The transition relay has a time delay built into it of sufficient duration to keep its contacts closed until enough time has elapsed for the transition of the main tap switches to have been completed. At the end of the prescribed time the transition relay operates, opening the holding circuit and causing the transition contactor to open. The interlocks on the transition contactor (*TC*1, *TC*2) again make up the circuit to the transition relay, which again "picks up" and is then ready for a repetition of the same cycle when it is initiated by an impulse from the master controller. There are two sets of relay equipments, one for each transition resistor.

The resistors are located over the exhaust air stream from the radiator of the main transformer, and the control is so interlocked with the blowers that it will not operate unless the blowers are running. As another safety factor a thermostat has been placed over each resistor so that, when they exceed a safe temperature, the thermostat will close, energizing the thermostat relay (*RTR*) which latches in its energized position and de-energizes the resistor transition circuits. The resistor transition equipment cannot then be operated until the resistor has cooled, and the thermostat relay has been reset by hand. The resistor thermostats are in the nature of "backup" protection, as the resistors themselves have been designed liberally enough so that, with the aid of the ventilation from the transformer radiator, it would be permissible to let them stay on the preventive-coil bus energized continuously without damage to themselves. They have a very high temperature coefficient of resistance so that, as they heat up, they inherently reduce the current flowing through them. However, in order to protect the adjacent equipment and cab structure from excessive heat, it was considered desirable to add the thermostat to each resistor.

The resistor transition switches are standard tap switches equipped with a reduced tip gap to obtain short travel and space filler to reduce the surplus volume in the cylinder. Minimizing the clearance volume of the cylinder reduces the volume of air required to start the switch moving, and reducing the switch travel cuts down the time required for closure. These refinements in the switch, combined with a magnet valve that is operated on approximately twice normal voltage, suffice to give a switch with the required operating speed.

This arrangement of the control circuits appears to have been eminently satisfactory, and where the segments in the master controller have been properly aligned so that the impulse to the magnet valve is started before its corresponding tap switch has been de-energized, no difficulty has arisen in insuring that the resistor switch is closed before the tap switch breaks its contacts. In normal notching the duration of the impulse from the master controller is of the order of $^{1}/_{100}$ of a second.

When the trial of resistor transition on a New Haven electric locomotive was first considered, two trains immediately came to mind as offering the best chance to observe the effects. These two trains were exceptionally heavy morning and night

Figure 5. Sequence diagram for representative notch transitions with transition resistors

commuter trains operating as local expresses between New York and New Haven; each required higher locomotive output than any other passenger train handled electrically. The electric locomotives regularly assigned were the 0361–0366 class. Short-time load demands, when operating the two trains in question, reach a peak of 7,600 horsepower, more than twice the continuous rating. These peak demands come about through frequent stops on a fast schedule for half of the run in each direction.

These two trains therefore were selected for the initial test runs. Other trains were handled as the locomotive was used in the regular 0361–0366 pool.

Two results of the resistor transition were immediately apparent. One was the virtual elimination of the usual barking of contactors on heavy current during acceleration. The second was the smoothing out of the tractive effort increments on acceleration, resulting in less tendency for the locomotive drivers to slip. This was remarked upon almost immediately by those operating the locomotive.

At first, the resistor transition apparatus was cut out except when a road foreman or others familiar with the equipment were riding the locomotive. In a short time, however, it became apparent that it could satisfactorily be left cut in, depending in the event of trouble on the thermostats or the instructions issued to the crews for cutting it out. The latter was a simple process, involving only the opening of a small double pole, single-throw control knife switch which made the transition contactors inoperative and returned the locomotive to normal operation.

Experience in regular operation since this time has developed practically no trouble, and the equipment has been continually in service and cut in, except for several instances of thermal relays tripping, probably due to enginemen operating in between notches on the master controller, and one period of approximately two weeks due to an error in judging the position of the timing relay contacts. The eight months of use have demonstrated that the resistor transition equipment is reliable in its operation without any more attention than is given other electric apparatus on the locomotive.

The duty on tapping contactors has been lessened. Unfortunately, due to operating conditions, there was no opportunity to determine quantitatively how much benefit was obtained, but qualitatively much benefit was observable. This means that aside from the operating advantages already described, there was a reduction in maintenance of tapping contactors, which is an important item on a-c electric locomotives. Against this, however, must be placed the additional maintenance of the resistor transition equipment, particularly the contactors and the segments and fingers on the master controllers.

Another feature of the equipment is that a certain amount of care must be taken by the engineman when operating the controller. The control-circuit scheme is based on a train of events initiated by an impulse from the controller, and subsequent impulses must be spaced far enough apart in time so that the initial train of events has been completed, or else the most desirable operation is not obtained. When accelerating from standstill, a short pause normally occurs between each two notches, and the operation is always correct, but in notching on or off too fast when up to speed, the resistor transition may be only partly effective because of lack of time between notches. This is only of interest from the standpoint of duty on preventive coils and tapping contactors; tractive effort considerations are not critical under these conditions.

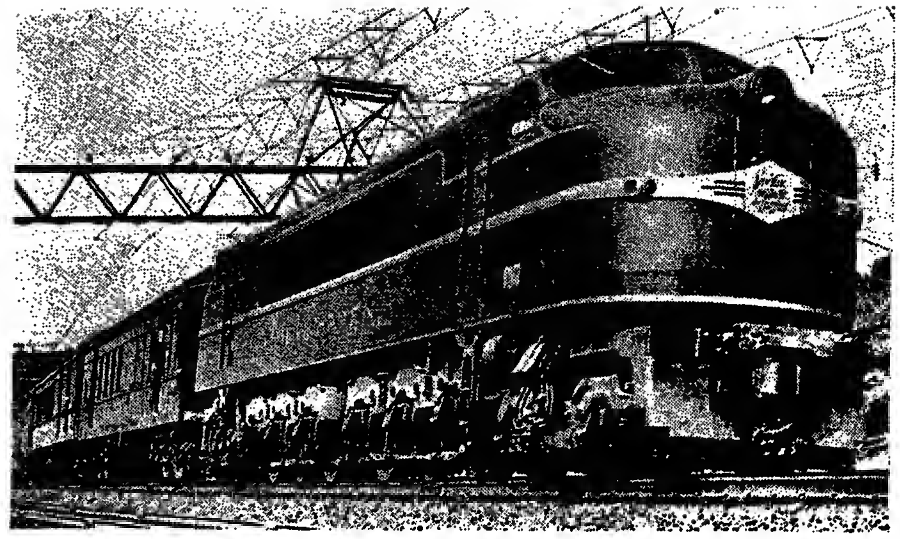

Figure 6. New York, New Haven, and Hartford Railroad Company locomotive 0361 upon which resistor transition equipment is operating

Conclusions

While the resistor transition equipment was applied to a New Haven passenger locomotive as representing one of the latest type of a-c locomotives in service, it would seem that the application would find its greatest usefulness in freight locomotives where smooth-starting tractive-effort characteristics are practically a necessity, and where starting duty is both prolonged and severe.

In general, the resistor transition scheme, developed and applied as described, has given gratifying results in its apparent improvement in the acceleration of the locomotives to which it has been applied, through the eduction in the arcing duty on the tap switches as evidenced by the almost complete lack of any arc noise and the very much smoother operation of the locomotive when notching.

Although the resistor transition has a beneficial effect on tap-switch surges after closure of the higher tap switch during a transition, because of the fact that it will prevent saturation, particularly of the large preventive coil, it is still necessary to analyze carefully each case to insure that excessive tap-switch surges are not obtained with the given values of series air-core reactance in the small coils. The fact that the transition resistor is still energized after the next higher tap switch has closed means that the current flowing through the resistor is superimposed upon the small preventive-coil exciting current, with the result that the surge current may actually not be greatly different from what it would have been, had a resistor not been connected to the circuit. However, with some combinations of equipment, the presence of the resistor will result in a definite reduction in the surge, and each case must therefore be analyzed on the basis of its own merits.

A further study of the scheme and its application would seem to be warranted for heavy duty a-c freight and passenger locomotives.

Electric Equipment for Large Electrochemical Installations

T. R. RHEA
ASSOCIATE AIEE

H. H. ZIELINSKI
MEMBER AIEE

Synopsis: The increased demand for aluminum, magnesium, chlorine, copper, and zinc for war purposes has made the electrolytic processes for these materials the largest consumers of electric energy in this country.

The most frequently encountered d-c and voltage requirements of these four principal electrolytic processes are discussed. An illustrative current-time and voltage-time characteristic curve for starting a chlorine cell line is shown, and the requirements that such characteristics impose on the electric equipment are discussed. The current-voltage characteristics of aluminum, magnesium, chlorine, and zinc cell lines are also shown.

A typical installation of conversion equipment for an electrolytic process plant is given, and the reasons for selecting the particular types of electric equipment and its physical and electrical arrangement are discussed.

As part of this discussion, there are included characteristic curves of rectifiers showing the effect of ignition control on power factor for 6-, 12-, and 36-phase combinations. A table giving a "rule-of-thumb" relationship between the number of phases and kilowatt limits which have been found in practice to provide operation reasonably free from telephone interference is included. There is also given a tabulation of phase shifter combinations, by means of which multiphase operation can be obtained with various combinations of standard six-phase rectifier transformers.

THE electrochemical industry has very recently become one of the most important consumers of electric energy in the United States with increasing production of aluminum and magnesium and, in the near future, will become an even more important user. The "Big Four" of the electrochemical industry—aluminum, magnesium, chlorine, and the sister metals, copper and zinc—have now installed over 2,500,000 kw. of conversion apparatus of all types in this country, and the end of the year 1942 will see an additional million kilowatts installed in these four branches of the electrochemical industry.

This conversion equipment operates at almost 100 per cent load factor and converts power at a yearly rate of 25,000,000,000 kilowatt-hours, or nearly one quarter of the total energy used for all industrial purposes. This percentage may at the end of this year well increase to perhaps 40 per cent of the total industrial power.

There are many other electrochemical processes of less importance. Perhaps the next largest in installed conversion capacity produces fused sodium chloride with approximately 60,000 kw. Following this in importance are processes for production of hydrogen, manganese, potassium perchlorate and sodium chlorate, and other similar processes. The application problems are similar to those of the four major industries.

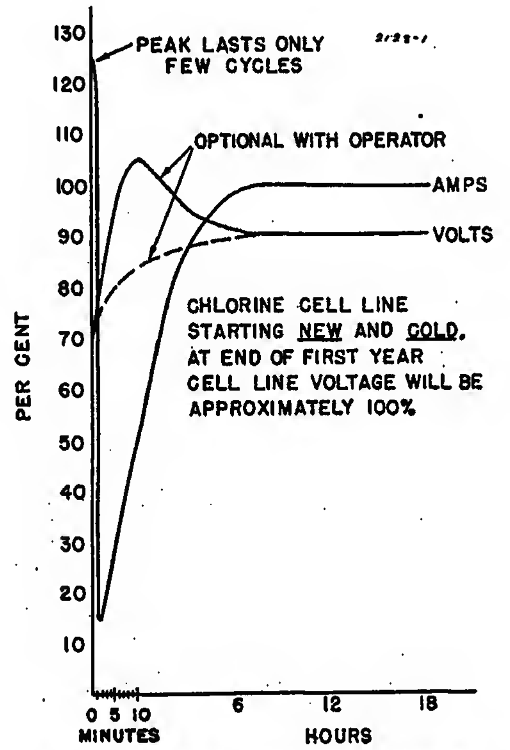

Figure 1. Chlorine cell-line characteristic

While these figures include conversion apparatus of all types (rectifiers, rotary converters, and motor generator sets), the rectifier is now the prevalent choice of the industry for converting such large amounts of power into direct current. Since 1937 very few large electrolytic installations using rotating conversion equipment were made in this country or in central Europe. During the last two or three years, the ignitron-type rectifier has been chosen for most of the installations in this country, although the multi-anode type of rectifier is still the choice of foreign designers.

The application engineer dealing with the electrochemical industry is at a certain disadvantage compared with application engineers for other industries, inasmuch as the chemical industry has published very little data concerning their electrical requirements. This may be attributed to the fact that electrochemical processes and techniques are often of a highly secret nature, not only in time of war, but also under peacetime conditions when the process is a matter of competitive endeavor. The electrical-application engineers would welcome more complete and precise knowledge of the electrical characteristics of the various electrolytic cells, presented not from the point of view of the chemist, but from the point of view of the electrical engineer. A few typical characteristics are discussed below, but this subject needs considerably more analysis.

Electrochemical Process Characteristics

Aluminum

A typical electrolytic cell line or "pot" line for the production of aluminum consists of a number of cells connected in series and is supplied with a normal direct current of 60,000 amperes at perhaps 650 volts. Such a line may require very little adjustment in d-c voltage except for minor variations of cell resistance and of the counter electromotive force of the cells. Adjustable voltage is however required, if the number of cells is decreased below normal, or for baking out a new or "green" cell line. The variation of the a-c supply voltage may require means of maintaining pot-line current and voltage at a constant value. Means for accomplishing such voltage regulation will be discussed later. Under ordinary operating conditions, after such a line is once put into operation, it will run for months or even years, with a voltage and current variation of not more than five or ten per cent.

Another typical aluminum cell line with cells of the so-called Soderberg type has a normal capacity of 32,000 amperes at 650 volts. With this type of cell more frequent adjustment in the d-c voltage is found very useful for the purpose of starting "green" cells or baking out cell linings.

Magnesium

As far as the application of the electrical conversion equipment is concerned, a magnesium cell-line is very similar to the

Paper 42-138, recommended by the AIEE committee on electrochemistry and electrometallurgy for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 21, 1942; made available for printing May 25, 1942.

T. R. Rhea and H. H. Zielinski are both engineers in the chemical section of the industrial engineering department of General Electric Company, Schenectady, N. Y.

aluminum line. The magnesium cell line may have a normal d-c rating of 60,000 amperes at 600 volts, although a large installation is now in the process of erection which, based on European practice, will use a large number of 20,000-ampere 350-volt cell lines. Another installation is using 32,000-ampere 600-volt lines.

Wider adjustment in the d-c voltage is required on a magnesium cell line as compared with one for aluminum, because a new cell line is usually started with only a few cells and is built up over a period of several weeks by adding new cells in series. Both in this country and abroad, installations have been made with a wide range of adjustable d-c voltage, even though normal operation is at practically constant voltage.

Chlorine

Typical chlorine cell lines use from 7,500 to 10,000 amperes at 500 to 700 volts, depending upon the type of cell used or the number of cells connected in series. Some cells are designed for 1,800 to 2,000 amperes, and four or five of these may be connected in parallel on a common d-c bus. Usually each 7,500- or 10,000-ampere cell line is supplied from one rectifier unit, without interconnection with other cell lines on the d-c side except in case of emergency. This arrangement provides flexibility to meet the day-to-day variations in cell-line requirements. Such lines are operated at essentially constant d-c voltage. Figure 1 shows typical voltage- and current-time curves for a chlorine line which is placed into operation for the first time.

It should be pointed out that these curves are not based on tests, as the authors might desire, but on previously published information and on theoretical considerations.

The Figure 1 shows an initial instantaneous peak rising to perhaps 125 per cent after the cell line is first thrown on full voltage and before the counter electromotive force or battery action of the cell is established, a phenomenon which happens within a few cycles. The sodium-chloride solution initially has a high resistance, while it is cold and dilute. For the next six or eight hours the current rises as the resistance decreases with increasing concentration of the solution.

The initial voltage reduction to 60 or 70 per cent required of the conversion equipment to keep down the initial inrush of current is well within the capability of ignition control of a rectifier. Minor adjustments in the voltage required from day to day are also usually made by means of ignition control. Larger d-c voltage changes may be obtained with taps on the rectifier transformer as will be discussed later.

It should be noted that the characteristics of the individual cells are somewhat obscured if a number of lines are operated in parallel.

Copper and Zinc

A typical copper or zinc cell line is quite different from the chlorine line as regards the conversion equipment. A zinc line may require about 10,000 amperes at 500 to 600 volts, depending on the number of cells connected in series. Foreign installations have been made using voltages up to 800 or 850 volts. For normal operation the cell line is operated at substantially constant d-c voltage. Usual applications require some transformer taps for d-c voltage adjustment on a cell line as the number of cells in series are changed.

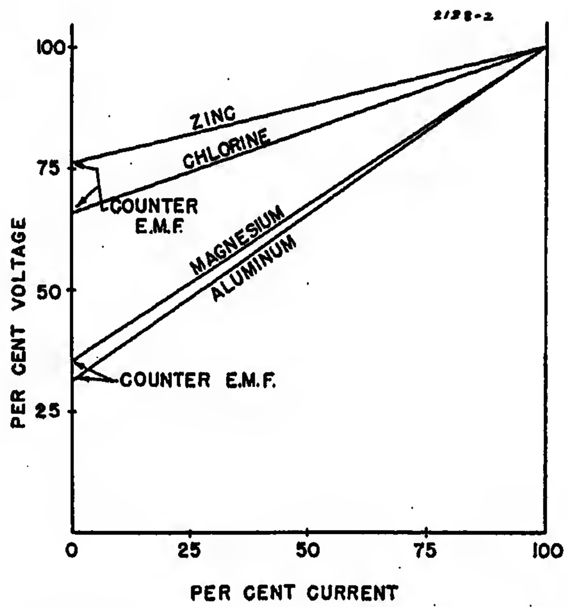

Figure 2. Electrolytic cell-line characteristic

Since, however, the electrolytic production of copper or zinc is a batch process, where a cell is periodically taken out of service for the purpose of stripping copper or zinc from the electrodes, the cell-line voltage must at the same time be lowered to such a low value that the disconnection of one cell may be made at slightly above zero current. The voltage reduction required to accomplish this is approximately 25 per cent, usually obtained by ignition retard.

Figure 2 shows a typical voltage-current characteristic of a zinc line. It is easily understood that the removal of one cell from the circuit by means of short-circuiting this cell should, from the standpoint of operation, be done as quickly as possible in order to revert to full current and full production without too much loss of time.

It is important that some cell current be maintained, at least at a low value, at all times to prevent the copper or zinc already deposited from going back into solution.

Figure 2 also shows cell-line characteristics for other cell lines. Chlorine has a counter electromotive force of approximately 66 per cent. For alumina dissolved in cryolite, the authors estimate a counter electromotive force of about 30 per cent based on the theoretical voltage of dissociation of 1.38 volts per cell and the approximate total voltage drop of 5.9 volts per cell. The counter electromotive force of fused magnesium chloride based on similar data is shown to be approximately 35 per cent. The authors have no accurate data on the length of time for which this counter electromotive force persists after an interruption in the current supply.

Some cell lines have their mid-point grounded through a resistor for the purpose of lowering the cell potential to ground. Such installations usually have a relay and alarm system in the ground connection to notify the operator of accidental grounds on the cell circuit. Grounding the mid-point of the cell line seems to be common practice abroad but is only occasionally used in this country. The disadvantages of its use are slightly more electrical losses to ground because of current bypassing some cells.

Selection of Electric Equipment for Electrochemical Processes

Rectifiers Versus Rotating Apparatus

The mercury-arc rectifier has become so well established in the electrochemical field that it is hardly necessary to dwell at great lengths on the advantages it has over rotating apparatus. However, it is desirable to review very briefly some of these advantages.

The space requirements for the installation of rectifiers are quite moderate, and no reinforced foundations are needed such as are required for rotating apparatus.

In the larger units at 600 volts direct current, the rectifier-conversion equipment may be installed for approximately \$35 to \$40 per kw. This includes the incoming 13.8 kv 60-cycle a-c switchgear, autotransformers, rectifier apparatus, cable and copper bus bars for the main d-c bus, building, and installation labor. This approximate installation cost figure would cover a layout as shown in Figures 5A and 5B.

An especially important consideration in wartime is the fact that the amount of particularly scarce materials, such as copper and steel, is considerably less in a

rectifier installation than in rotating apparatus. Incidentally, it is for this reason that the rectifiers have for some time been more widely used in Europe than they have been in this country.

The efficiency of the modern ignitron-rectifier equipment in the voltage range around 600 volts is in excess of 95 per cent, including the transformer losses and the power consumed by the rectifier auxiliary equipment, such as pumps and ignition apparatus.

The efficiency of the conversion equipment is of special importance in the electrochemical industry, because these processes operate at close to unity load factor, and the electric energy which the conversion equipment supplies over a year's time may cost as much or more than the cost of the conversion equipment itself.

An operating advantage of the rectifier installation over a rotating-apparatus installation is particularly emphasized by the problem of restarting a large-capacity cell line after a complete power failure or shutdown. Assuming that such a cell line is supplied from six 10,000-ampere rotary converters, it is necessary after a power failure to restart and resynchronize all of the rotary converters with the d-c breakers open. Since it is impossible to close all of the d-c breakers simultaneously, one of the rotary converters will assume the entire load, its breaker will trip off on overload, and succeeding breakers will follow.

Table I. Phase Shifters Required for Multiphase Operation

Rectifier Transformers: Number of 6-Phase Units	Rectifier Transformers: High-Voltage Connections	Phase-Shifting Auto-transformers Required	Number of Phases Operation
1	Delta or wye	None	6
2	1 delta, 1 wye	None	12
3	2 delta, 1 wye	2 10-degree	18
4	2 delta, 2 wye	2 15-degree	24
5	3 delta	2 12-degree	30
	2 wye	2 6-degree	
6	3 delta, 3 wye	4 10-degree	36
7	4 delta, 3 wye	2 4.29-degree; 2 8.57-degree; 2 12.86-degree	42
8	4 delta	2 15-degree	48
	4 wye	4 $7^1/_2$-degree	

To meet this problem with rotary converters, a large cell-line breaker is resorted to, which may be rated 60,000 amperes continuously. By using this rather unwieldy device, all of the rotary converters may be paralleled on the d-c bus with this cell-line breaker open and then the breaker closed.

A rectifier application easily circumvents this problem. With rectifiers, all d-c and a-c breakers are closed with the ignition circuit de-energized. The potroom load is picked up by energizing the ignition circuits of all rectifiers simultaneously. No cell-line breaker is needed. It is obvious that the time element, in re-establishing service after a power interruption, is very small indeed for a rectifier station as compared with a rotary converter installation.

Rectifiers provide a certain amount of d-c voltage adjustment by means of ignition retard, which allows quick and easy compensation for changes in the a-c supply voltage or for changes in the cell-line conditions; whereas with rotary converters, the use of boosters must be resorted to. It should be pointed out, however, that the continuous use of ignition control is not resorted to in practice beyond four or five per cent, since a wider use is accompanied by lowering of the power factor and an increase in the tendency of the rectifier to arc back.

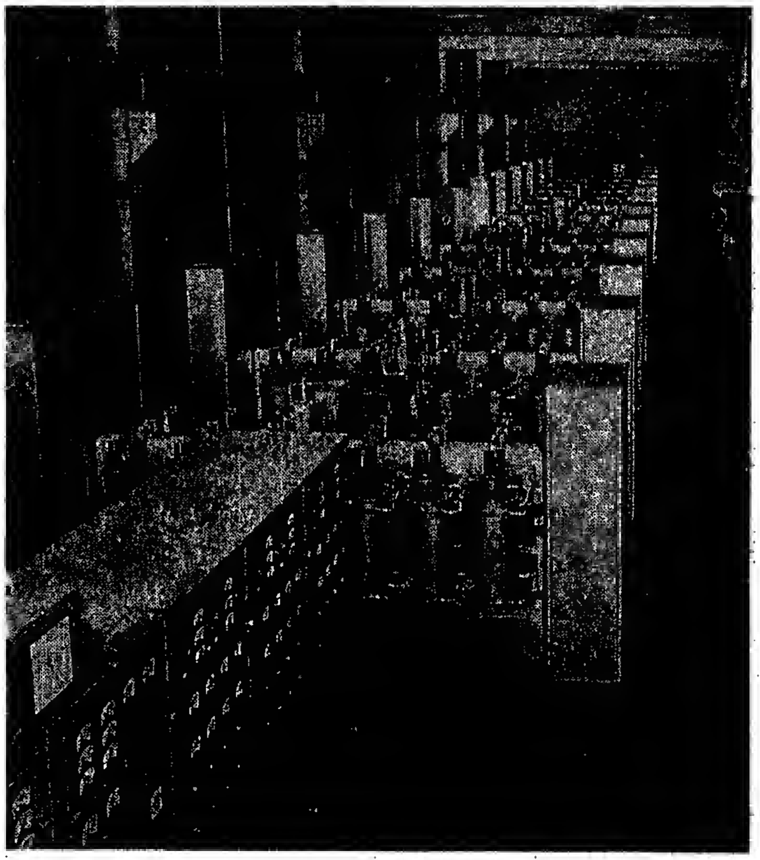

Figure 3. Large rectifier substation

All in all, it may be fairly stated that the many advantages of rectifiers over rotating apparatus makes their selection for a large electrochemical installation a foregone conclusion.

A considerable advance in the art of rectifier design is represented by the single-anode rectifier tank. As illustrated in Figure 3, these single-anode tanks or ignitrons are assembled in groups of 12 to supply 5,000 cathode amperes. This ignitron design has resulted in an increase of efficiency by a reduction of the arc drop to 20 volts or less; which, for such installations, means an over-all efficiency of about 95 per cent. The lower arc drop and the high efficiency result from the fact that the anode encased in a single tank can be placed closer to the mercury-pool cathode.

Because each anode is confined in a relatively small tank compared to the large multianode arrangement, with the ignitron it is possible to make much tighter vacuum seals, and therefore better to maintain the vacuum. Furthermore, if a tank leaks, or trouble develops with one tank, it is a relatively simple matter to replace this tank, whereas it is much more serious when a large multianode tank has to be taken out of service. For these reasons the single-anode ignitron rectifier is now the choice of the electrochemical industry, foreign countries excepted.

Selection of Rectifiers

Figure 4 shows the general arrangement of an electric system for three 60,000-ampere 600-volt electrolytic cell lines. While this sketch does not represent in detail an actual installation, nevertheless all of the features shown are commonly installed, and the sketch will serve as a basis for discussion of the various reasons why the equipment shown was selected.

Each 60,000-ampere cell line operates as a unit. Therefore, the largest available size rectifier units are chosen, in order to obtain maximum economy in first cost. The rectifier transformers are selected so as to supply two rectifier units from one transformer, or a total of 10,000 d-c cathode amperes. This is about the upper limit. The maximum of 10,000 cathode amperes d-c per rectifier transformer has been found both in this coun-

try and abroad to be a conservative upper limit because of large copper sizes to be handled, stresses in the transformer during arc-back, and for other design reasons. Thus the logical choice of rectifier units for this case is the 5,000-ampere, 12-anode ignitron, similar to those shown in Figure 3.

In view of its relative simplicity of design and sturdiness of construction, the six-phase double-wye or quadruple-wye secondary connection is most widely used, both here and in foreign countries. Some 12-phase rectifier transformers have, of course, been used for small installations. As shown on Figure 4, the transformer selected has quadruple-wye secondary connections. Two wye, with their interphase winding, supply one 5,000-ampere rectifier, and two duplicate wye, with interphase winding, supply the other rectifier.

Number of Phases

As the six-phase, 10,000-ampere cathode d-c rectifier transformer is selected, there are now required six such units to supply the 60,000-ampere pot line. This is a total of 36,000 d-c kw. Investigations of rectifier wave shape and its influence on telephone communications indicate that the telephone influence is, to a very large extent, dependent on the characteristics and the total installed capacity of the a-c supply system, to which the rectifier installation is connected, and also on the number of phases selected. It has been fairly well established that such an amount of power operating at six phase would cause widespread telephone interference, if no coordinative measures are taken. Therefore, the number of phases should be selected with reference to the ratio of the total rectifier capacity and the total system capacity supplying the rectifier installation.

Table II contains a "rule of thumb" of rectifier kilowatt ratings and number of phases selected for 60-cycle rectifier operation. This table is, of course, subject to interpretation and should be used with extreme caution, since, for instance, there have been some cases of telephone interference caused by 200-kw rectifiers at the end of a long feeder. It is, however, generally applicable to rectifier installations on relatively large power systems; and so far as the authors know, there have been no cases of telephone interference caused by rectifiers in industrial plants within the limits shown in Table II.

The total kilowatts and the number of rectifier transformers on each pot line indicate in accordance with Tables I and II that the installation here discussed should use 36-phase relationship. Since there are six six-phase units, the rectifier tubes will fire in 36-phase relationship, if the primary voltages are shifted by ten degrees for each rectifier unit.

Table I gives a convenient reference for the number of phase shifters and the degree of phase shift required for combinations of six-phase transformers for multiphase operation. The use of 18-phase operation is inadvisable, because its principal harmonics are the 17th and 19th, having the greatest audio-sensitivity. The 36-phase relationship eliminates theoretically all harmonics below the 35th.

It has generally been found impractical to make sufficiently accurate estimates of the telephone influence in advance of a rectifier installation, because of the many variables and unknowns, which allow only approximate estimates of the telephone influence. Therefore, it has become the practice, supported by experience, to evaluate only approximately the telephone influence and choose the number of phases in some such "rule-of-thumb" fashion as shown in Table II.

If it should ever become necessary in a specific case, remedies such as increasing the number of phases or a-c line filters can be applied after the installation has been made.

It should be clearly borne in mind that the foregoing discussion refers to a 60-cycle supply. Since telephone influence is sensitive to certain harmonics, Table II does not apply to 25-cycle systems. An installation with the same number of kilowatts should have a little over double the number of phases for a 25-cycle system as it has for a 60-cycle system.

In addition to the reduction in telephone influence, the multiphase operation offers definite economic advantages, since the increase in the number of phases improves the power factor as indicated in Figure 6. This figure is based on design data of an actual installation whose basic unit is the six-phase transformer. It can be seen that when the number of phases is raised from 6 to 36, the power factor improves from 92 to 95 at zero ignition retard. The increase in the number of phases also reduces the losses.

Instead of using basic six-phase transformer units, it is possible to use basic 12-phase transformer units. Such 12-phase transformers are much more commonly used in Europe than in this country, although they may be considered practical devices and have a definite field of application for smaller installations. All interphase transformers, indicated in Figure 4, are usually built in the common transformer tank.

The introduction of the phase-shifting autotransformer, as shown in Figure 4, results in some additional reactance in the circuit which would cause it to take slightly less load than a circuit without phase shifter. However, such unequal load distribution is easily compensated by a slight amount of ignition retard on the unit without phase shifter; and it is not considered necessary to insert any external reactance, although this is the practice in foreign countries.

The rating of rectifier transformers for

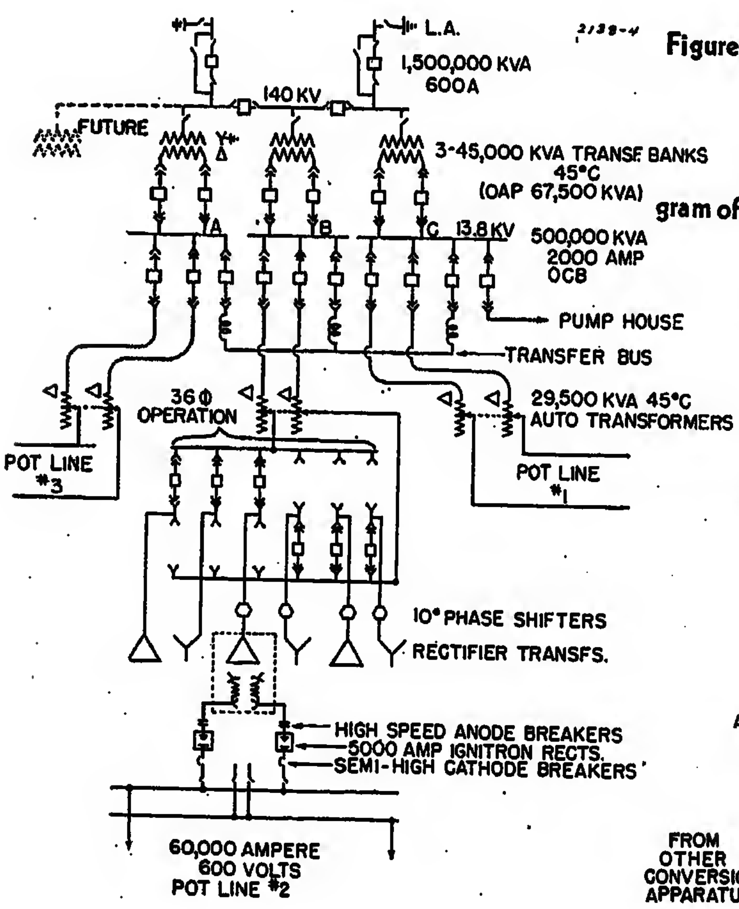

Figure 4 (left). Electric system for large electrochemical installation

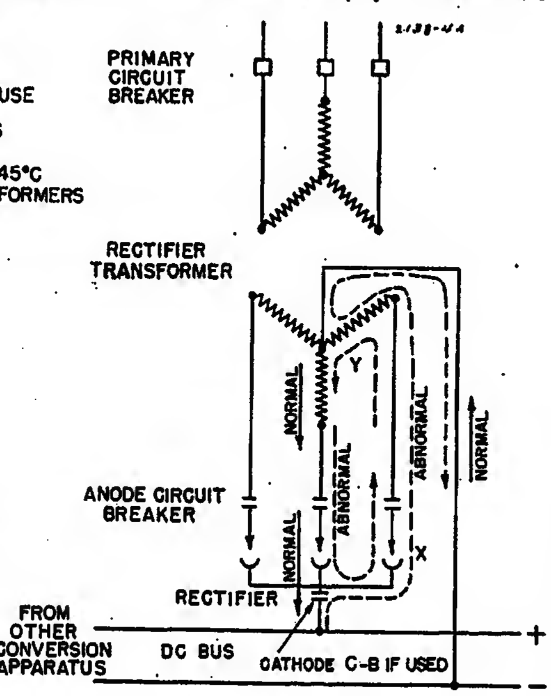

Figure 4A (below). Simplified diagram of rectifier with arc back (X) on one anode

chemical installations is on a basis of 45 degrees centigrade temperature rise for continuous full load. This conservative rating for the transformers has universal acceptance in this country for electrochemical service, because the load factor is almost 100 per cent, and such installations may run for years under this full load condition. The 45 degrees centigrade temperature rise greatly reduces the maintenance on the oil and also provides some inherent spare capacity for emergencies, when it may be necessary to run the cell line on a reduced number of rectifiers, while one unit is undergoing maintenance.

With conservative design margins in both transformers and rectifiers, and with the high degree of reliability of modern rectifiers, such an installation as shown in Figure 4 would not normally require additional spare capacity. If the cell line is run with five instead of six units the overload is 20 per cent. It is generally practical, although not always desirable, to reduce the cell-line load while the single unit is off the line for maintenance. If it is essential to run the cell line with 100 per cent current at all times, a 10,000-ampere spare unit should be provided.

D-C Voltage Control

The installation illustrated by Figure 4 is assumed to require operation at d-c voltages as low as 100 for starting up a new cell line with only a few cells. Furthermore, the a-c voltage supply is assumed to vary five or six per cent from day to day, a condition which would cause the cell-line current to vary a slightly greater percentage. Both these conditions are frequently met in actual operation.

It is quite inadvisable to reduce the voltage from 600 down to 100 volts by ignition control. Figure 6 indicates that voltage reduction by ignition control, even as little as 16 per cent, reduces the power factor from 95 per cent to 82 per cent. Furthermore, operation of mercury-arc rectifiers with a large amount of ignition retard, for a long period of time, will increase the frequency of arc-backs. Experienced rectifier operators, therefore, use as little ignition retard as possible, and the application of ignition control should be limited to such cases where the voltage reduction is of only temporary character, as, for instance, when starting a cell line, where ignition retard of 30 to 40 per cent is permissible for a few minutes.

The other method of d-c voltage control, which uses a change of rectifier-transformer voltage, is not connected with these drawbacks. If only five or ten per cent change of d-c voltage is required over a long period of time, as would be the case for a chlorine line, this change should be obtained by taps in the rectifier-transformer high-voltage winding. These taps would be changed with the transformer de-energized, as such changes are sufficiently infrequent to make an interruption for this purpose acceptable.

However, with the change of d-c voltage required in the case of the installation here discussed, the only practical way of accomplishing this change of a-c voltage is through the use of an autotransformer with no-load taps. In this particular case the autotransformer would be supplied with seven no-load taps from 100 to 600 d-c volts rectifier output. Since these rather large changes in d-c voltage are required only once in several weeks, as a number of cells are added or removed from the circuit, changing these taps with the cell line de-energized imposes no serious hardship on the cell-room operator.

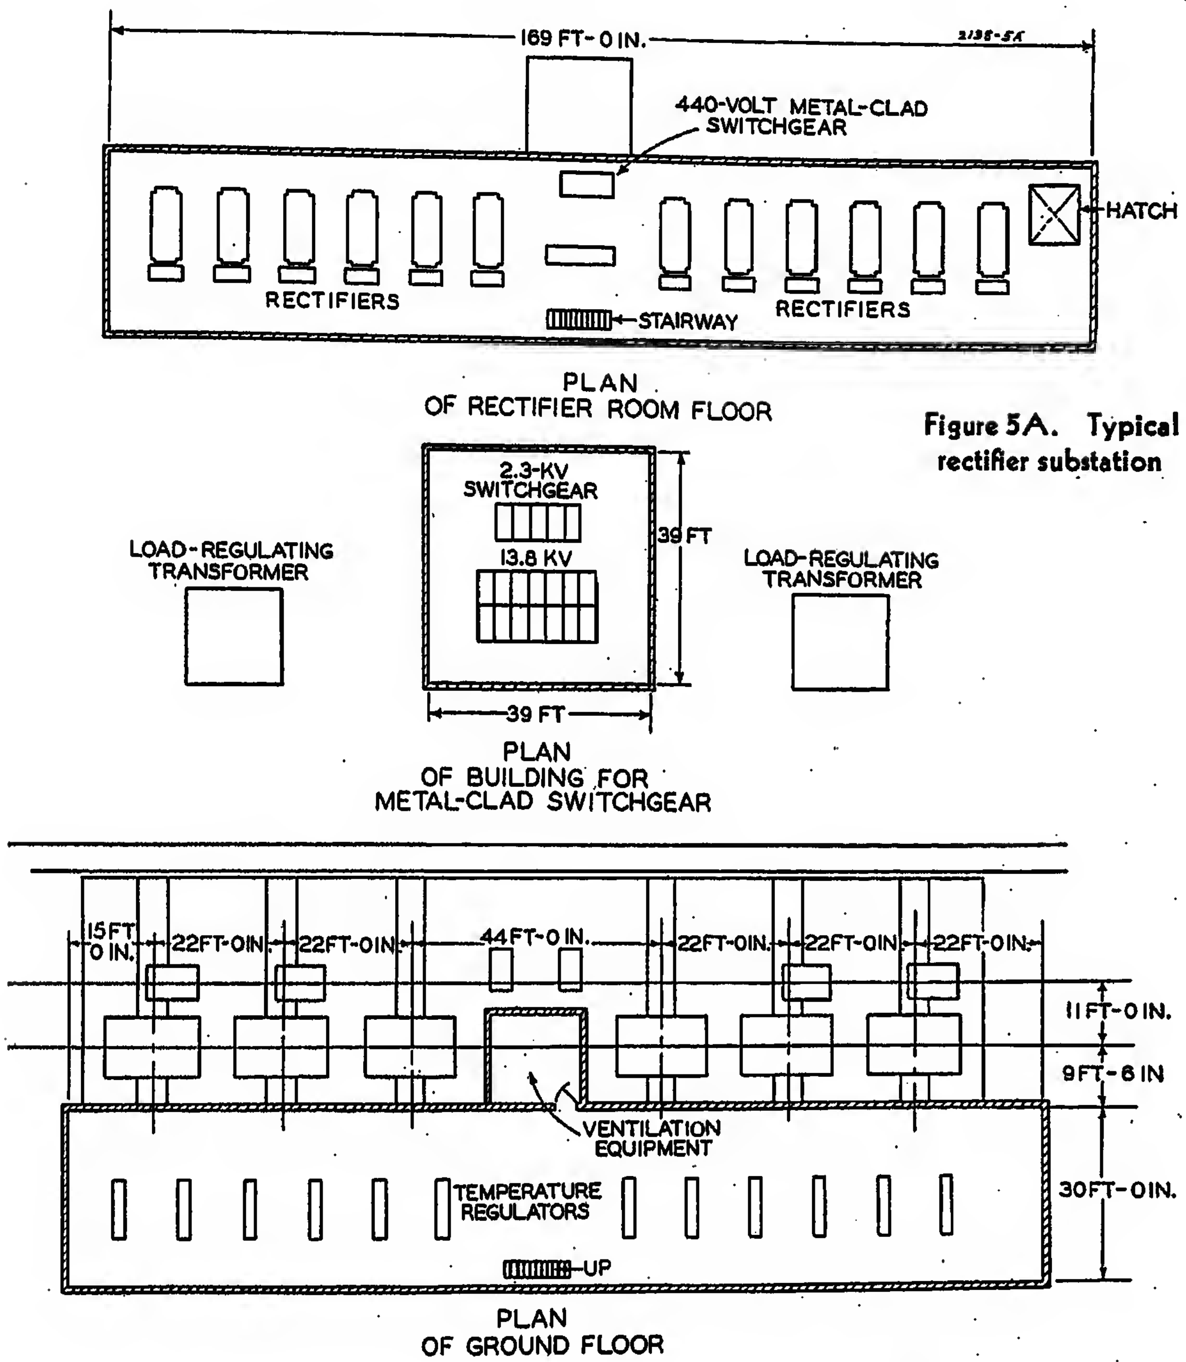

Figure 5A. Typical rectifier substation

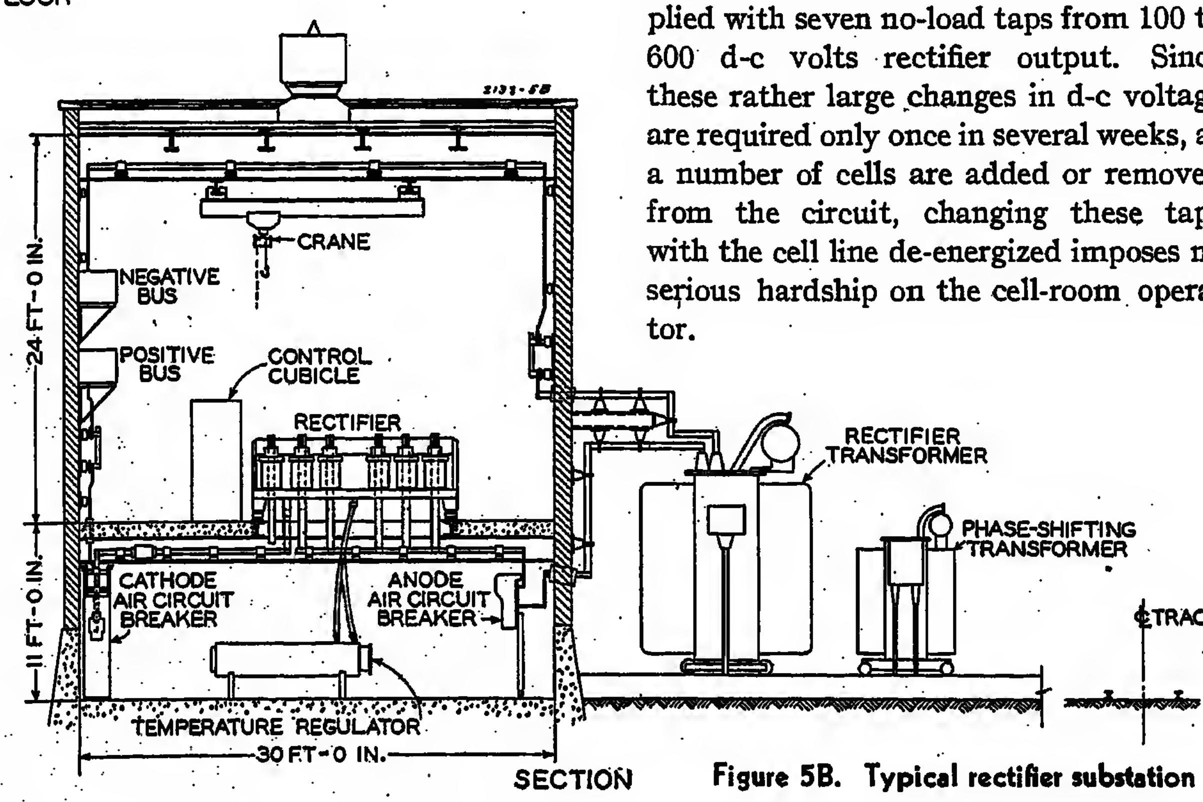

Figure 5B. Typical rectifier substation

In addition to the no-load taps, the autotransformer should in this case have load-ratio control to provide a plus or minus 60 d-c volts adjustment within the range of any of the seven taps of the no-load tap changer. This results in extremely flexible control and permits the operator to compensate for fluctuations in the incoming a-c power supply and also to bridge the gap between the no-load taps. The total range of 120 d-c volts load ratio control has been covered with 16 and 32 steps. Load-ratio control is also quite useful to the operator in maintaining constant cell-line current, as cell conditions change, and operators, who have this tool available, attest to its usefulness for this purpose.

The autotransformer with these features is also a tool for reducing the d-c voltage for the purpose of baking out a "green" cell line or for short-circuiting the d-c bus and simultaneously baking out all rectifier units themselves when they are first installed.

An exactly similar result can be obtained by the use of an induction voltage regulator when due attention is paid to the shifting of the primary voltage supply with respect to the ignition-system voltage. Induction voltage regulators are somewhat more expensive but are frequently used abroad.

With such flexible tools for voltage control available, it is not necessary to use any considerable amount of ignition control, except to balance the load between the various rectifier units.

The load-ratio control feature of the autotransformer makes possible automatic kilowatt input control for the pot line. This feature is not required by the cell-room operator, who will generally take all the kilowatts he can obtain, but by consideration of power contract formulas. By using constant kilowatt control, the load factor can be maintained at better than 98 per cent, and, with some power contract formulas, this feature alone will pay for the autotransformer very quickly.

It will be noted from Figure 4 that two autotransformers are chosen for each pot line. Each autotransformer is of sufficient size to supply with normal temperature rise four rectifier transformers and, in an emergency, five rectifier transformers. This spare capacity is required for reliability. When one autotransformer is out of service for maintenance of load-ratio control contacts, or in the event of failure of a cable connection to the main bus, the cell line can be operated for the duration of the emergency at five-sixths capacity.

Autotransformers, which are usually wye-connected, often have a tertiary stabilizing delta winding, as indicated in Figure 4. This tertiary winding will be of a certain minimum size as dictated by design consideration. If designed for a standard voltage commonly used to supply auxiliary plant load, the tertiary winding can be made to serve a double purpose. In a particular case, each tertiary winding was designed for 3,000 kva at 2,400 volts. This provides a very economical source of plant power, since no additional 13.8-kv high-voltage switching is required to make it available, and very little additional copper in the tertiary winding.

The autotransformer winding, being 13.8-kv wye-connected, provides a convenient means of grounding the neutral of the 13.8-kv system. While not shown by Figure 4, in an actual installation all six of the autotransformer neutrals are brought through disconnecting switches to a common grounding bus; and this bus is connected to ground through a current limiting resistor. Such neutral grounding greatly facilitates the relaying of the system and adds to its reliability and safety.

Table II. "Rule-of-Thumb" Kilowatt Ratings and Phases for 60-Cycle Rectifier Operation on Relatively Large Power Systems

Kilowatts	Phases
1,000– 2,000	6
2,000– 6,000	12
6,000–20,000	24
20,000–30,000	30
30,000–50,000	36
50,000 and up	48–72

Automatic Current Regulation

Automatic current regulation can be furnished by means of regulators operating on the rectifier ignition circuits. In general, such devices are not required for electrochemical installations, because the conditions are sufficiently constant, and they have been applied only to meet special conditions. They may be justified when the a-c system voltage varies, and it is desired to keep the d-c pot-line current constant. They are also of value where the rectifier must parallel with other conversion units of dissimilar characteristics.

Where such devices are used, the amount of ignition control is limited, and the undesirable effects on power factor are avoided. Where they are used in conjunction with load-ratio-control autotransformers, the ignition control is limited to perhaps five or six per cent range, and when these limits are reached, the load-ratio-control autotransformer taps are automatically changed by the regulator.

D-C Switchgear

High-speed d-c switching, particularly where more than one rectifier supplies the same load, is considered a highly desirable application requirement. By high-speed switching is meant a d-c circuit interrupting device which will begin to open in one-half cycle or less, and will therefore limit the peak current, and will completely interrupt it in approximately one cycle. The primary oil switch in the supply circuit to the rectifier transformer will have a normal operating time from six to eight cycles and would permit arc-back currents to reach undesirably high values.

Two methods of high-speed d-c switching are in common use: The older method uses a high-speed cathode breaker which trips on reverse current and removes the faulty rectifier from the d-c bus. Since the short circuit still exists on the secondary circuit of the rectifier transformer, it is necessary to attempt either to extinguish the arc in the rectifier by ignition blocking, or to open the main oil switch.

The second method of applying high-speed switching is the use of the high-speed anode breaker as indicated in Figure 4 and Figure 4A. The use of the high-speed anode breaker is an important development in the application of rectifiers, and, while there have been some papers written on this subject, the authors feel that it is desirable to review briefly the reasons for their wide acceptance by the operators.

The use of an anode circuit breaker provides the best protection not only for the rectifier but for the process being supplied by direct current, since its use gives a greater guarantee of continuity of service. The high-speed anode circuit breaker has one pole placed in each anode circuit and replaces a single-pole high-speed cathode breaker.

Referring to Figure 4A, normal current flow at a given moment is indicated by the solid-line arrows. When an arc-back occurs, one of the anodes (the right-hand one, not supposed to be carrying current at that instant) allows current to flow in the reverse direction. It will be seen that an arc back therefore causes two short circuits, one on the d-c bus indicated by the "abnormal" dotted arrow marked X, and the other on the a-c system indicated by the "abnormal" dotted arrow Y.

It is desirable to remove these short circuits quickly. An interrupter in the

anode circuits removes the short circuits from the a-c and the d-c systems simultaneously.

The high-speed anode circuit breaker opens in response to the reverse direction of current in the anode. The current peak is limited to one-half cycle or less and the current completely interrupted in approximately one cycle.

In comparison, the high-speed cathode circuit breaker would only interrupt the feedback from the d-c bus into the faulty anode, but some additional means has to be used to remove the short circuit from the a-c system, either by opening the primary oil circuit breaker or by attempting to suppress the arc in the rectifier by ignition control, while the use of the high-speed anode circuit breaker goes directly to the source of the trouble and quickly and promptly interrupts the anode circuit. It should be noted that the use of an anode circuit breaker is not a substitute for a primary oil circuit breaker, but only a supplement of it. Transformer fault protection and normal switching generally require the use of primary circuit breakers when such large transformer unit is connected to an a-c bus.

Some of the specific advantages of high-speed anode circuit breakers, particularly in those cases where more than one rectifier supplies a common d-c bus, are:

(*a*). The transformer is protected against the high currents which may result when a rectifier arcs back. Such high currents impose very severe stresses on the transformer.

(*b*). The other rectifiers are protected against supplying large d-c currents to the faulty rectifier. Such protection against heavy currents reduces materially the tendency for the normal rectifiers to arc back "sympathetically."

(*c*). The remaining normal anodes on the same rectifier are not called upon to supply heavy currents to the faulty anode, and their tendency to arc back, either immediately or in the future, is greatly reduced. Arc-backs beget arc-backs.

(*d*). The use of anode breakers, with high-speed reverse-current trip on each pole, greatly simplifies the protective control system. There are no additional relays nor wiring to go wrong.

(*e*). When one rectifier transformer supplies two rectifiers, as is usually the case in electrochemical work, the use of high-speed anode circuit breakers will remove one of them on arc-back and permit the other to continue in uninterrupted service.

The principle of the high-speed anode circuit breaker has been well proven in service. It is so fundamentally a correct device for the protection of mercury-arc rectifiers that future electrochemical application without them will be rare indeed.

It will be noted from Figures 4 and 4A that a semihigh-speed cathode breaker is indicated. These semihigh-speed cathode breakers provide overload protection in the forward direction, since high-speed anode breakers which trip on reverse current are not particularly well suited to trip on straight overloads in the normal direction. The semihigh-speed cathode-breaker overload trip is given a slight time delay to permit the breaker to stay in until the high-speed anode breaker has cleared the arc-back. The semihigh-speed cathode breaker is also useful for normal emergency trip of the entire cell line.

Station Control

The station operator's control devices for controlling a station similar to that shown in Figures 3 and 4 are concentrated on an operator's control board.

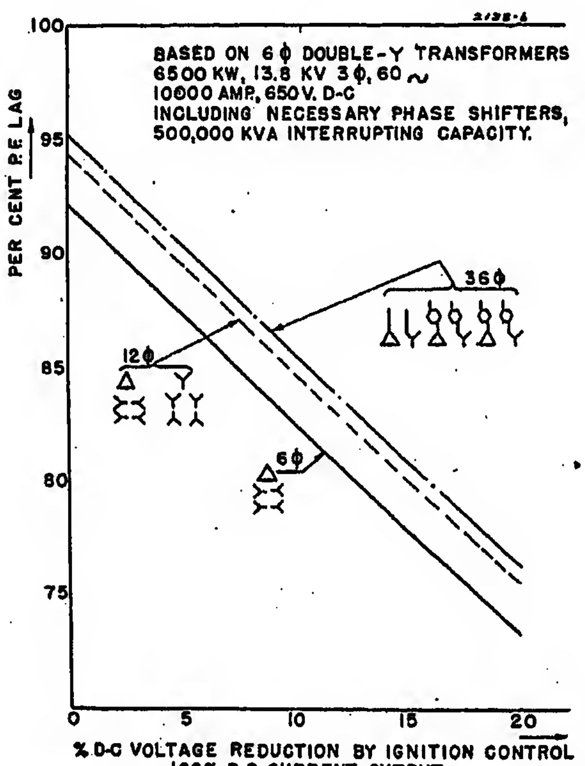

Figure 6. Power-factor characteristics for varying amount of grid control

The operator's functions in energizing such a cell line or taking it off the line are relatively simple. For energizing the cell line, the auxiliary circuits for water and vacuum pumps are energized, and then the a-c circuit breakers are closed. The anode and cathode breakers are next closed with the ignition circuit de-energized. The ignition circuit is then energized, permitting the rectifiers to take load. As previously mentioned, the d-c breakers cannot be closed with the ignition circuit energized, because the first breaker closed will trip again due to overload.

For some types of cell lines, and under some conditions, the operator may wish to start the cell line with the lowest possible d-c voltage permitted by ignition control, and energize the ignition circuit only after it has been retarded. All of these operations are performed at the operator's control board shown in Figure 3.

A cell line can be de-energized by simply tripping the cathode breakers. If one of the cathode breakers should lag materially behind the others, it will be forced to interrupt the entire cell-line current which represents an exceedingly heavy duty. If the operator desires and has the time, he may reduce the current interrupted by these breakers by first reducing the voltage and current on the entire cell line through the ignition control.

The power to cell lines should not be interrupted by de-energizing the ignition circuit. If this is attempted, the entire cell-line current somewhat attenuated will be finally transferred to a single anode. This is a serious overload for the particular anode and may cause serious damage to it. Even if all the cathode breakers are tripped simultaneously, they will open at slightly different moments. However, the magnetic energy stored in the cell-line circuit is dissipated quickly and without harm in the arc chutes of the cathode breaker.

Another method of de-energizing the cell line is to open the main a-c feeder breakers, a method which would correspond to the case of a complete power failure. Except for increased maintenance on the breaker, such interruption will not have any particularly bad effects, because the energy flow from the system is interrupted, and the current is transferred finally to the last conducting anode, only after it has died down to a relatively low and safe value.

Such stations as those illustrated by Figures 3 and 4 are continuously attended. The operations under normal circumstances are relatively simple and are usually confined to the observation of the instruments and the rectifiers. Where no automatic current nor voltage regulation is used, it is necessary to adjust the voltage from time to time by operating the tap changer or load-ratio control of the transformer, and perhaps occasionally to balance the load between the rectifiers by means of a slight amount of ignition control.

Temperature-Regulating Equipment

The losses in the rectifiers are usually removed by water cooling. There are a few installations of air-cooled rectifiers in Europe but no important installations in this country. In water-cooled rectifiers, the coolant is usually recirculated through some form of heat exchanger. Where the raw water supply is sufficiently cool,

clean, and abundant, these heat exchangers are generally water-to-water. Where the water supply is less favorable, these heat exchangers may be water-to-air.

The temperature-regulating heat exchangers as shown in the typical station layout of Figure 5 are usually located directly beneath the rectifier and the coolant continuously circulated between the rectifier and the heat exchanger. For most efficient rectifier operation, the temperature of this coolant is maintained at approximately 47 degrees centigrade. Thermostatically controlled valves on the heat exchanger maintain this temperature by automatically controlling the amount of raw cooling water flowing through the heat exchanger.

The recirculated liquid coolant is usually distilled water and may be treated with sodium dichromate to inhibit corrosion. These water-to-water heat exchangers can be manufactured for cooling water temperatures as high as 35 degrees centigrade (95 Fahrenheit). For a 36,000-kw rectifier installation considered in Figure 4, there would be required 420 gallons per minute of 85 degrees Fahrenheit raw cooling water.

In water-to-air heat exchangers, the coolant is also continuously circulated between the heat exchanger and the rectifier. A by-pass valve, thermostatically controlled, will pass more or less of the recirculated coolant through the heat exchanger while the fans run continuously.

Heat exchangers, when sodium-dichromate corrosion inhibitor is used, are at cathode potential and are therefore usually insulated from ground. Rubber hose is used to connect it to the rectifier and to the raw water supply.

The use of water-to-air heat exchangers, because of blower losses, may lower the station efficiency perhaps one tenth of one per cent, but since these blowers operate at full speed only a few months in the summer time, this is not an important consideration. The choice of water-to-water or water-to-air heat exchangers should only be considered from the standpoint of expense and quality of the raw water supply available. The installed cost of the water-to-water heat exchangers is considerably less than water-to-air, if the raw water is delivered to the building at no cost.

Station Arrangement

A typical station arrangement for a large electrochemical installation is shown in Figures 5A and 5B.

The transformers are installed outdoors and are usually of the oil-insulated self-cooled type.

The temperature-regulating heat exchangers are installed on the first floor of the main rectifier building directly below each of the rectifiers to which they are connected. For such large installations this arrangement gives the best economy of building space.

The rectifiers are mounted on the second floor at about the same elevation as the transformer secondary connections. Bus connections to the individual rectifier anodes are made preferably below the rectifier assembly. The cathode connections to the cathode breakers are also made from below. In this particular illustration, the neutral or negative connection from the interphase transformer is carried across the station directly below the roof.

The d-c breakers may be installed either on the ground floor or on the rectifier floor. An argument in favor of installing them on the rectifier floor is that the operator is then able to see that the breakers on a particular rectifier are open when work has to be done on this rectifier. However, space is generally available in the basement, and a narrower building results if these devices are placed in the basement.

On the second or rectifier floor of the building, is placed the operators' control board as illustrated in Figure 3. The control boards for two or even three pot-line equipments may be grouped together and under the control of one operator.

On the ground floor, aisle space is provided so that a portable degassing transformer may be moved from one rectifier to the other for initial degassing, or for degassing after a single unit has been returned to service after repairs.

The control cubicles containing the control devices for the pump and other auxiliaries for each rectifier are installed on the end of each rectifier.

The a-c switchgear in this particular illustration of Figure 5A is shown located in a separate building with the two autotransformers adjacent thereto.

It should be noted that this installation is typical of many electrochemical installations in that all of the 13.8-kv power cable enters the transformers and switchgear through pot heads, and there are no exposed 13.8-kv bushings in the system. This protection is a matter of some importance to those electrochemical installations where corrosive atmospheres or conducting dust is present.

A-C Power Supply

Reliability of power supply for electrochemical installations is considered essential, since loss of power even for a short time may be very costly, in addition to being naturally objectionable from the standpoint of the operator. In the case of chlorine cell lines, loss of power requires the immediate stoppage of auxiliary gas pumps and of the feed to the cells; otherwise chlorine gas may be liberated in the cell room with undesirable effects on the operators and the surrounding neighborhood. With aluminum and magnesium plants, the loss of power for an hour or more may cause the cells to freeze. In general, loss of power may mean an interruption of production for a much longer period than the duration of such power interruption and may require a costly and slow restarting of the process.

Therefore, the electric equipment and its power supply, which are the heart of this process, must be of the most reliable type and must include such spare capacity as may be indicated by experience. Even the best or most efficient or most reliable electric equipment will have an installed cost not usually exceeding 30 per cent of the total installed cost of the entire electrolytic plant which it supplies.

As shown in Figure 4, two autotransformers supply each pot line so that the reliability of power supply is insured, at least on a reduced basis if one autotransformer or its cable feed is lost. Each autotransformer has a continuous rating of two thirds of a pot line.

By proper separation of circuits, even these large electrochemical installations may be kept within a 500,000-kva short-circuit capacity breaker. Normal distribution voltage in well over 90 per cent of the electrochemical installations in the United States is 13.8 kv.

The double bus systems shown on the output side of the autotransformers permit any of the six main rectifier transformers to be connected to either of the autotransformers. While not indicated in Figure 4, the double bus system permits the autotransformers to be connected to different bus sections with no interconnections between feeders. This would be particularly important, if each autotransformer is fed from a different bus section in the powerhouse, and these powerhouse bus sections are tied together through a synchronizing or transfer bus. The fact that there is no interconnection on the output side of the autotransformers avoids any possibility of by-passing the synchronizing bus.

The outdoor substation supplying the three pot lines should logically have 45-degree transformers, to be consistent with the rectifier transformer practice. In the arrangement shown in Figure 4, the main stepdown transformers are provided with

fans, so that, in the event of the loss of one bank, the fans can be started on the remaining two banks, and power transferred to them through the transfer bus.

The transfer bus is normally disconnected and the bus sections *A*, *B*, and *C* are independent, thus localizing the effects of short circuits and other disturbances.

Because of the current-carrying capacity required on the main outdoor transformer bank, Figure 4 indicates that the delta for the secondary windings of these transformers is made on the metal-clad bus by using two 2,000-ampere, triple-pole breakers. This is a method frequently resorted to in order to obtain the necessary current-carrying capacity in metal-clad switchgear.

The system should, of course, be supplied with two-incoming high-voltage lines, in accordance with the standards of reliability required. Since interruptions on the incoming high-voltage lines are the most frequent, the cost of high-voltage circuit breakers and protective relaying is justified.

Factors Affecting the Mechanical Deterioration of Cellulose Insulation

F. M. CLARK
ASSOCIATE AIEE

Synopsis: The rate of mechanical deterioration of cellulose insulation is dependent on the conditions of its use. Those factors of major importance are the temperature applied and the presence of oxygen and moisture. Moisture even in small amounts greatly affects the mechanical stability of the cellulose insulation. In general, the mechanical life of the insulation is reduced by half for each doubling in water content. Deterioration promoted by oxidation is most effective at temperatures below 120 degrees centigrade and is accelerated by the presence of moisture.

The rate of deterioration for substantially dry insulation at temperatures above 120 degrees centigrade is dependent upon its previous history. Intermittent exposure to high temperature effects are additive. The "eight-degree-centigrade rule," indicative that the rate of mechanical deterioration is doubled for each eight-degree-centigrade increase from a base temperature of 120 degrees centigrade or higher, applies most closely for practical use when the insulation under study has lost more than 50 per cent of its tensile strength.

CELLULOSE insulation is widely used as the dielectric in high-voltage electric apparatus. Like mineral oil with which it is usually associated, cellulose in commercial practice is subject to chemical change to an extent which is dependent upon the conditions of its use. The deteriorating effects of temperature and oxygen are generally recognized and have been the subject of exhaustive research and discussion. The effect of moisture, as described in this paper, has not been carefully evaluated in previous studies of cellulose stability, despite the fact that it appears to play a dominant role in the chemical and mechanical changes exhibited by the cellulose when exposed to temperatures within the range encountered in the commercial use of transformers and other high-voltage electric apparatus.

As a material for insulating electric apparatus cellulose is used in a variety of forms. In its widest application cellulose is used in the form of paper sheets or tapes for the insulation of conductors which may vary greatly in size and shape. In some applications it is subjected to relatively low electric stresses and serves chiefly as a spacing material for the separation of adjacent conductors. In other applications it is subject to severe electric stress which in the case of capacitors and similar apparatus may be as high as 300 or 400 volts per mil. In most of its uses the cellulose is impregnated with mineral oil or varnish or both. It may, on the one hand, be found in apparatus operating under conditions allowing more or less free access of air or, on the other hand, in apparatus where contact with air or other source of oxygen is substantially eliminated by the use of hermetically sealed containers or by other means. In all of its applications, however, it is essential that chemical deterioration of the cellulose, resulting in the loss of dielectric efficiency and mechanical strength, shall be completely eliminated or carefully controlled in order that the insulation may be able to withstand the severe electric and mechanical stresses set up, not only in the normal use of the apparatus but also under short circuit or overload conditions.

One of the most difficult of all engineering problems is the translation of laboratory "life" data into terms of practical usage. The present paper concerns itself entirely with laboratory data correlating those factors of time, temperature, moisture, and oxidation which have been found to be important in affecting the mechanical stability of cellulose insulation. The results obtained are reported in order to assist the engineer in his efforts to use materials efficiently. The relative importance of the deteriorating factors investigated can only be finally determined from a study of the results obtained under the conditions of commercial use.

Objects of Investigation

In a previous paper[1] it has been related that the chemical and mechanical deterioration of cellulose is a complicated phenomenon greatly influenced by the decomposition products formed as a result of the chemical changes involved. Among those products are organic acids, water, hydrocarbons and their derivatives, and gases such as the oxides of carbon. It has been demonstrated that once initiated the chemical changes involved are accelerated to a degree dependent on the retention of the decomposition products. The present paper has as one of its objects the evaluation of the influence exerted by the presence of moisture on the mechanical stability of cellulose when aged under conditions which do not allow the escape of the deterioration products formed.

It has already been shown[2] that cellulose sheets or tapes will deteriorate mechanically when heated even in the absence of oxygen. The pyrochemical effect as contrasted to the effects of severe oxidation become pronounced as the temperature is raised above 120 degrees centigrade. Cellulose when heated passes through a "stable period" during which the mechanical properties are maintained. The presence of oxygen is chiefly effective in reducing the duration of this "stable period." It is a further object of this paper to demonstrate the effect of moisture on the duration of this "stable period."

Cellulose insulation as in transformers is subject to wide variations in temperature. Under overload conditions localized temperatures are obtained far in excess of those normally associated with the daily use of the apparatus. Engineering practice is to assume that the effects of such abnormal temperatures are additive. It is another object of this paper to examine the validity of such an assumption.

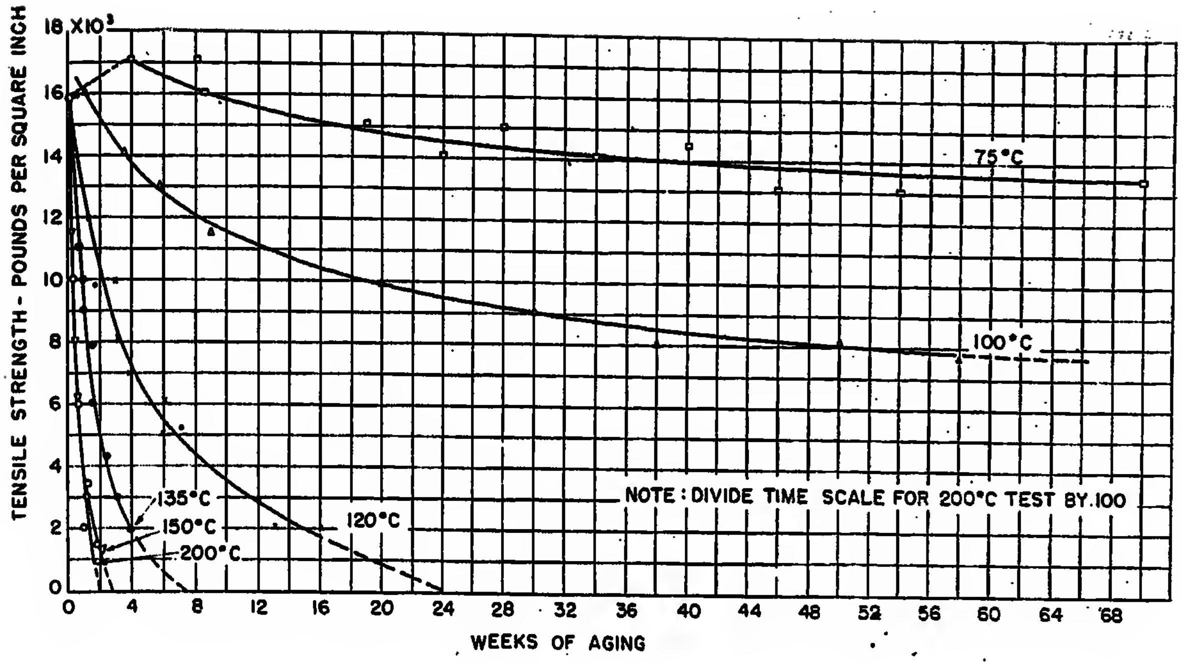

Figure 2. The tensile strength of vacuum-dried and oil-impregnated 0.003-inch Manila insulating paper as affected by aging in sealed containers under oil, the surface of which was in contact with oxygen gas

Chemical reactions involving organic materials are accelerated by heat. In a general sense, it is accepted that such chemical reactions are increased twofold for each ten-degree-centigrade increment in temperature. Montsinger in previous publications[3,4] has called attention to the importance of properly evaluating the influences of temperature as a criterion of the ability of transformer insulation to withstand the effects of temporary overloads encountered in the use of transformers. He has suggested the "eight-degree rule," indicative that the rate of the mechanical deterioration of cellulose doubles for each eight-degree-centigrade rise in temperature. It is a final object of this paper to demonstrate the rate of cellulose deterioration as affected by temperature increase under widely different conditions of possible use.

Testing Technique

Experience in the study of cellulose deterioration at elevated temperature demonstrates the necessity of closely controlling all those factors which have long been recognized as of fundamental importance in the study of sludge formation in mineral transformer oil.[5,6] The temperature must be carefully controlled. In order to obtain duplicate test results, the temperature should be controlled to ±0.5 degree centigrade.

The testing receptacle in which the cellulose is aged must be carefully selected if reproducible results are to be obtained. Access of air or other gases must be controlled. The ease of escape of products formed as a result of the deterioration must be clearly described and evaluated in terms of practical usage. The widely different results (Figure 1) accompanying a change in the conditioning treatment of the insulation or in the design of the vessel used for the aging only serve to emphasize the confusion which may arise when details of this type are ignored.

In the "sealed-tube" tests hereinafter described, the tube is of Pyrex glass and measures 200 millimeters in length and 25 millimeters in diameter. When sealed it has a volume of 59 milliliters. The conditioned oil and the oil-immersed paper insulation fill the tube to the 50-milliliter mark, the remaining 9 milliliters being filled with the stated gas conditioned as described. The paper used is cut before conditioning in strips, each one-half inch wide and ten inches long. The paper used throughout this study is 0.003-inch Manila cable paper. Ten strips of such paper, conditioned as described, are used in each test. This gives a ratio of approximately one-quarter pound of paper per gallon of oil. The tensile strength of the paper is determined in a room maintained at 65 per cent relative humidity, 70 degrees Fahrenheit. The oil-impregnated papers are tested immediately after having been taken from immersion in the oil. The tensile strength is determined in a Schopper testing apparatus. The results reported are the average of ten individual tensile strength tests.

The mineral oil used throughout this paper is a typical American transformer oil (58 seconds Saybolt Universal viscosity at 37.8 degrees centigrade) and is manufactured from Gulf Coast crude. Before use it is completely degassed and dried. During test it is saturated with the gas with which it is in contact, as is described in each particular instance.

Moisture Determination

The problem of determining the moisture content of cellulose sheets has been recognized as difficult and subject to variation because of the instability of the cellulose itself. Urquhart and Williams[7] have determined that oven drying at 110 degrees centigrade are as satisfactory as vacuum drying over phosphorous pentoxide at 15 degrees centigrade. Such methods may be well suited for roughly determining the water content of cellulose containing large amounts of moisture, such as is present in ordinary paper exposed to atmospheric conditions, but they fail to give accurate test values when the water content of the paper is materially reduced.

A satisfactory method of test for determining the water content of insulating papers has been established as follows:

Approximately 50 grams of paper, preferably cut into pieces about three by three-fourths inches in size (less weight of paper if suspected to be high in water content, more weight if suspected to be of low water content) is immersed quickly in 500 milliliters of dry liquid such as mineral transformer oil contained in a thoroughly dry 1,000-milliliter round bottom flask. Dry nitrogen gas is passed through the liquid at the rate of 100 milliliters per minute with a fritted gas washing tube to obtain the best dispersion. The temperature of the liquid is raised to 110 degrees centigrade plus or minus two degrees. The gas after passing from the liquid-paper suspension is passed through two liquid air-cooled traps connected in series where the moisture and other volatile materials are condensed. The outlet for the nitrogen gas is protected by a conventional drying tube to prevent suck back of atmospheric moisture. The nitrogen gas is passed through the test flask for three hours after which the water collected in the liquid air traps is quantitatively determined. The nitrogen gas treatment is repeated in three-hour steps at 110 degrees centigrade until all water has been driven from the paper under test. The quantitative test for the water collected is carried out as follows:

Ten milliliters of an acetyl chloride solution in dry benzene (118 grams per liter of solution) are added to a dry 250-milliliter glass stoppered flask and cooled in an ice bath. Two milliliters of dry pyridene are added dropwise to the acetyl chloride solution with continual shaking. A white precipitate of acetyl chloride-pyridene complex is formed.

The frozen condensate in the traps is dissolved in 25 cubic centimeters of dry acetone and added to the cold acetyl chloride-pyridene complex. The acetone is added in 5-5–2.5–2.5 milliliter portions to the first trap and in 5–2.5–2.5 milliliter

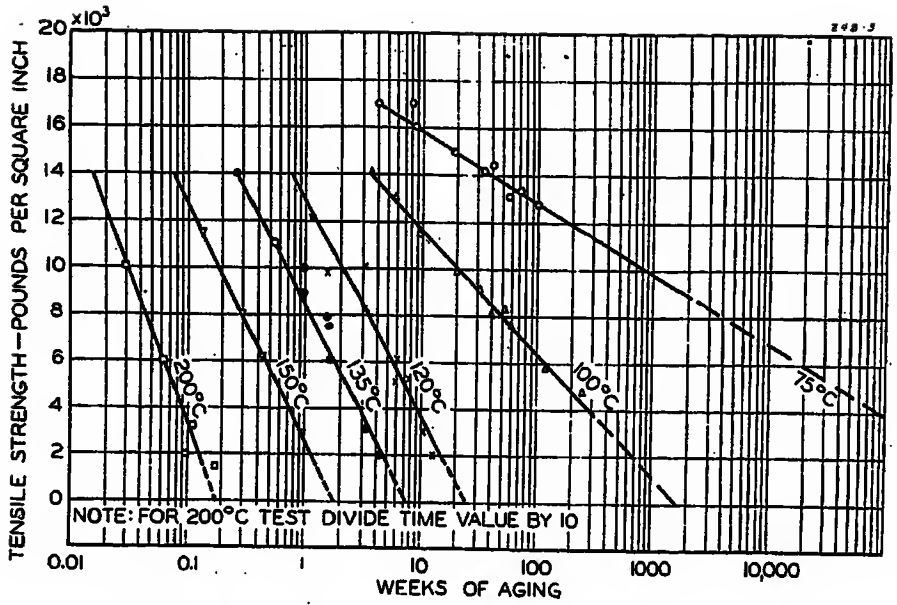

Figure 3. The tensile strength of vacuum-dried and oil-impregnated 0.003-inch Manila insulating paper as affected by aging in sealed glass containers under oil, the surface of which was in contact with oxygen gas

portions to the second trap. The stoppered flask is then removed from the ice bath and allowed to stand at least 15 and not more than 30 minutes with occasional shaking out of contact with direct sunlight. Four milliliters of dry ethyl alcohol are added and the mixture is well shaken. Sixteen milliliters more of dry ethyl alcohol are then added and after being shaken and allowed to stand for five minutes, the mixture is titrated with 0.5 normal sodium hydroxide to a phenol phthalein end point. A blank test is run with all conditions identical in order to correct for residual moisture in the reagents and apparatus. The amount of moisture in the paper, expressed in terms of its dry weight is then calculated.

Using this procedure definite and reproducible test results have been obtained. Care must be taken, however, to avoid decomposition and subsequent removal of the "water of constitution" from the cellulose sheet. If the analysis be carried beyond the point at which the water evolution from the paper drops to zero, subsequent heating will result eventually in some decomposition of the cellulose.[1] The formation of water as a result of this decomposition will obscure the real moisture content determination.

The determination of the moisture content of a cellulose sheet is difficult and fraught with many technical pitfalls. The method described gives results which appear lower than those heretofore reported for mineral oil-treated cellulose insulation.[11] Pending further experimental data, the moisture contents described in subsequent paragraphs might well be considered as "relative" rather than as fixed and absolute values. Such a precaution in no wise diminishes the importance of the studies demonstrating the marked effect of moisture on the mechanical life of the cellulose insulation.

Expression of Test Results

Because of its greater degree of reproducibility, the tensile test has been adopted as the gauge of mechanical strength of the cellulose sheet and its rate of deterioration. Typical time relationships are illustrated in Figure 2. Because of the difficulty in clear presentation, however, such relations are not generally used in this paper. The semilogarithmic relationship between the tensile strength and the duration of aging have been found to be better suited for clear presentation (Figure 3).

The Effect of Temperature

There are many technical processes which employ cellulose products at high temperature. This has led to the initiation of many researches concerned with the stability of cellulose products over short periods of heating. The general conclusion reached has been that cellulose suffers some decomposition at temperatures above 150 degrees centigrade. The problem of the insulation engineer however is the problem of time and temperature. The stability of cellulose during short periods of heating[1,2] are frequently misleading. Knecht[8] has shown that, when cotton is heated for 336 hours at 80 degrees centigrade, chemical changes occur which endow the cellulose with reducing powers. It is the effect of these often overlooked chemical changes, culminating in mechanical deterioration, with which this paper is concerned. The time of heating is obviously of importance.

The effect of time and temperature over the range from 75 to 200 degrees centigrade on the tensile strength of vacuum-dried and oil-impregnated 0.003-inch Manila paper is illustrated in Figure 2.

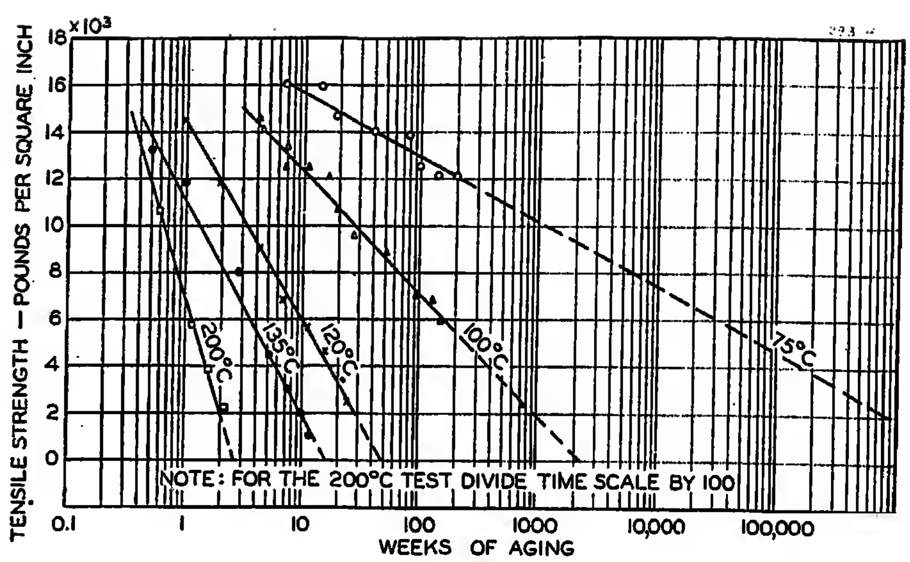

Figure 4. The tensile strength of vacuum-dried and oil-impregnated 0.003-inch Manila insulating paper as affected by aging in sealed glass containers under oil, the surface of which was in contact with nitrogen gas

During the aging runs the insulation was immersed in dry oil in sealed Pyrex glass tubes, the surface of the oil being in contact with oxygen as already described. The semilogarithmic relation of tensile strength and time of heating is illustrated in Figure 3. Figure 4 illustrates similar data for vacuum-dried, oil-impregnated 0.003-inch Manila paper, the surface of the oil in which the paper is immersed being in contact with dry nitrogen gas. The marked effect of temperature on the mechanical stability of Manila paper is illustrated in Figure 5 which shows the "50 per cent life" in tensile strength over

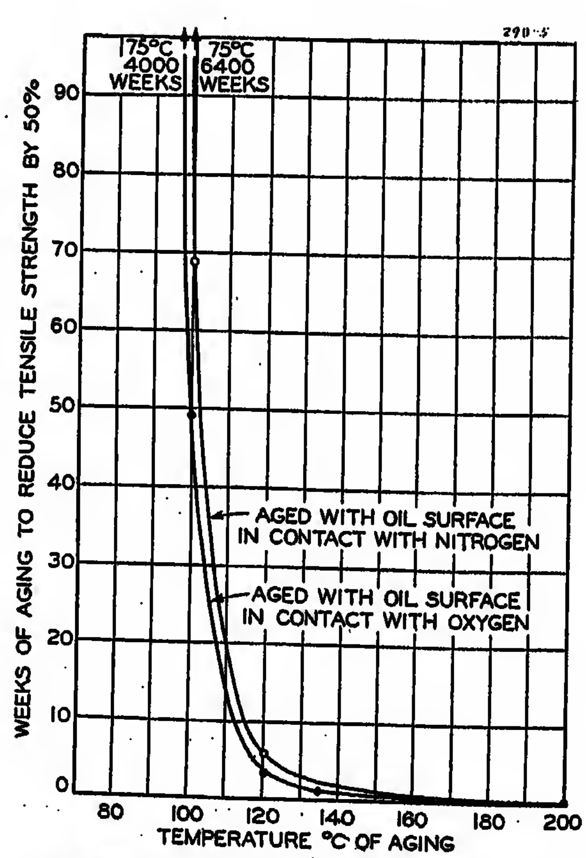

Figure 5. Showing the marked effect of temperature increase above 75 degrees centigrade in the mechanical life of vacuum-dried and oil-impregnated 0.003-inch Manila insulation paper when aged in sealed glass containers under oil, the surface of which was in contact with oxygen or nitrogen gas as indicated

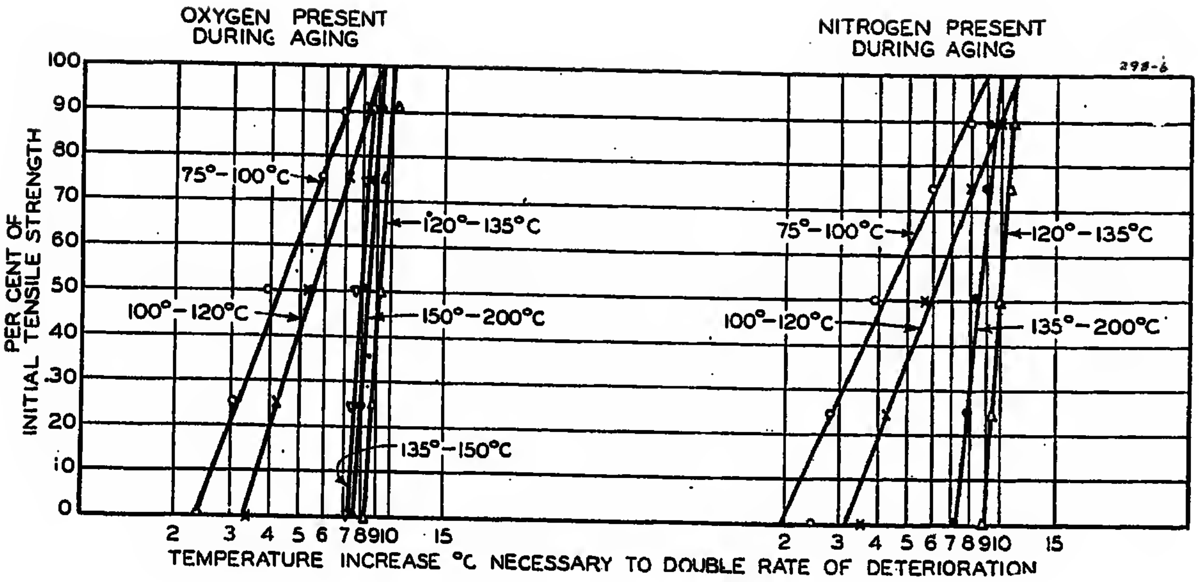

Figure 6. The rate of mechanical deterioration of vacuum-dried and oil-impregnated 0.003-inch Manila paper becomes more sensitive to temperature increase as the deterioration progresses

The effect is most pronounced when the temperature of test is below 120 degrees centigrade

the temperature range from 75 to 200 degrees centigrade. It is clearly evident that as the temperature rises above 75 degrees centigrade the deterioration proceeds at a rapidly increasing rate. It is the proper evaluation of this rapidly increasing rate of deterioration which is of fundamental importance in the application of cellulose insulation in high-voltage electric apparatus.

Inspection of the data presented in Figures, 2, 3, 4, and 5 at once leads to the conclusion that the rate of mechanical deterioration of Manila insulating paper cannot be expressed in terms of any single temperature expression. Figure 6 plots as a semilogarithmic expression the relation between the deteriorating mechanical strength and that temperature rise which is necessary in order to produce a twofold increase in the mechanical deterioration over the temperature range shown. For temperatures in the range from 75 to 100 degrees centigrade the effect of temperature change is extremely marked, whether the deterioration be produced in the presence or absence of oxygen. In this range, an increase in temperature of but 2.4 degrees centigrade will reduce the total life of the insulation by half. With temperatures of 120 degrees centigrade and higher, however, the deterioration is less sensitive to temperature increase. To double the rate of deterioration for these higher temperatures (reduce the total life by half), an increase ranging between approximately seven and ten degrees centigrade is necessary. The relation of the temperature of the aging to that temperature increase necessary to produce a twofold rate of deterioration when the tensile strength has been reduced to 50 per cent and zero per cent of its initial value is illustrated in Figure 7. The so-called "eight-degree rule" suggested by Montsinger is a good practical compromise for the higher temperatures of use (120 degrees centigrade and higher) when the tensile strength has been reduced to less than about 50 per cent of the initial value.

The Effect of Oxygen

The problem of evaluating the practical effect of oxygen on the mechanical strength of cellulose insulation during the normal use of a transformer or similar apparatus is difficult, because of the wide differences in transformer designs. The transformer designs of greatest importance for consideration, however, are the hermetically sealed type containing a gas cushion and the conservator type. Each of these has a limited supply of available oxygen. In the conservator transformer the amount of oxygen is limited to that carried into the transformer as an air solution in the mineral oil. In the hermetically sealed transformer the amount of oxygen is limited to that present in oil solution and in the gas cushion when the transformer is sealed. When this gas cushion consists of nitrogen gas, the amount of oxygen available within the transformer is negligible if the mineral oil is properly deaerated before the transformer is sealed.

In the laboratory study of the effects of oxidation on the mechanical strength of the cellulose insulation, an attempt has been made to exaggerate the hermetically sealed transformer design. The sealed tubes have been filled with oil and the oil-immersed insulation to 85 per cent of the volume. The gas cushion occupies the remaining 15 per cent of the volume. These are the approximate relationships of oil to gas volumes in the average hermetically sealed transformer. The effect of oxidation has been exaggerated by the use of pure oxygen in the gas space. Pure oxygen has been used to exaggerate the oxidation possibilities, since in a previous publication[2] the presence of air has been demonstrated to be of negligible oxidation effect within the duration of the laboratory tests made. The use of this type of test arrangement is considered to be more severe than the conditions which are met in either the conservator or the hermetically sealed type of oil-filled transformer.

It has been suggested[10,12] that the effect of oxygen on the mechanical deterioration of oil-treated cellulose insulation involves consideration of the acids formed as a result of the oxidation of the oil itself. In a general sense this is true. Therefore, since the most corrosive acids formed both from the oil oxidation and from the oxidation of the cellulose are volatile at the temperature of the tests described, sealed containers have been used for the aging study. This insures that all products of decomposition and oxidation, whether from the oil or from the cellulose, are retained within the test receptacle. From the practical standpoint this procedure is justified, since the mechanical deteriora-

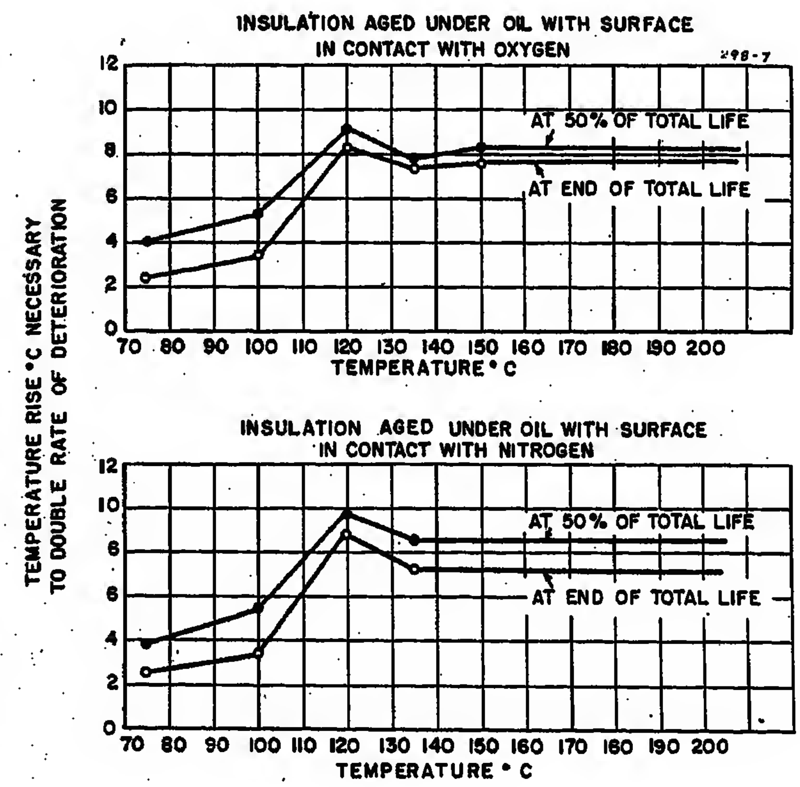

Figure 7. The "eight-degree rule" correlating temperature increase and mechanical deterioration of vacuum-dried and oil-impregnated 0.003-inch Manila paper applies with practical accuracy when the paper has deteriorated to at least 50 per cent of its initial value at temperatures of 120 degrees centigrade and higher

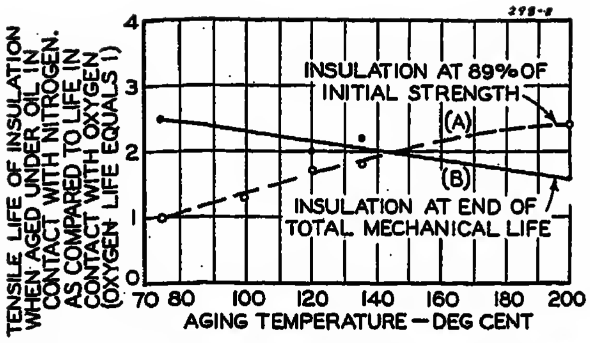

Figure 8. The elimination of oxygen increases the initial stability of vacuum-dried and oil-impregnated 0.003-inch Manila paper over the temperature range 75–100 degrees centigrade

The total life of the insulation, however is progressively less affected by the elimination of oxidation as the temperature of the aging is increased

tion reported therefore includes consideration of the accumulated effects of all the oxidation and decomposition that occurs.

In a previous publication[2] it was concluded that the "single effect of oxidation was restricted to the initial periods of treatment at temperatures lower than 120 degrees centigrade. At higher temperatures pyrochemical decomposition occurs . . ." The data presented extend and support this conclusion and indicate that the major effect of oxidation is produced when the insulation is exposed to the lower testing temperatures. At 75 degrees centigrade the deterioration due to oxidation becomes more pronounced as the mechanical aging progresses. At higher temperatures the pyrochemical decomposition of the cellulose tends to reduce the effects of oxidation.

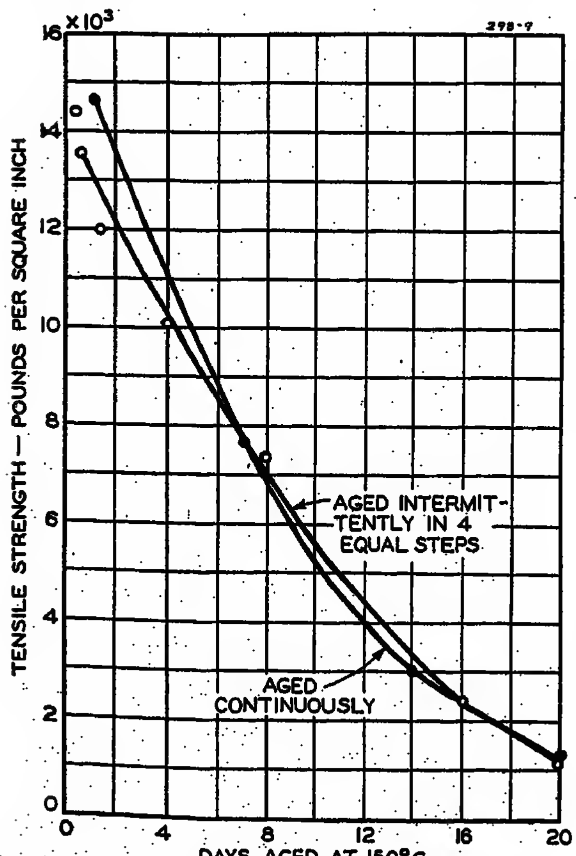

Figure 9. The mechanical aging of vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila insulating paper at 150 degrees centigrade in the presence of nitrogen gas is an additive function of the total period of heating when intermittently applied

Figure 8 illustrates the effect of oxidation on the deterioration of the vacuum-dried and oil-impregnated 0.003-inch Manila paper for two degrees of deterioration. Curve *A* illustrates the increased life of the insulation which is obtained as a result of the elimination of oxidation when the mechanical strength has been reduced to 89 per cent of its initial tensile strength. This value corresponds roughly to the end of the "stable period." The effect of oxygen elimination increases with the temperature of the exposure. This supports the conclusion that the duration of the "stable period" is reduced by oxidation processes. When, however, the total life of the insulation is considered (tensile strength zero), curve *B* supports the conclusion that the occurrence of pyrochemical decomposition during the later stages of the cellulose aging becomes more pronounced with the higher testing temperatures and reduces the beneficial effects normally associated with the elimination of oxygen.

Intermittent Aging

The total aging of cellulose insulation when exposed intermittently to high temperatures necessarily includes the deterioration which occurs during the heating and cooling periods. To determine whether the intermittent application of high temperature is strictly additive, the insulation contained in the sealed glass tubes was heated as rapidly as possible by immersion in an oil bath maintained continuously at 150 degrees centigrade, and cooled rapidly by transfer to an oil bath maintained continuously at 25 degrees centigrade. This reduced the effect of the heating and cooling periods to a minimum. The effect of such intermittent heating and cooling on the tensile strength of vacuum-dried, oil-impregnated, 0.003-inch Manila insulating paper aged under mineral transformer oil at 150 degrees centigrade is illustrated in Figures 9 and 10. The intermittent aging relation was obtained by heating the insulation at 150 degrees centigrade for four equal periods of time. Between these heating periods the insulation was maintained at 25 degrees for 24 hours. In the absence of oxygen, the effect of intermittent heating has been found to be strictly additive within the limits of experimental error (Figure 9). In the presence of oxygen (Figure 10) the additive effect again appears to be within the limits of experimental error until the insulation has lost approximately 50 per cent of its initial tensile strength. For a

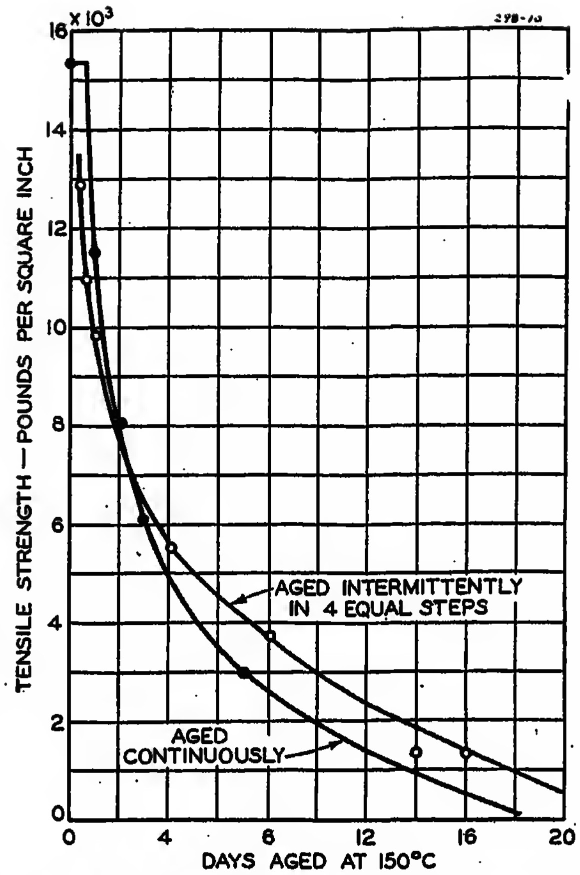

Figure 10. The effect of intermittent heating at 150 degrees centigrade on the mechanical strength of vacuum-dried, oil-treated, and oil-immersed 0.003-inch Manila insulating paper in the presence of oxygen

greater degree of deterioration the effect of intermittent aging appears less than additive, although the differences observed do not appear of major significance. Pending further investigation, it is concluded that the results obtained justify the engineering practice which considers the effects of intermittent heating at high temperature to be additive.

The Effect of Moisture on the Tensile Strength

Inspection of the data presented (Figure 6) correlating the effect of temperature on the rate of mechanical deteriora-

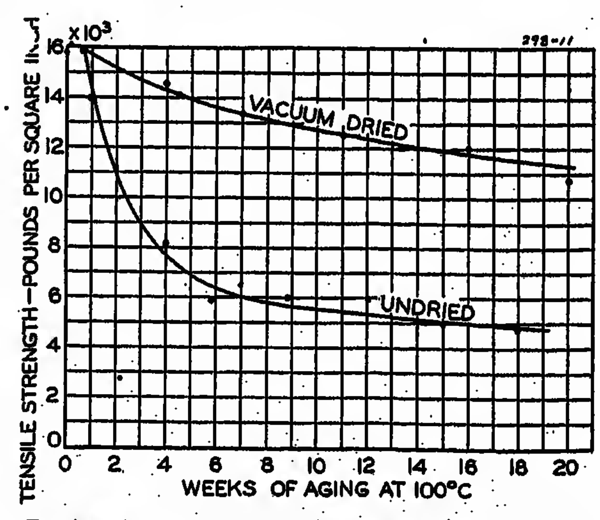

Figure 11. Showing the effect of moisture retained by cellulose in its normal condition on the mechanical stability of 0.003-inch Manila insulating paper during an aging run at 100 degrees centigrade in sealed glass tubes

During the aging the insulation is held under mineral transformer oil, the surface of which is in contact with nitrogen gas

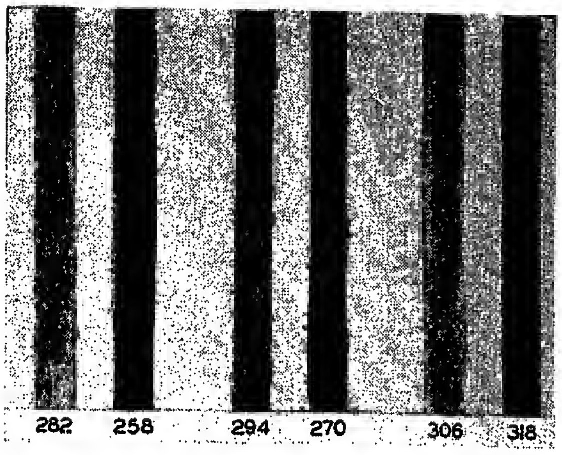

Figure 12. Illustrating the color darkening which accompanies the mechanical deterioration obtained when 0.003-inch Manila paper is aged in sealed tubes for two weeks at 120 degrees centigrade in the presence of moisture

Samples 282, 294, and 306—paper aged after having been vacuum dried and impregnated with mineral transformer oil, the surface of which is in contact with oxygen, nitrogen, and air respectively

Samples 258, 270, and 318—paper aged immersed in mineral transformer oil without previous drying, the oil being in contact with oxygen, nitrogen, and air respectively

tion leads to the observation that as the deterioration progresses it becomes more sensitive to temperature change. Thus, although in the early stages of heating, the paper deterioration increases approximately twofold for each seven to ten degrees centigrade rise in temperature, when the tensile strength has been reduced to as low as 25 per cent of its initial value, the rate of deterioration doubles for an increase of only about 2.4 to 9 degrees centigrade, depending on the testing temperature. This acceleration of the deterioration has been traced[1] to the effect of decomposition products retained in the body of the cellulose. Among such decomposition products is water. Because of the ability of water through ionization and otherwise to activate many of the products (acids and acidic materials) formed when cellulose undergoes deterioration, it is not unexpected to find that the mechanical strength of cellulose insulation is affected by the presence of moisture in even small amounts. Figure 11 illustrates the greater stability in the tensile strength of 0.003-inch Manila insulating paper which is obtained when the insulation is freed of its moisture before exposure to high temperature. In one instance the paper is heated under oil at 100 degrees centigrade without vacuum drying. In the other instance the paper is first vacuum dried to a low moisture content. The greater mechanical instability of the undried paper is accompanied by other visual evidence of greater chemical change. In contrast to the dried paper, the undried insulation after aging is darkened, reacts acidic, and smells strongly of a caramel odor, characteristic of overheated cellulose. Figure 12 illustrates the marked darkening in color which accompanies the greatly accelerated mechanical deterioration in the cellulose sheet when aged in the presence of moisture, even though the possibility of oxidation be eliminated by the use of nitrogen gas.

The data of Figure 11 are obtained as a result of an aging run in sealed glass vessels. It is suggested that the extreme variations reported in Figure 1 are due to the difference in the design of the aging vessel. On the one hand, the moisture and other volatile products originally present or formed during the test were allowed easy escape since the vessel was open to the air. On the other hand, the moisture and volatile products were completely retained in the sealed tube during the aging run. The wide difference in the test results reported in Figure 1 and in Figure 11 illustrates the wide variation which can be expected when the insulation is aged without careful attention to all of the conditions affecting the chemical stability of the cellulose. Not the least of these conditions is its moisture content.

The Effect of Moisture on the Rate of Deterioration as Affected by Temperature and Oxidation

The presence of moisture in cellulose insulation is of such importance in its effect on the mechanical stability at high temperature that it tends to modify the relationships set up for the dried insulation. To illustrate this, 0.003-inch Manila insulating paper containing 1.5 per cent moisture has been immersed in oil and aged at 100 and 120 degrees centigrade in sealed glass tubes of the type already described, the surface of the oil being in contact with oxygen or nitrogen gas. The results obtained are illustrated in Figure 13.

It has already been shown in Figure 8 that with dry insulation the presence of oxygen produces its maximum effect on the total life of the insulation when the aging is carried out at the lower testing temperatures. At 75 degrees centigrade the total life is increased about 2.5 times when an inert gas such as nitrogen is substituted for oxygen, thereby eliminating substantially all of the deterioration attributed to oxidation. When, however, there is a substantial amount of moisture present, its deteriorating influence accentuates the effect of oxidation. Figure 14 based on the data of Figure 13 demonstrates that in the presence of moisture the elimination of the oxidation reaction at 100 degrees centigrade has a more pronounced effect than is associated with elimination of oxygen on the life of the dried paper insulation.

In like manner, the effect of temperature increase on the aging of Manila insulating paper is materially modified by the presence of moisture. The deterioration becomes less sensitive to temperature change. This is illustrated in Figure 15.

Quantitative Effects of Moisture

The quantitative study of the effects of moisture on the mechanical aging of cellulose is made difficult by the fact that the equilibrium which exists between the amount of water retained by the cellulose and that present in the mineral transformer oil in which it is immersed shifts with changes in temperature.[9] The higher the temperature, the less water is retained by the cellulose. In the data relating to the water content of the cellulose in this and subsequent sections, the value given is the total water content of the oil and cellulose insulation within the sealed container at 25 degrees centigrade. At this temperature under the experimental conditions existing, substantially all of the water present is held by the cellulose and is so reported.

In order to eliminate the effects of oxidation which vary with the temperature of aging and the moisture content of the cellulose insulation, a typical set of test results, describing the deterioration of oil-impregnated and oil-immersed 0.003-inch Manila paper aged at 120 degrees centigrade in the presence of nitrogen, is selected to demonstrate the influence of

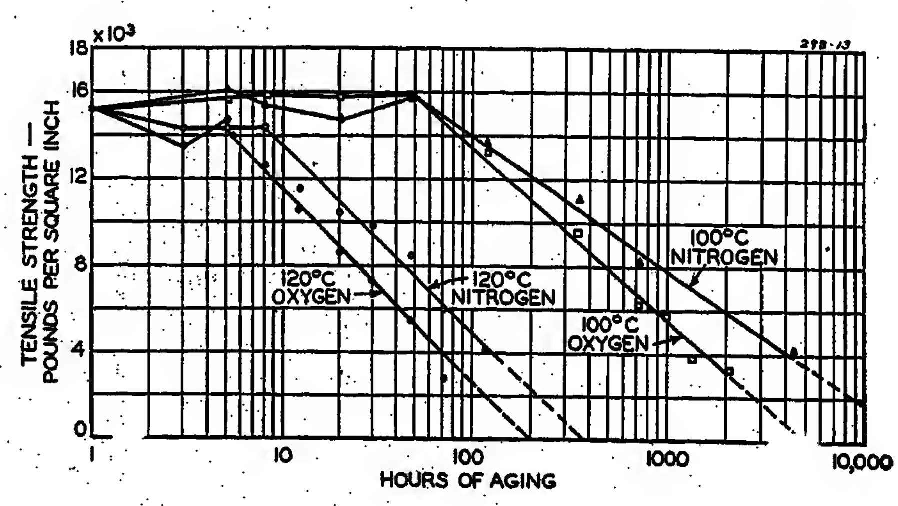

Figure 13. The aging of 0.003-inch Manila insulating paper containing 1.5 per cent moisture

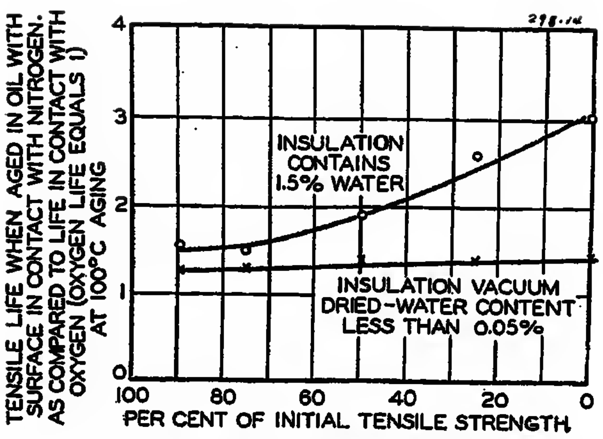

Figure 14. The importance of oxidation in promoting the mechanical deterioration of 0.003-inch Manila insulating paper is materially increased when the aging of the oil-treated and oil-immersed insulation is carried out in sealed tubes in the presence of moisture

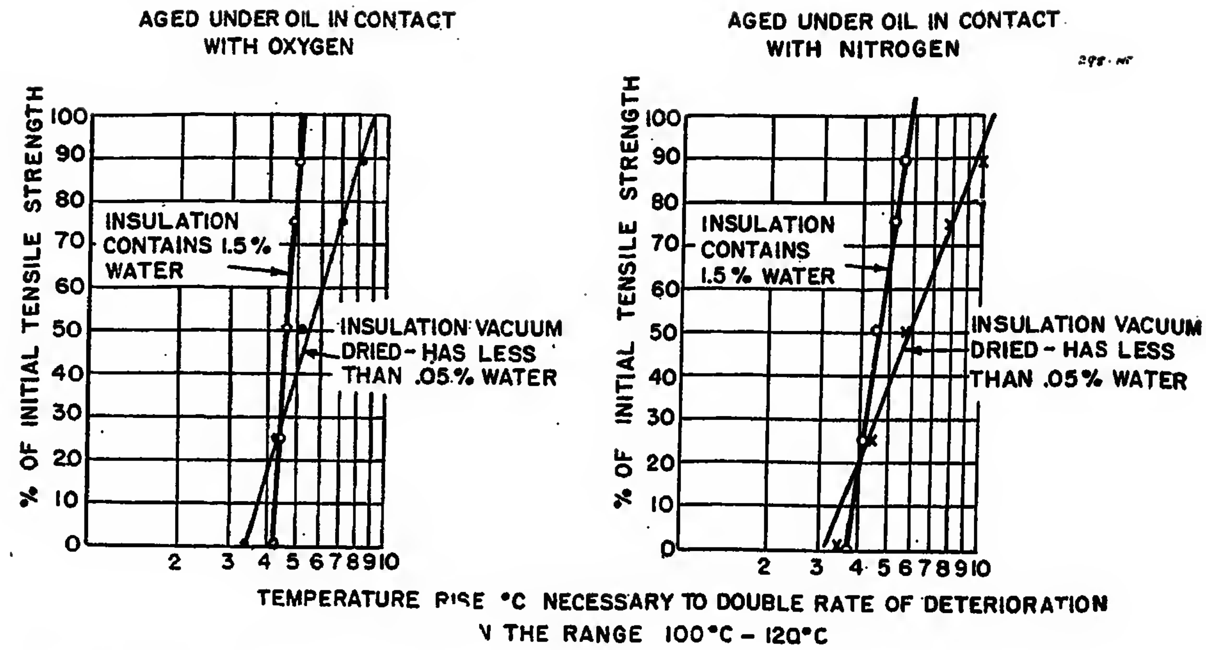

Figure 15. The presence of moisture in incompletely dried, oil-treated and oil-immersed 0.003-inch Manila insulating paper exaggerates the effect of temperature increase from 100 to 120 degrees centigrade during the major part of the mechanical life

The greater initial resistance to temperature increase characteristic of the well-dried insulation, however, is reduced as the result of water formation as the deterioration progresses

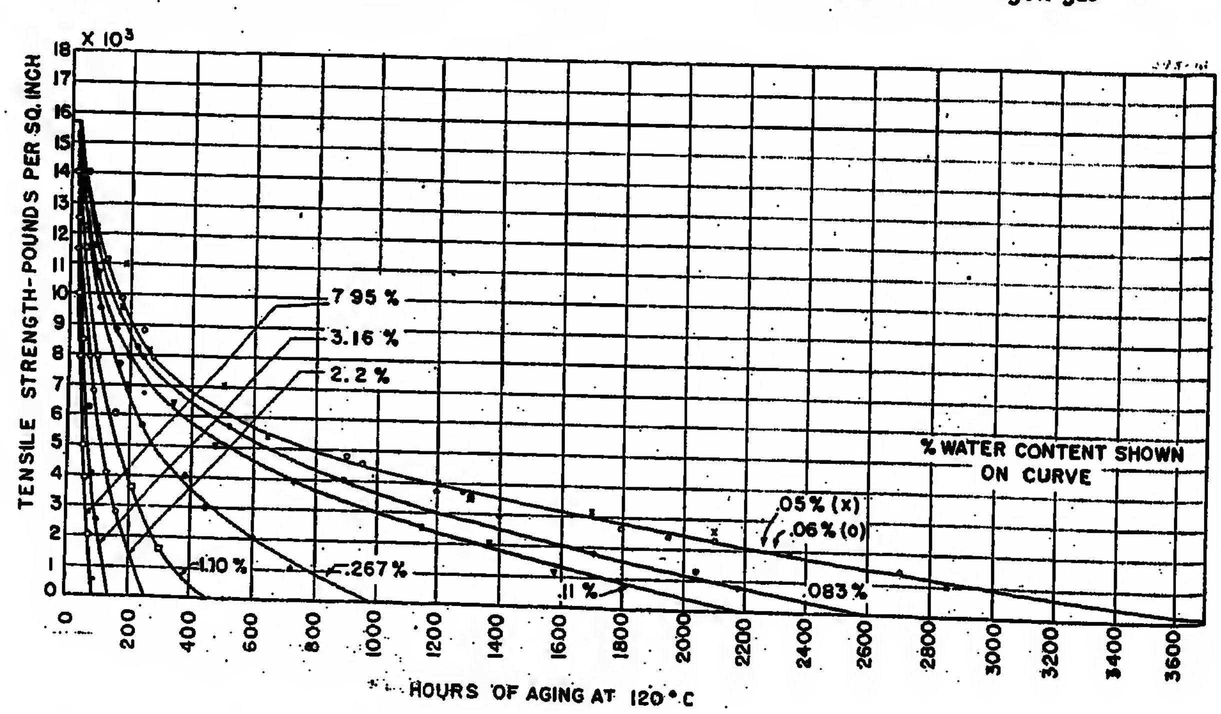
moisture. The insulation was first vacuum dried at 100 degrees centigrade for a period of time ranging from less than one hour to more than 100 hours, after which it was impregnated with gas-free, dry mineral transformer oil and sealed at once in glass vessels partially filled with the oil and oil-immersed insulation as already described. The gas with which the oil was saturated and with which the oil surface was in contact was dry nitrogen. The water content of the assembly was determined at the start of each aging run. The effect of moisture was marked. The total life of the insulation was reduced from a total of 3,700 hours (22 weeks), characteristic of the well-dried insulation, to a life of less than 100 hours (0.6 week), when the paper was substantially undried and contained about eight per cent moisture. Figure 16 represents the relationship found to prevail in a typical series of test results obtained simultaneously. As illustrated in Figure 17, there exists a logarithmic relation between the water content of the cellulose insulation and that period of time necessary to produce a given amount of mechanical deterioration in the cellulose sheet when aged at 120 degrees centigrade under the conditions applied.

In a previous paragraph it has been demonstrated that the effect of oxidation during the mechanical aging of cellulose insulation materially shortens the "stable period" during which the insulation can be heated at high temperature without evidence of mechanical deterioration. The effect of the initial water content of the cellulose of this "stable period" has been found to be negligible. In Figure 16 the stable period is shown to be approximately 40 hours, irrespective of the initial water content of the Manila insulating paper. Since oxidation is effective in determining the length of this "stable period" it is at once obvious that other testing factors which affect the oxidation reaction are of importance in determining its duration.

Because of the importance of mechanical stability in many of the dielectric applications of cellulose in electrical apparatus, the marked influence of moisture on the mechanical life of the insulation assumes practical value. Cellulose is a hygroscopic material and rapidly absorbs moisture from the surrounding medium.[9] The absorption of this moisture is effective in determining the subsequent rapidity in mechanical deterioration. From the data of Figure 16 it is obvious that, when oxidation is eliminated, the absorption of even small amounts of moisture by the dry insulation will materially reduce its mechanical life. Conversely, it is obvious that the absorption of relatively large amounts of moisture will have less effect on the aging of the improperly dried insulation. The relationship is illustrated in Figure 18.

To double the rate of mechanical deterioration in oil-treated and oil-immersed Manila paper in the absence of oxidation, the amount of moisture addition necessary is dependent upon the degree of deterioration which is selected for study. The total life of the insulation is halved (the deterioration rate doubled) by the addition of water equal to approximately 100 per cent of that originally present in the insulation. Thus, with a water content of 0.05 per cent, the life of oil-treated and oil-immersed Manila paper in the absence of oxygen is approximately 4,000 hours. With the absorption of an equal amount of moisture to give a total water content of 0.10 per cent, the total life of the insulation at 120 degrees centigrade is reduced to about 2,000 hours. On the other hand, to reduce by half the total

Figure 16. The effect of moisture content on the mechanical life of oil-impregnated and oil-immersed 0.003-inch Manila insulating paper when aged at 120 degrees centigrade in sealed glass containers, the oil surface being in contact with nitrogen gas



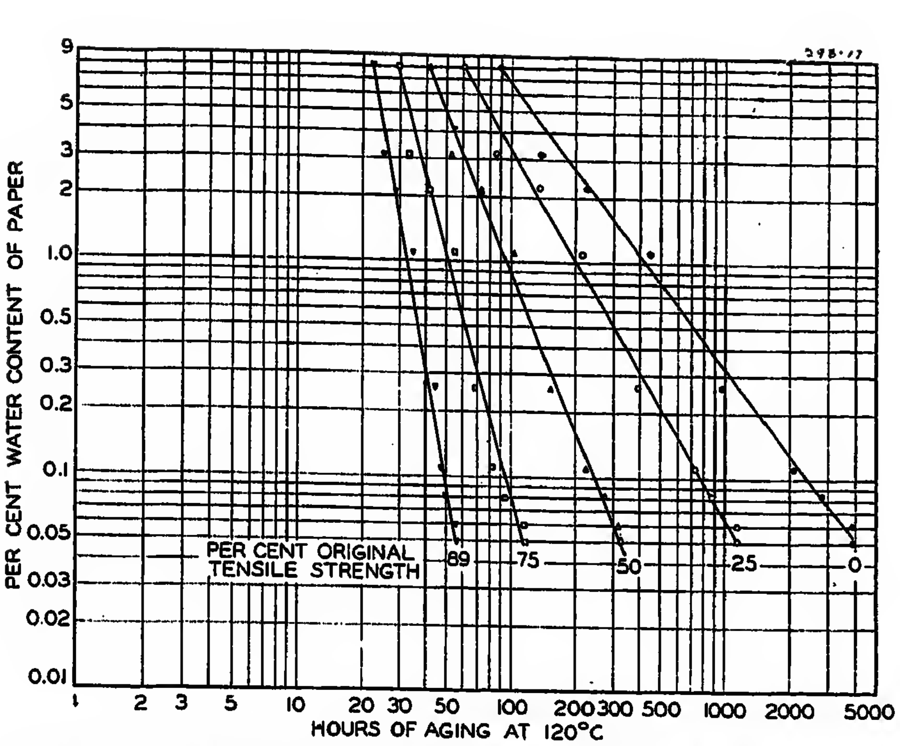


Figure 17. Under the conditions of test applying for the data of Figure 13, the water content of the cellulose insulation bears a logarithmic relation to the period of heating necessary to produce a given amount of mechanical deterioration

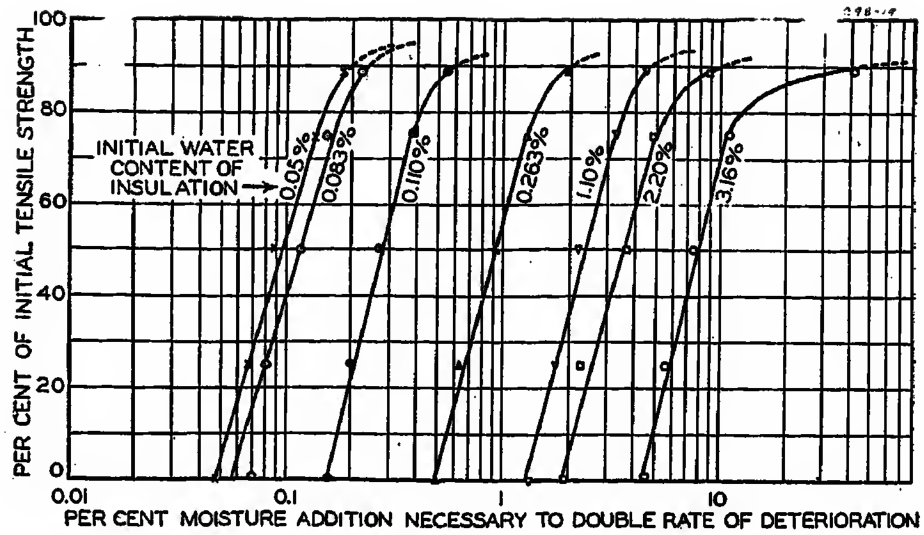

Figure 19. Illustrating the semilogarithmic relation which exists between the degree of mechanical deterioration of oil-treated and oil-immersed 0.003-inch Manila insulating paper and the amount of moisture addition necessary to double the rate of deterioration (halve the life) when heated in sealed glass vessels, the surface of the oil being in contact with nitrogen gas

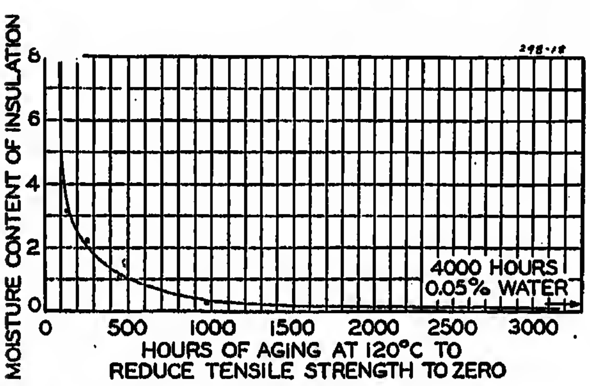

Figure 18. The elimination of moisture from cellulose insulation before being subjected to high temperature produces a rapidly increasing life as the moisture content is reduced below three per cent

Data based on the ultimate life values illustrated in Figure 16

life of the same insulation containing 3.16 per cent water from its value of 140 hours aged at 120 degrees centigrade, the addition of approximately 4.4 per cent more water is necessary. The relationship between the degree of mechanical deterioration of the oil-treated and oil-immersed 0.003-inch Manila insulating paper and the amount of moisture necessary to double the rate of deterioration (halve the life) in the absence of oxidation is shown in Figure 19.

Figure 19 is of importance. It demonstrates that as the point of mechanical strength selected for comparison approaches the original tensile strength of the insulation, the effect of water additions is reduced in the absence of oxygen, that is, greater water additions are necessary to reduce the life by half. This supports the observation that the "stable period," the length of time that the material can be heated without apparent mechanical change, is not greatly affected by changes in the water content of the insulation. Figure 19 also indicates that the effect of water additions becomes more pronounced as the degree of deterioration of the insulation progresses. This supports the observation that those reagents active in promoting mechanical deterioration include acidic products formed as a result of the initial chemical changes, the action of which is made more severe because of the presence of moisture.

Summary Conclusions

The general conclusions which are drawn from this investigation are:

1. The rate of mechanical deterioration in cellulose insulation depends on the conditions of its use. Among those factors of major importance are the temperature applied and the presence of oxygen and moisture.

2. As the temperature is raised above 75 degrees centigrade, the mechanical deterioration of cellulose insulation proceeds at a rapidly increasing rate.

3. Oxidation is most effective on the total mechanical life of the cellulose when the insulation is aged at temperatures below 120 degrees centigrade.

4. The effect of intermittent heating at 150 degrees centigrade on the mechanical deterioration of cellulose insulation is additive.

5. The mechanical life of a cellulose sheet is radically reduced when the water content of the dry insulation is increased in amount up to approximately 0.5 per cent of its dry weight. In general terms, the mechanical life of cellulose insulation is reduced by half for each 100 per cent increase in water content.

6. The effect of oxidation on the mechanical life of cellulose insulation becomes more pronounced in the presence of moisture.

7. The rate of deterioration for the substantially dry insulation as affected by temperature increase above 120 degrees centigrade is dependent upon its previous history. The "eight-degree rule," indicative that the rate of mechanical deterioration is doubled for each eight-degree-centigrade increase from a base temperature of 120 degrees centigrade or higher, applies most closely for practical use when the insulation under study has lost more than 50 per cent of its initial tensile strength.

Steady-State Theory of the Amplidyne Generator

TROY D. GRAYBEAL
ASSOCIATE AIEE

Synopsis: The fundamental steady-state theory of the amplidyne generator is presented in this paper together with methods for calculating the characteristics of the generator from the machine constants. Experimental data obtained on a test machine are compared with calculated results to show the accuracy of the methods and to substantiate the theory. The effects of such factors as brush losses, commutation, and overcompensation and undercompensation on the operation of the generator are explained. Overcompensated and undercompensated machines are treated from the standpoint of both steady-state operation and electrical stability. Methods are given for the determination of the machine constants from open-circuit and short-circuit tests performed on the machine. This method offers the advantage that the machine constants so determined apply for actual conditions of operation and need not be modified to include the effects of such factors as brush and commutation losses, eddy currents, and hysteresis.

THE amplidyne generator which has found wide industrial application in various types of control apparatus is closely related from the standpoint of operating principle to the Rosenberg generator and the metadyne, differing principally in the manner in which it is used. The Rosenberg generator is a constant current source of d-c electrical energy; the metadyne in its usual form is a machine for converting constant potential d-c energy into constant current d-c energy, while the amplidyne generator is a dynamoelectric power amplifier.

One of the outstanding features of the Rosenberg generator is that the open-circuit output voltage varies with the square of the speed for constant field excitation.[2] Therefore, the polarity of the machine is independent of the direction of rotation. When the terminal voltage is maintained constant, by a storage battery, for instance, the output current is essentially independent of the speed for very wide limits of speed variation. Because of these particular properties, this generator in conjunction with storage batteries has been widely used for train lighting service.[1,3,4]

Although the Rosenberg machine was first described in 1905,[1] apparently little was known as to the variety of characteristics this type of machine would assume if other coils in addition to the primary field were used in providing excitation. An investigation of this nature, conducted by J. M. Pestarini in France and published in 1930,[5–7] led to the conception of the metadyne. As defined by Mr. Pestarini, the metadyne is a generalized d-c machine consisting of a d-c armature and commutator, any number of field poles each of which may be excited in any manner, and any number of brushes arranged to bear on the commutator in positions for which satisfactory commutation can be obtained. In accordance with this definition, all rotating d-c machines including the ordinary d-c generator are metadynes. In common usage, however, the term "metadyne" refers only to those several forms of d-c machine which convert constant potential energy into constant current energy. The "figure-eight-connected" metadyne was found suitable for electric locomotive control and was successfully applied to many of the electric railways in France[6] and later to electric traffic systems in England.[8,9] Modifications of this general scheme have been used in this country for control of the locomotives of modern streamlined trains.

Investigation by the General Electric Company of possible applications of different forms of the metadyne to the control of industrial apparatus led to the development of the amplidyne generator.[12–14] This machine, which falls into the general class of metadynes designated as "cross-connected," represents a generalization of the Rosenberg generator in which the field poles are excited by several coils supplied from different sources either internal or external to the machine.

The amplidyne generator is used principally as an element of control mechanisms and plays a part similar to that of the ordinary vacuum tube. It absorbs weak current or voltage signals, amplifies them, and delivers them to the next unit of the control mechanism at a greatly increased power level. This machine offers the principal advantage that it may be built at very reasonable cost to deliver large power outputs. On the other hand, it is limited in application because of its comparatively slow speed of response. The time lag between a change in the input signal and the corresponding change in the output is comparatively large, because the machine consists entirely of highly inductive circuits. Its chief field of application is in control mechanisms operating on d-c or very low-frequency a-c signals. Essentially, the maximum available output voltage varies inversely with the square of the frequency of the applied signal.

The amplidyne generator is applicable to both "open" and "closed-cycle" control. The greater field, however, is in closed-cycle-control mechanisms because of certain inherent differences between the two types, as well as the more general use in recent years of closed-cycle control. "Open" control is that type of automatic control in which the quantity (time, voltage, displacement, and so forth) which actuates the control mechanism is essentially independent of the control operation. A simple example of this type is the automatic-starting compensator used for starting induction motors, synchronous motors, and so forth. These devices initially connect the machine terminals to a reduced voltage supply. By means of a time relay full line voltage is applied to the machine after normal speed is attained. This mechanism is a time-operated open-control device since it allows a definite time independent of acceleration for the starting period. "Closed-cycle" control is that type of automatic control in which the quantity which actuates the control mechanism is affected by the control operation. A good example of this

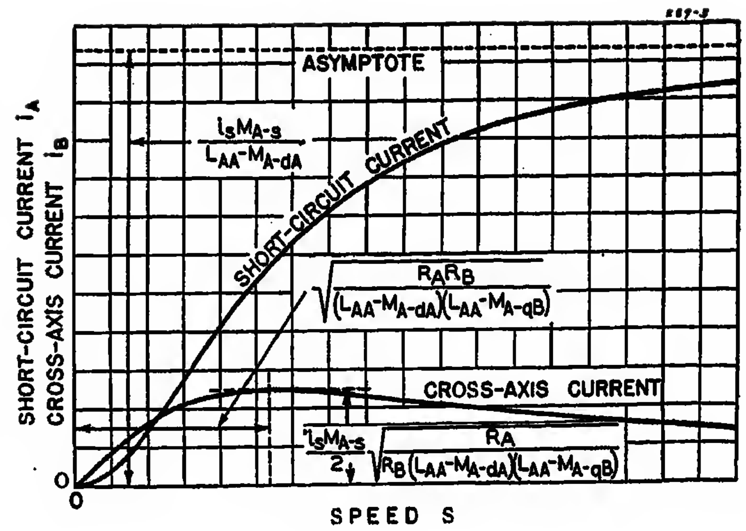
Figure 3 (right). Calculated curves illustrating the nature of the short-circuit characteristics of an undercompensated amplidyne generator



type is automatic ship steering. Here, the angle between the ship compass and the hull is used to control the rudder, and this angle in turn is affected by the rudder operation.

In the first type of control the source of the controlling quantity usually has sufficient power to operate the control mechanism directly. In the second type the source of control usually is some form of measuring instrument which seldom can deliver any appreciable amount of power. Therefore, the original signal must be amplified in order that sufficient power be available to drive the control mechanism. The amplidyne generator provides a very satisfactory means of obtaining the necessary power amplification when a d-c control signal is used, and when a large amount of power is required to drive the control mechanism.

Closed-cycle-control mechanisms usually operate on the difference of two quantities, that is the difference between the desired quantity and the quantity which actually results from the output of the control mechanism. In the ideal case this difference would be zero, but this result is never obtained in practice. Comparison with the ideal, however, furnishes a standard by which the actual operation of the control mechanism may be judged.

In studies of the operation of a control mechanism the over-all behavior of the complete system including all main and control units must be analyzed, and the individual units so designed and adjusted that stable operation of the entire system is obtained. At the same time, the operation must be compared with that of the ideal in order that actual working tolerances may be kept to a satisfactory minimum. It is essential, therefore, that the operation of each individual unit, particularly in the control system, be expressible in simple quantitative terms. The load-voltage characteristic equation of the amplidyne generator (equation 14 of the appendix) defines the over-all operation of this machine and may be used in such analyses. It is valid for any type of load supplied by the generator, provided that the range of operation on the magnetization curve is sufficiently low that saturation effects are negligible. In most control applications this condition would be fulfilled, since a linear relationship between the signal and the output from the amplifying unit is usually desirable.

In instances where satisfactory operation is not attained for one reason or another, a comprehensive knowledge of the behavior of the various units comprising the control mechanism is necessary in order that proper adjustments or modifications may be made. Other characteristics of the amplidyne generator such as the variation of voltage and short-circuit current with speed and the effects of various coils on these characteristics provide this information. Overcompensation and undercompensation are necessary considerations, because these factors influence the stability of the machine. Generally speaking, overcompensation results in a higher output for the same signal input but causes inherent tendencies toward instable operation.

The essential electric elements of the amplidyne generator are an ordinary d-c armature and commutator, two complete sets of brushes spaced 90 electrical degrees apart, and windings connected as shown in Figure 1. The signal to be amplified, usually direct current, is applied to coil s. Current in this coil gives rise to a flux in the main axis of the machine, that is in the axis in line with the brushes AA'. Motion of the armature conductors in this flux generates a voltage in the cross axis, that is between the brushes BB'. Since these brushes are connected electrically, a current flows which produces a flux in the cross axis by virtue of armature reaction. The coil qB may be omitted in an actual machine but is included in the figure, since commutating poles used to secure good cross-axis commutation produce an effect on the machine constants similar to that of the coil qB. If present, this coil may be connected so as to add to or subtract from the magnetomotive force produced by the current flowing in the armature coils. The armature rotating in the cross-

Figure 5. Calculated curves illustrating the nature of the load characteristics of the amplidyne generator and the effect of different degrees of main-axis compensation on these characteristics

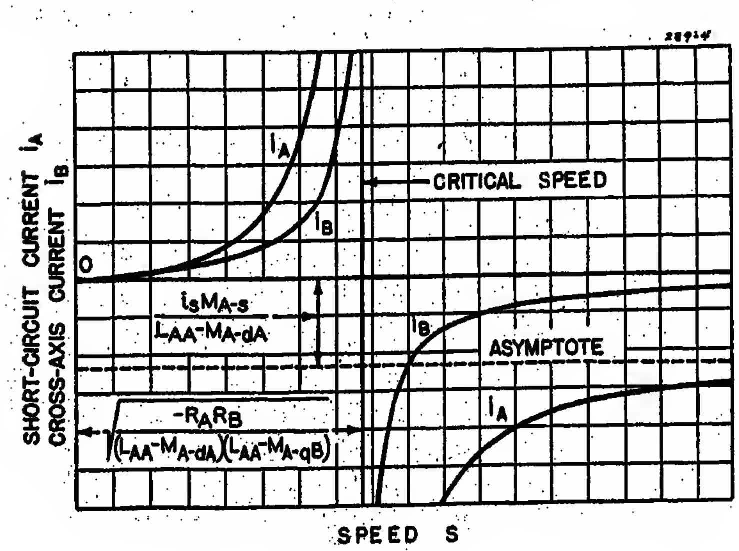


Figure 4 (left). Calculated curves illustrating the nature of the short-circuit characteristics of an overcompensated amplidyne generator

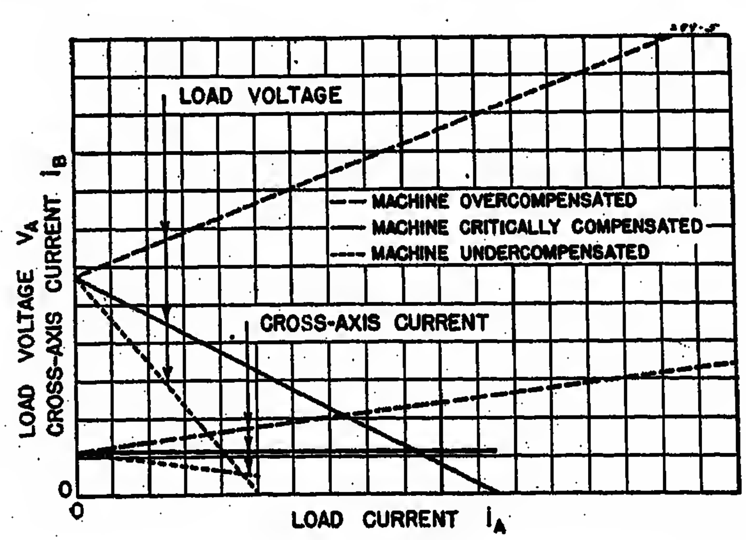
The machine is unstable even in the steady state for any speed above the critical speed



axis flux gives rise to a voltage in the main axis which appears between the brushes AA'. This is the source of the output voltage of the machine. The purpose of the coil dA is to compensate for armature reaction in the main axis.

Open-Circuit Characteristics

The open-circuit or no-load characteristics of the amplidyne generator are expressed by equations 8, 9, and 10 of the appendix. The signal current is a function only of the signal voltage and the resistance of the signal coil. The cross-axis current varies linearly with the speed, and the output voltage varies with the square of the speed. The nature of these characteristics is illustrated by the calculated curves of Figure 2. The cross-axis current and the output voltage on open circuit are independent of the number of turns in the compensating coil dA.

The magnitude of the open-circuit voltage of the machine is governed by the mutual inductance between the signal coil and the armature and by the two cross-axis constants L_{AA} and M_{A-qB}. With other factors constant, doubling the number of turns in the armature coils increases the output voltage eight times if the coil qB is not present. In order to obtain a high output voltage, the cross-axis circuit resistance must be low as this factor appears in the denominator of the open-circuit voltage equation. The voltage acting in the cross axis is usually quite small, of the order of a few volts, so that brush drop represents a considerable portion of the total cross-axis circuit resistance. It is imperative, therefore, that material of very low contact resistance be used for the cross-axis brushes.

Short-Circuit Characteristics

The short-circuit characteristics of the amplidyne generator are expressed by equations 11, 12, and 13 of the appendix. The signal current depends only upon the signal voltage and the resistance of the signal coil. The nature of the two current characteristics depends upon the degree of compensation of the machine, that is upon the relative number of turns in the compensating coil dA. These characteristics are illustrated for an undercompensated machine by the calculated curves of Figure 3. The cross-axis current i_B has an initial slope the same as that of the open-circuit cross-axis current curve. The slope, however, decreases with increase in speed becoming zero when the condition $S\,(L_{AA}-M_{A-dA})(L_{AA}-M_{A-qB}) = R_AR_B$ is satisfied. As the speed increases further, the cross-axis current decreases and approaches zero asymptotically.

The short-circuit current i_A, beginning with an initial slope of zero, increases with the speed approaching asymptotically a definite finite value which depends upon the degree of compensation of the machine. As the ratio $R_AR_B/(L_{AA}-M_{A-qB})$ is made smaller by careful design of the machine, the short-circuit current approaches more closely the asymptotical value for any given maximum speed.

The asymptotical value of the short-circuit current, as obtained from the limit of equation 13 as S becomes infinite, is given by the expression $M_{A-s}i_s/(L_{AA}-M_{A-dA})$. With the compensating coil dA connected in the usual manner with regard to polarity, the value of the asymptote becomes larger and larger as turns are added to the compensating coil. When the number of turns are such that M_{A-dA} is equal to L_{AA}, the asymptote disappears, and the short-circuit current varies directly with the square of the speed of the machine. This condition may be used to define the boundary between overcompensation and undercompensation in the main axis. If the number of turns in the compensating coil are further increased so that M_{A-dA} is greater than L_{AA}, the value

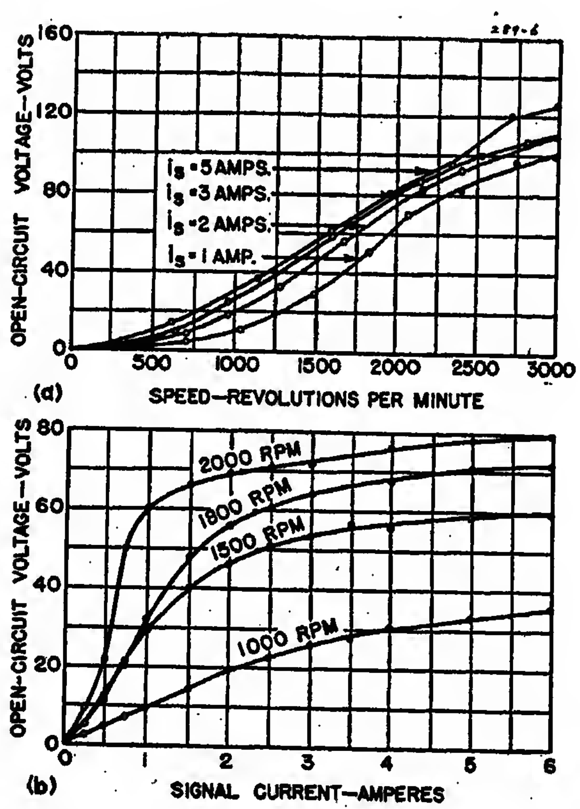


Figure 6. Experimental curves illustrating the effect of hard carbon brushes

For satisfactory operation the speed would have to be restricted to a maximum of 1,000 rpm and the signal current to 2.5 amperes. Brush drop resulting from higher speeds and signal currents causes excessive distortion as indicated by the crowding of the curves of (a) and the nonlinearity of the curves of (b). A critically compensated machine is stable in the steady state, regardless of the speed or the type of load. An overcompensated machine becomes unstable and builds up as a series generator for certain conditions, depending upon the speed of the machine, the degree of overcompensation, and the type of load supplied. If the machine supplies a constant impedance load, stable operation in the steady state occurs as long as the condition $(R_A+R_L)R_B > S^2(M_{A-dA}-L_{AA})\times(L_{AA}-M_{A-qB})$ is fulfilled. The resistance of the load impedance is R_L. Thus, in the practical application of an overcompensated machine, instable operation may result if the load resistance is too low or if the speed of the machine is too high.

A critically compensated or overcompensated amplidyne generator may display a form of transient instability characterized by the output voltage, and also by the output current, building up to a very high value before coming to the final steady-state value when a sudden increase of load occurs. Transients of this character arise from the magnetic coupling between the compensating coil, the main-axis armature circuit, and the signal coil. In general, the compensating coil is more closely coupled with the signal coil than is the armature, because of the air gap. For critical compensation, the compensating coil must contain a few more turns than the equivalent number of turns on the armature. Thus, a sudden change of current in the load circuit will induce a current in the signal circuit of such direction as to increase the strength of the main-axis flux. This, in turn, causes a greater output voltage and greater output current from the machine. In some cases this action may be cumulative and result in free oscillation. In order to eliminate the possibility of transients of this character, the number of turns in the compensating coil dA must be reduced to the point where the transient components of current induced in the signal coil by sudden changes in the load current give rise to effects which oppose the original change of load current. This condition is fulfilled when M_{dA-s} is less than M_{A-s}.

To obtain the maximum output for a given maximum speed and signal current, the degree of compensation of the machine should be as high as possible. In order that the condition of critical compensation may be more closely approached without introducing tendencies toward instability, the compensating coil dA should be arranged with respect to the signal coil s so as to allow a lower coefficient of coupling between the two. This coefficient of coupling theoretically should be the same as that between the compensating coil and the armature.

Experimental Data and Results

In order to check experimentally the theory and equations presented in this paper, an amplidyne generator was constructed from a General Electric type *RI*, three-horsepower, induction motor. The armature of this machine was used without modification since it was wound with a four-pole wave winding. The stator was rewound with a four-pole distributed winding, part of the slots being used for an interpole winding in order that satisfactory commutation could be obtained at the cross-axis brushes. The compensating coil dA consisted of 14 turns per coil, four coils per pole, with taps brought out so that 9, 10, 11, 12, 13, or 14 turns per coil could be used. The signal coil was wound with five turns per coil, four coils per pole. The interpole winding consisted of 50 turns surrounding each of the four stator teeth located in the cross-axis neutrals. While this design is not particularly efficient from the practical standpoint because of insufficient space for copper in the stator slots, it provides a satisfactory means for an experimental check of theory.

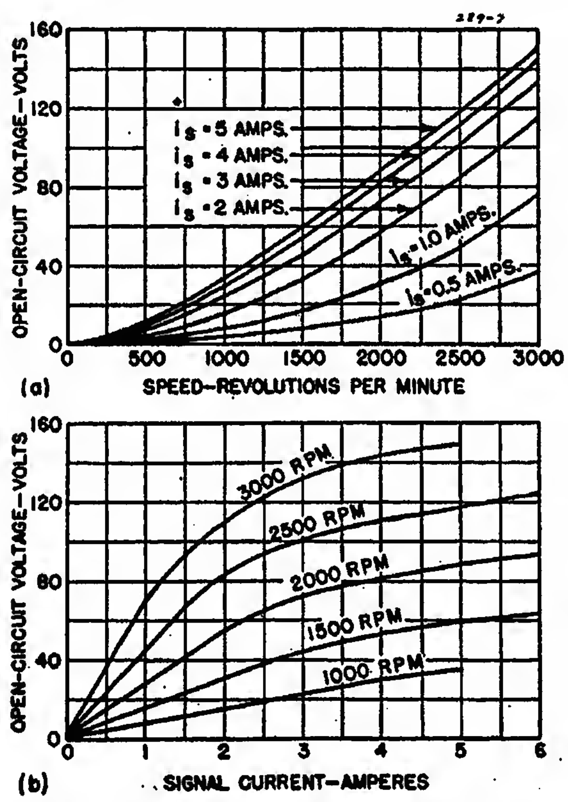

Figure 7. Experimental open-circuit characteristic curves of an amplidyne generator equipped with soft graphite brushes in the cross axis

In making adjustments for satisfactory operation of the machine, it was found that the higher taps of the compensating winding gave so much overcompensation that they could not be used. The machine would build up as a series generator to a very high value of armature current when the machine was loaded. On the highest tap the machine would oscillate at a frequency of approximately 80 cycles per second for very low values of load resistance.

Physically, the amplidyne generator may be considered a two-stage amplifier. The first stage is represented by the voltage generated in the cross-axis circuit by the flux produced in the main axis by the signal coil. The second stage is represented by the voltage generated in the output circuit by virtue of the flux established in the cross-axis circuit by the cross-axis current. When load current flows in the output circuit a component of flux, in addition to that produced by the signal coil, is produced in the main axis. This component adds to the flux of the signal coil if the machine is overcompensated and subtracts if the machine is undercompensated. Thus, an overcompensated amplidyne generator is in effect a regenerative amplifier. It is unstable if too much of the output is fed back into the first stage of the machine by virtue of too many turns in the compensating coil. On the other hand, an undercompensated amplidyne generator is a degenerative amplifier and is quite stable. For this reason the tests were made with the compensating coil dA connected with nine turns per coil, giving a slightly undercompensated machine.

Hard carbon brushes were entirely unsatisfactory, as illustrated by the curves of Figure 6, because of the comparatively low voltages generated in the cross-axis circuit. Soft graphite brushes gave very satisfactory operation, but in this case the adjustment of the interpole shunt was quite critical. Best conditions of cross-axis commutation were obtained with a diverter which would by-pass approximately ten per cent of the total cross-axis current.

The characteristics of the test machine after the necessary adjustments were made to secure satisfactory operation are illustrated by the curves of Figures 7, 8, and 9. According to theory, the curves of Figure 7a should be parabolas, while the curves of the other five figures should be straight lines. In actual operation of the machine several factors such as magnetic saturation and brush drop cause the curves to deviate from the theoretical form.

The total ampere turns acting to produce flux in the space between brushes A and B and between brushes A' and B'

(see Figure 1) is proportional to the *sum* of the ampere turns acting in the cross axis and the ampere turns acting in the main axis. The total ampere turns acting to produce flux in the space between brushes B and A' and between brushes B' and A is proportional to the *difference* between the ampere turns acting in the cross axis and the ampere turns acting in the main axis. Thus, the total flux and the degree of magnetic saturation are greater in the air gap between brushes A and B and between brushes A' and B' than between brushes B and A' and between brushes B' and A. The total voltage generated in the cross-axis circuit is proportional to the total flux distributed around the armature between brushes B and B', and the total voltage generated in the output circuit is proportional to the total flux distributed around the armature between brushes A and A'. Since the same components of flux are involved in the generation of both of these voltages, the effects of magnetic saturation appear simultaneously in both the cross-axis and main-axis circuits.

In Figure 7b, the 1,000-rpm curve is essentially linear for signal currents up to four amperes, and the 2,000-rpm curve for signal currents up to two amperes. At higher signal currents magnetic saturation caused a decrease in the machine inductances with the result that the curves fall below the points represented by the initial linear relationship.

Since the measured resistance of the cross-axis circuit was slightly greater than one ohm, the change of the resistance of the graphite brushes with current was sufficient to cause a noticeable effect. This accounts for the upward turn of the 0.5-ampere and 1.0-ampere curves of Figure 8a near 2,500 rpm. For the 2-ampere curve the effects of magnetic saturation were appreciable for speeds above 2,200 rpm (as illustrated by the corresponding curves of Figure 8b). The slight decrease in the generated cross-axis voltage at high speed due to saturation was offset by the decrease in brush resistance. The resulting curve of cross-axis current was linear.

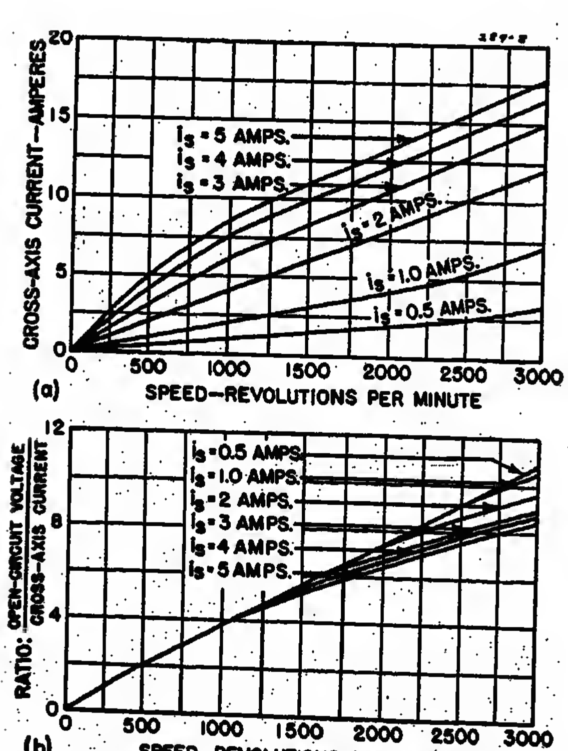

Figure 8. Open-circuit speed characteristics of the first and second stages respectively of an amplidyne generator

Nonlinearity of the curves of (b) are an indication of magnetic saturation of the machine

Characteristics of the Machine From Open-Circuit and Short-Circuit Tests

In order to calculate the operating characteristics of the amplidyne generator, machine constants must be used which are valid for actual conditions of operation. The values of the constants are influenced by magnetic saturation, by brush losses and commutation, and by hysteresis and eddy current losses. Therefore, any set of constants obtained from direct measurements of the impedances or inductances must be modified to include these factors. Such modifications are difficult to make accurately, since the effects of the losses on the machine constants cannot be expressed in simple quantitative terms. The necessity for making modifications can be eliminated to a large extent if the constants of the machine are calculated from test data from open-circuit and short-circuit tests performed on the machine.

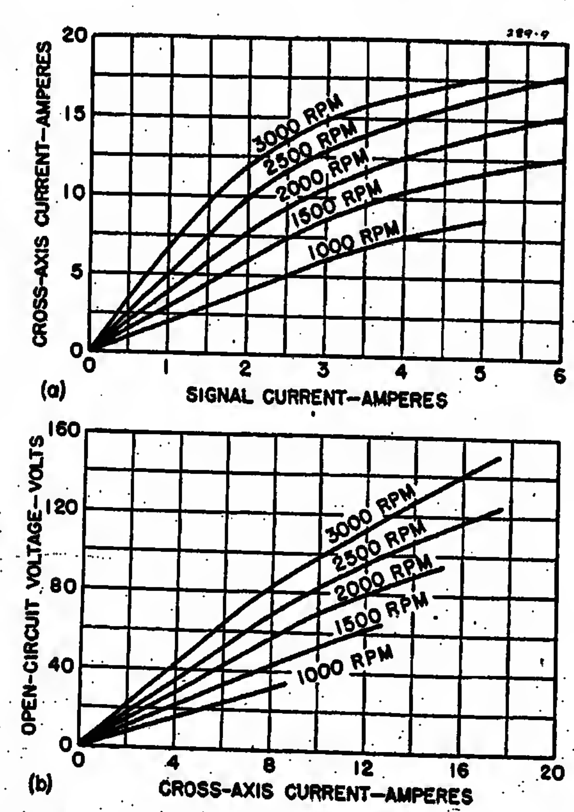

Figure 9. Open-circuit saturation curves of the first and second stages respectively of an amplidyne generator

Nonlinearity of the curves of (b) results from magnetic saturation of the machine, while nonlinearity of the curves of (a) result from magnetic saturation and brush drop at the cross-axis brushes

The two constants B and C are calculated from open-circuit test data in accordance with the following equations which result from equations 19 and 20 of the appendix:

$$\left.\begin{aligned} B &= i_B/Si_s \\ C &= V_A/Si_B \end{aligned}\right\} \text{Open-circuit test data used in these equations}$$

The constants A and R_A are calculated from short-circuit test data in accordance with the following equations which result from equations 21 and 22 of the appendix:

$$\left.\begin{aligned} R_A &= CSi_B/i_A \\ A &= (Bi_s/i_A) - (R_A/CS^2) \end{aligned}\right\} \text{Short-circuit test data used in these equations}$$

These four constants together with equations 19 to 23 are sufficient for the calculation of any of the steady-state characteristics of the amplidyne generator. The speed S in the equations above may be expressed in revolutions per minute instead of radians per second. In this case the speed S in equations 19 to 23 derived from these four constants must also be expressed in revolutions per minute.

The accuracy of this method for determining the characteristics of the amplidyne generator is shown by the curves of Figures 10 and 11, which were calculated on the basis of constants determined from open-circuit and short-circuit test data. For comparison actual test values are indicated by small circles and triangles plotted on the same axes.

In Figure 10a, the test points of the open-circuit voltage and cross-axis current curves for one-ampere signal current

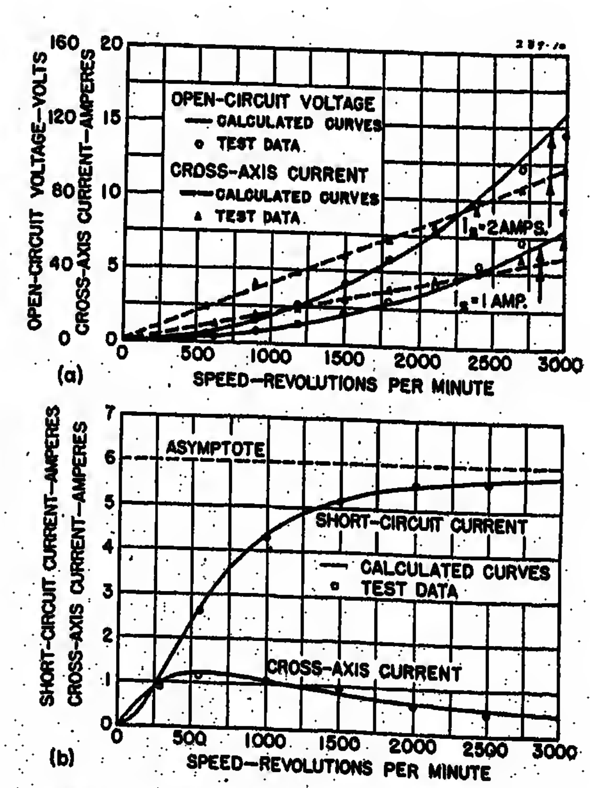

Figure 10. Comparison of calculated open-circuit and short-circuit characteristic curves with actual test data

fall above the calculated curves for speeds above 2,200 rpm. This discrepancy is due to the decrease in the resistance of the cross-axis brushes with increase in cross-axis current at the higher speeds. For the two-ampere signal current curve of cross-axis current, the change in brush resistance with current was offset by saturation, with the result that the test points agree very closely with the calculated curve. The test points of the corresponding open-circuit voltage curve fall below the calculated curve for speeds above 2,200 rpm because of saturation effects in the second stage of the machine.

Conclusions

Commutation and brush effects, particularly in the cross-axis circuit, have a very pronounced effect upon the operation of the amplidyne generator. Bad commutation and brush losses cause a considerable decrease in the available output. In order that the machine operate satisfactorily, the use of proper brush material and the realization of good commutation are imperative. To insure good commutation interpoles may be used to excellent advantage. The brushes in the cross-axis circuit must be of low resistance and produce as small a contact drop as possible.

The characteristics of the machine may be calculated on the basis of open-circuit inductances and resistances. The constants used for calculations must correspond with actual conditions of operation; but the main- and cross-axis coils may be treated as magnetically independent. The speed voltages appear in the opposite axes from the fluxes which produce them. The effects of magnetic saturation appear in both the main- and cross-axis circuits simultaneously. Saturation effects are difficult to include in calculations, because the degree of saturation changes with the speed and with the load.

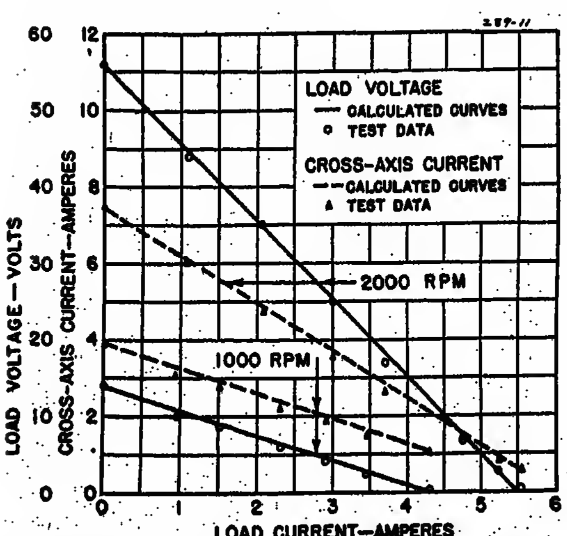

Figure 11. Comparison of calculated load characteristic curves with actual test data

Constants for the calculation of the steady-state characteristics of the amplidyne generator may be determined from open-circuit and short-circuit tests performed on the machine. This method offers the advantage that the values so obtained apply for actual conditions of operation. For purposes of design the characteristics may be predicted on the basis of the inductance coefficients, which may be obtained by the methods used for the more standard electrical machines by calculation of the various flux linkages involved. This method, however, is subject to considerable error because of the uncertainty of many factors, principally those relating to commutation, brush drop, and the associated losses.

The output load-voltage characteristic of an undercompensated machine is drooping (of negative slope) for all conditions of operation. The corresponding characteristic of an overcompensated machine may be either drooping or rising (of positive slope), depending upon the speed and the degree of overcompensation. Low speed together with a low degree of overcompensation gives a drooping characteristic which becomes horizontal and then rising if either of these two factors is sufficiently increased. A machine having a rising characteristic is unstable, even for steady-state operation, if the load resistance is less than a definite critical value which depends upon the slope of the characteristic curve.

Transient instability may result in an overcompensated or in an undercompensated machine, if the mutual inductance between the compensating coil and the signal coil is greater than the mutual inductance between the signal coil and the armature. Transient instability arising from this cause is characterized by the load current and the load voltage building up to very high values before coming to their final steady-state values when a sudden increase of load occurs. With a sudden decrease of load, the opposite effect takes place. In some instances this action may be cumulative and may result in free oscillation of the machine. If the compensating coil is arranged so that a fairly high leakage flux exists between it and the signal coil, a greater output is available from the machine without loss of stability.

The open-circuit voltage varies directly with the square of the speed, while the short-circuit current approaches asymptotically a definite value which depends upon the signal current and the design of the machine. For maximum power output and power amplification the speed should be as high as possible.

The available power output and also the power amplification become infinite for d-c operation of the machine at constant speed as the resistance of the cross-axis circuit approaches zero. As the resistance of the signal coil approaches zero, the power supplied by the signal source approaches zero, and the power amplification again becomes infinite. Since both of these resistances may be made quite low, the power amplification of an amplidyne generator operating on direct current is very high. The machine used in obtaining data for this paper gave a maximum value of approximately 300. This corresponds with an ordinary d-c generator having a field loss of one third of one per cent. By use of a specially designed stator core which would allow more copper in the signal coil and interpole windings, a power amplification of at least ten times this value could easily be obtained.

Appendix. D-C Operation of the Amplidyne Generator

If a d-c signal is applied to coil s (Figure 1), the steady-state behavior of the machine is expressed by the following equations:

$$e_s = i_s R_s \tag{1}$$

$$e_q = i_B R_B = KS\phi_d 10^{-8} \tag{2}$$

$$e_d = i_A R_A + V_A = KS\phi_q 10^{-8} \tag{3}$$

If the speed of the machine is measured in electrical radians per second, the constant K is the equivalent number of series armature turns between opposite brushes, that is the number of series turns which would give the same number of flux linkages if each of these turns linked all the flux in either axis. The expressions $K\phi_d$ and $K\phi_q$ are the total number of armature flux linkages in the main and cross axes of the machine respectively. The total flux which is effective in producing speed voltage in the output circuit, that is ϕ_d, includes the mutual flux from coils dA and s as well as the leakage flux of the armature. Likewise, the total flux which is effective in producing speed voltage in the cross-axis circuit includes the mutual flux from coil qB as well as the leakage flux of the armature. In terms of open-circuit self- and mutual inductances the flux linkages in the main and cross axes are:

$$K\phi_d = N_A\phi_d = (M_{A-s}i_s - L_{AA}i_A + M_{A-dA}i_A)10^8 \tag{4}$$

$$K\phi_q = N_A\phi_q = (L_{AA}i_B - M_{A-qB}i_B)10^8 \tag{5}$$

The negative sign is used before the mutual inductance M_{A-qB}, because the coil qB is assumed connected so as to compensate partially for armature reaction in the cross axis. This sign should be positive if the coil is connected the other way. Making use of these relations, equations 2 and 3 may be written:

$$i_s SM_{A-s} - i_B R_B - i_A S(L_{AA} - M_{A-dA}) = 0 \tag{6}$$

$$i_B S(L_{AA}-M_{A-qB})-i_A R_A=V_A \quad (7)$$

The open-circuit characteristics of the machine are obtained from the solution of these equations with the load current i_A equated to zero:

$$i_s=e_s/R_s \quad (8)$$

$$i_B=i_s SM_{A-s}/R_B \quad (9)$$

$$V_A=i_s S^2 M_{A-s}(L_{AA}-M_{A-qB})/R_B \quad (10)$$

The short-circuit characteristics of the machine are obtained from equations 1, 6, and 7 with the load voltage V_A equated to zero:

$$i_s=e_s/R_s \quad (11)$$

$$i_B=\frac{SM_{A-s}R_A}{S^2(L_{AA}-M_{A-dA})(L_{AA}-M_{A-qB})+R_A R_B}i_s \quad (12)$$

$$i_A=\frac{S^2 M_{A-s}(L_{AA}-M_{A-qB})}{S^2(L_{AA}-M_{A-dA})(L_{AA}-M_{A-qB})+R_A R_B}i_s \quad (13)$$

If the machine is supplying a constant resistance load, the voltage V_A in equation 7 is replaced by $i_A R_L$ in which R_L is the resistance of the load. The solutions for the three currents are exactly the same as the short-circuit characteristics except that the resistance of the main-axis circuit becomes (R_A+R_L) instead of R_A. The load voltage is found from the relation $V_A=i_A R_L$ after the currents are obtained.

The load characteristics of the machine are obtained from equations 6 and 7 by elimination of i_B and V_A respectively:

$$V_A=\frac{-[S^2(L_{AA}-M_{A-dA})(L_{AA}-M_{A-qB})+R_A R_B]}{R_B}i_A+\frac{S^2 M_{A-s}(L_{AA}-M_{A-qB})i_s}{R_B} \quad (14)$$

$$i_B=\frac{-S(L_{AA}-M_{A-dA})}{R_B}i_A+\frac{SM_{A-s}i_s}{R_B} \quad (15)$$

These latter two equations are valid regardless of the type of load supplied by the machine. Equation 14 expresses the relation between the three variables V_A, i_A, and i_s, and may be used to define the over-all operation of the amplidyne generator in any control circuit in which it is connected, provided the machine operates low enough on the magnetization curve so that saturation effects may be neglected.

The equations given above may be simplified by the following substitutions:

$$A=(L_{AA}-M_{A-dA})/R_B \quad (16)$$

$$B=M_{A-s}/R_B \quad (17)$$

$$C=(L_{AA}-M_{A-qB}) \quad (18)$$

In terms of these constants the characteristic equations are:

Open-circuit characteristics:

$$i_B=BSi_s \quad (19)$$

$$V_A=BCS^2 i_s \quad (20)$$

Short-circuit characteristics:

$$i_B=\frac{BR_A S}{ACS^2+R_A}i_s \quad (21)$$

$$i_A=\frac{BCS^2}{ACS^2+R_A}i_s \quad (22)$$

Load characteristics:

$$V_A=-(ACS^2+R_A)i_A+BCS^2 i_s \quad (23)$$

$$i_B=-ASi_A+BSi_s \quad (24)$$

List of Symbols

e_d—Generated voltage in the main-axis or output circuit

e_q—Generated voltage in the cross-axis circuit

e_s—Voltage applied to the signal coil

L_{AA}—The self-inductance of the armature between either the main-axis brushes or between the cross-axis brushes

M_{A-dA}—The mutual inductance between the armature and the compensating coil dA

M_{A-qB}—The mutual inductance between the armature and the cross-axis coil qB

M_{A-s}—The mutual inductance between the armature and the signal coil s

M_{dA-s}—The mutual inductance between the compensating coil dA and the signal coil s

R_A—Resistance of the main-axis circuit internal to the machine. Includes the resistance of the armature, the main-axis brushes, and the compensating coil dA

R_B—Resistance of the cross-axis circuit. Includes the resistance of the armature, the cross-axis brushes, and the cross-axis coil qB

R_L—Resistance of the load impedance

R_s—Resistance of the signal coil s

S—Speed in electrical radians per second

V_A—Output or load voltage

ϕ_d—The total flux linking the armature in the main axis

ϕ_q—The total flux linking the armature in the cross axis

Analysis of Short Circuits for Distribution Systems

CHARLES F. DALZIEL
MEMBER AIEE

Synopsis: This paper presents a discussion and analysis of short circuits for low-voltage distribution systems. Many distribution systems are supplied from transformers connected in delta on the low-voltage side with the mid-tap of one secondary winding, or with one corner of the delta, connected to ground. As a result, short circuits on these systems often involve failure to ground, and an accurate analysis for these faults is of value. An original analysis of power-leg-to-ground and light-leg-to-ground short circuits is presented together with formulas for line-to-line and three-phase faults. A study of short circuits on the secondary circuits of single-phase transformers supplied from three-phase systems is also included, thereby giving a comprehensive treatment of distribution short circuits. The paper also includes a discussion of the effects of resistance in limiting short-circuit currents and the voltage rise of the secondary neutral above ground potential caused by transformer failure and resistance to ground.

DISTRIBUTION transformer banks supplying 240-volt three-phase and 120/240-volt single-phase loads generally have the mid-point of one secondary winding connected to ground. This is done to protect the low-voltage distribution systems against high voltage in the event of transformer failure and to provide a ground for the low-voltage systems. An accurate analysis of short circuits and related problems on these systems is important in the selection and setting of protective equipment and in reduction of personal and fire hazards. The ratings of these transformer banks are from about 6 to 1,000 kva. The most common short circuit in conduits and machines is failure to ground. In addition to the unsymmetrical conditions imposed by a fault to ground, special considerations are required, since it is assumed that the transformer secondaries are connected in delta and the ground return is furnished by a connection to the mid-point of one secondary winding. Other connections are in common use. Three-phase four-wire circuits may be supplied from transformers with the low-voltage secondary windings wye-connected with the neutral grounded, and transformers without mid-taps supplying three-phase three-wire 240 volts often have one corner of the secondary delta connected to ground. This paper presents an analysis of power-leg-to-ground and light-leg-to-ground instantaneous symmetrical short-circuit currents and a discussion of short-circuit currents on distribution systems resulting from high-voltage transformer failures. Consideration of three-phase and line-to-line low-voltage short circuits and low-voltage short circuits on single-phase distribution transformers is also included.

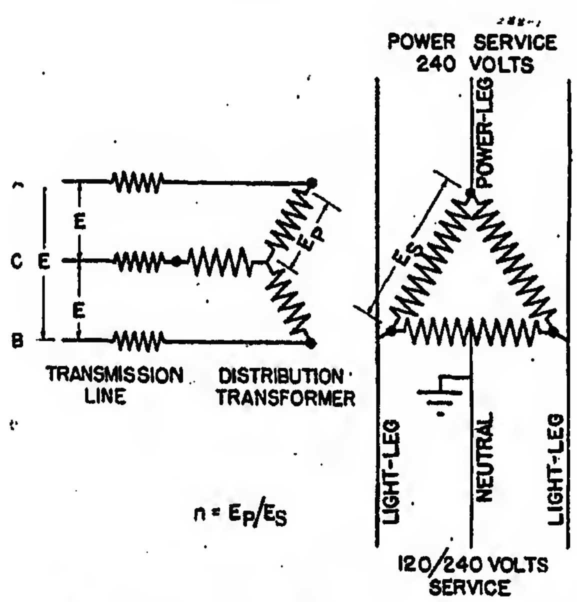

Figure 1. Typical distribution transformer with mid-point of one secondary winding grounded

The schematic diagram of Figure 1 gives the terminology and connections in common use for obtaining 240-volt three-phase three-wire and 120/240-volt single-phase three-wire services from a single transformer bank. For cases where the power load predominates, such as in industrial plants, the three transformers are ordinarily of the same capacity. Where single-phase loads predominate, for example, in rural installations, the two transformers used to furnish the power-leg are usually the same size, but they may be smaller than the third unit. In this study it is assumed that the three transformers are identical. However, in solving practical problems differences in capacity may be accurately taken into account for power-leg-to-ground short circuits, and approximations may be introduced for light-leg-to-ground faults.

Effect of Resistance in Limiting Low-Voltage Short-Circuit Currents

Although resistance may produce a negligible effect in limiting short-circuit currents on high-voltage systems, it may have a considerable effect when faults occur on low-voltage circuits.[1] It is evident that the higher the voltage, the higher are the ohmic values of equipment impedance. Therefore, impedances having about the same ohmic values regardless of voltage rating may produce a negligible effect on high-voltage short-circuit currents when in combination with high-impedance equipment, but they may be very important on low-voltage circuits when connected in series with other low-impedance apparatus.[2] For 120- or 240-volt circuits resistance is often the predominating current-limiting factor, and omission of it (in the interest of simplicity) may lead to serious error. The importance of resistance is illustrated in Figure 2, wherein line-to-ground fault current* is plotted against ground or fault resistance for a few selected voltages. Resistance is included in both analysis and examples of the present discussion.

Power-Leg-to-Ground Short-Circuit Analysis

Transformers Connected in Wye-Delta

It is apparent from inspection of Figure 3, that a power-leg-to-ground short circuit is a special type of single-phase fault. The voltage effective in producing the fault current is $\sqrt{3}E_s/2$. The fault current is equal to the sum of two equal low-voltage secondary currents which are inphase with each other. Neglecting the effects of load and transformer exciting current, the instantaneous symmetrical secondary current is given by:

$$I_s = \frac{\sqrt{3}E_s/2}{z_{TL}+z_{(S-P)}+0.5z_{(S/2-S/2)}+2z}$$

in which

E_s = the voltage of the secondary winding on open circuit, in volts

* Refer to standard references for analysis of ordinary unsymmetrical short circuits (for example, reference 3 or 4).

Paper 42-88, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted March 16, 1942; made available for printing May 4, 1942.

Charles F. Dalziel is associate professor in the department of electrical engineering and supervisor of engineering science and management, war training, University of California, Berkeley, Calif.

The author wishes to thank the various students in electrical engineering at the University of California for their assistance in obtaining the experimental data used in this paper. Acknowledgments are also due to the General Electric Company for the test data from one of their standard H60-100-2400/4160Y-120/240 transformers.

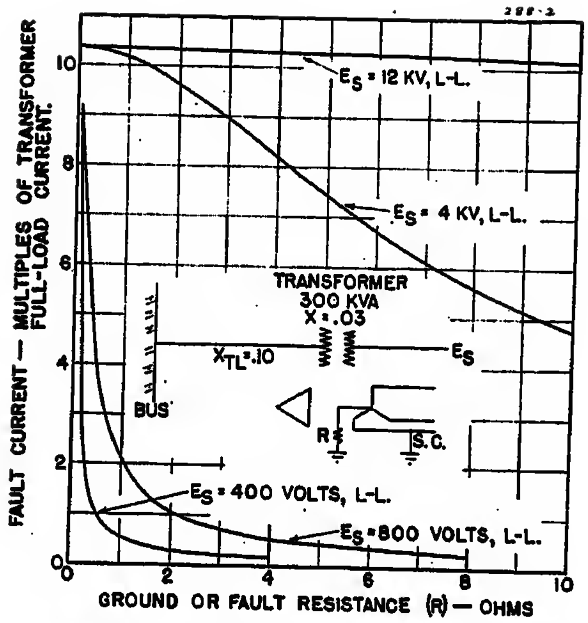

Figure 2. Effect of resistance in limiting short-circuit currents

z_{TL} = the impedance of the transmission line and other series equipment in ohms referred to the secondary voltage

$z_{(S-P)}$ = the impedance of the low-voltage secondary winding to the high-voltage primary winding in ohms (see Figure 3C)

$z_{(S/2-S/2)}$ = the impedance of one-half the low-voltage secondary winding to the other one-half low-voltage secondary winding in ohms (see Figure 3C)

z = The impedance of the external low-voltage circuit to fault, including arc, conductor, and conduit impedances, the resistance to ground, and the impedance of the ground return circuit in ohms

The fault current is:

$$I_F = 2I_s = \frac{\sqrt{3}E_s}{z_{TL} + z_{(S-P)} + 0.5z_{(S/2-S/2)} + 2z} \quad (1)$$

Let

E = the transmission-system voltage line-to-line, in volts

$n = E_p/E_s = E/\sqrt{3}E_s$, the transformer turn ratio

Then

$E_s = E/n\sqrt{3}$

and

$$I_F = \frac{E/n}{[Z_{TL} + Z_{(P-S)}]/n^2 + 0.5z_{(S/2-S/2)} + 2z} \quad (2)$$

where

Z_{TL} = the impedance of the transmission system in high-voltage ohms. This assumes that the reactance of one wire to neutral is the same for both single-phase and three-phase balanced currents. This is true for circuits with equilateral spacing or completely transposed circuits. It is unlikely that the distribution feeder would be either equilaterally spaced or completely transposed between the source and a particular transformer installation, and for greatest accuracy the actual single-phase reactance between the two high-voltage primary line conductors carrying current should be used

$Z_{(P-S)}$ = the impedance of the high-voltage primary winding to the low-voltage secondary winding in high-voltage ohms. See Figure 3C.

The primary line currents are obtained by inspection of Figure 3B:

$$I_A = I_B = I_s/n = I_F/2n, \text{ and } I_C = 0 \quad (3)$$

Transformers Connected in Delta-Delta

The analysis for the case in which the transformers are connected in delta-delta is similar to that of the preceding derivation with the exception of the modifications required due to the high-voltage delta connection. See Figure 4.

$$I_F = 2I_s = \frac{\sqrt{3}E_s}{3z_{TL} + z_{(S-P)} + 0.5z_{(S/2-S/2)} + 2z} \quad (4)$$

For this case $n = E_p/E_s = E/E_s$. In terms of the transmission voltage and actual transmission impedances in high-voltage ohms, the fault current is given by

$$I_F = \frac{\sqrt{3}E/n}{[3Z_{TL} + Z_{(P-S)}]/n^2 + 0.5z_{(S/2-S/2)} + 2z} \quad (5)$$

From inspection of Figure 4B

$$I_B = I_C = I_s/n = I_F/2n, \text{ and } I_A = 2I_B = I_F/n \quad (6)$$

Light-Leg-to-Ground Short-Circuit Analysis

Transformers Connected in Wye-Delta

The light-leg-to-ground short-circuit analysis is developed from the method of symmetrical components as follows: The schematic diagrams of Figure 5 are based on the assumption that the system is entirely symmetrical. The dissymetry imposed by the terminal conditions which represent this type of fault is inserted in the analysis at the appropriate point.

Let

$n = E_p/E_s = E/\sqrt{3}E_s$, the transformer turn ratio

z_{TL}' = the impedance of the transmission line and other series equipment in ohms referred to one-half the secondary voltage, that is,

$$z_{TL}' = Z_{TL} \Big/ \left[\frac{E_p}{E_s/2}\right]^2 = Z_{TL}/(2n)^2 \quad \text{where}$$

Z_{TL} = the impedance of the transmission line and other series equipment in high-voltage ohms

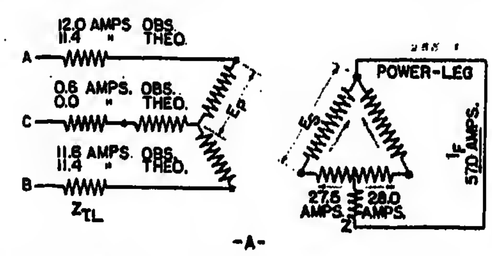
$z_{(S/2-P)}$ = the impedance of one-half the low-voltage winding to the high-voltage primary winding in ohms, and

$z_{(S/2-P)} = Z_{(P-S/2)}/(2n)^2$*

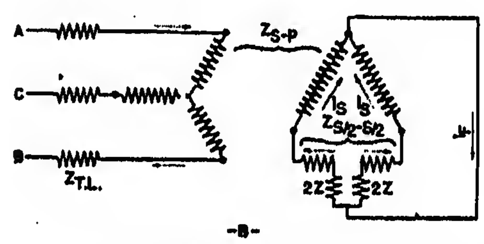
$z_{(S/2-S)}$ = the impedance of one-half the low-voltage winding to the entire low-voltage winding in ohms (see Figure 5D)

z = the impedance of the external low-voltage circuit to fault, including arc, conductor, and conduit impedances, the resistance to ground, and the impedance of the ground return circuit, in ohms

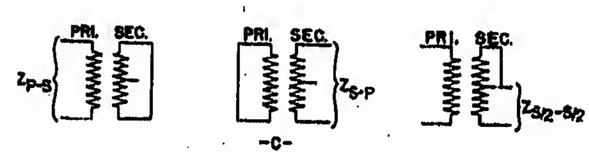
The positive- and negative-sequence impedances to fault are obtained from inspection of Figure 5B. All impedances are actual ohms, or expressed in ohms referred to one-half the secondary voltage



A. Schematic diagram with experimental values inserted



B. Equivalent circuit for analysis



C. Determination of transformer impedances

Figure 3 Power-leg-to-ground short-circuit analysis

Transformers connected in wye-delta

on open circuit. Z_{2F} is taken equal to Z_{1F} for determination of instantaneous symmetrical short-circuit currents. The proper generator impedances may be included in the term Z_{TL} when transient or sustained currents are desired.

The positive-sequence impedance to fault is

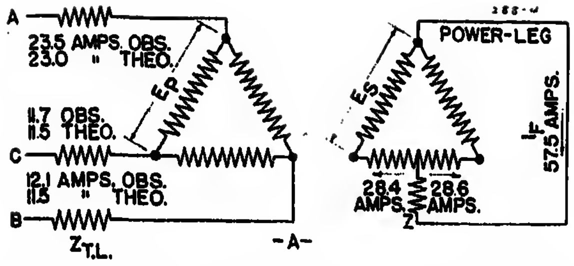
$$Z_{1F} = z_{TL}' + z_{(S/2-P)} + z$$

The zero-sequence impedance to fault is obtained from Figure 5C.:

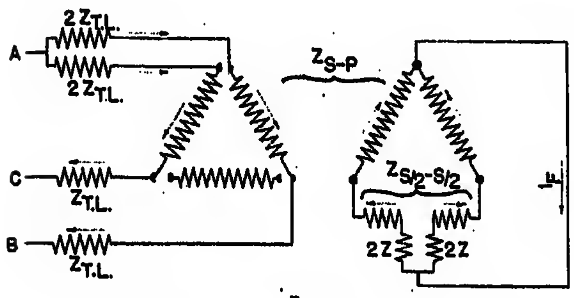
$$Z_{0F} = z_{(S/2-S)} + z$$

The equations for a line-to-ground

* The first subscript denotes the winding upon which the impedance measurements are made, or the side to which they are referred. The second subscript refers to the winding short-circuited for the impedance test. See Figure 5D.



A. Schematic diagram with experimental values inserted



B. Equivalent circuit for analysis

Figure 4. Power-leg-to-ground short-circuit analysis

Transformers connected in delta-delta

short circuit are (see reference 3 or 4 for details):

$$I_1=I_2=I_0=I_F/3, \text{ and } I_F=\frac{3E}{Z_{1F}+Z_{2F}+Z_{0F}}$$

The voltage effective in producing fault current is $E_s/2$. Substituting the above expressions for the impedance to fault and the voltage effective in producing the fault current gives

$$I_F=\frac{3E_s/2}{2[z_{TL}'+z_{(s/2-P)}]+z_{(s/2-s)}+3z} \tag{7}$$

In terms of the transmission voltage and actual transmission impedances in high-voltage ohms, the above becomes

$$I_F=\frac{\sqrt{3}E/2n}{2[Z_{TL}+Z_{(P-S/2)}]/(2n)^2+z_{(s/2-s)}+3z} \tag{8}$$

The primary currents are obtained from inspection of Figure 6:

$$I_C=(I_1+I_2)/2n=2/3(I_F/2n)=I_F/3n, \text{ and } I_A=I_B=I_F/6n \tag{9}$$

Transformers Connected in Delta-Delta

The analysis for the case in which the transformers are connected in delta-delta is similar to the foregoing with exceptions which are apparent from inspection of Figures 7 and 8.

$$Z_{1F}=Z_{2F}=z_{TL}'+z_{(s/2-P)}+z$$

For this case

$$z_{TL}'=Z_{TL}\bigg/\left[\frac{E_P/\sqrt{3}}{E_s/2}\right]^2=3Z_{TL}/(2n)^2$$

$$Z_{0F}=z_{(s/2-s-P)}+z$$

in which

$z_{(s/2-s-P)}$ = the impedance of one-half the low-voltage secondary winding to the entire low-voltage winding and high-voltage winding in ohms. See Figure 7D.

Following the procedure of the previous derivation:

$$I_F=\frac{3E_s/2}{2[z_{TL}'+z_{(s/2-P)}]+z_{(s/2-s-P)}+3z} \tag{10}$$

Or, in terms of the transmission voltage and actual transmission impedances in high-voltage ohms

$$I_F=\frac{3E/2n}{2[3Z_{TL}+Z_{(P-S/2)}]/(2n)^2+z_{(s/2-s-P)}+3z} \tag{11}$$

The primary line currents are obtained from inspection of Figure 8. The zero-sequence currents circulate in both delta-connected windings, and the relative division could be worked out by using the methods developed for analyzing three-winding transformers. However, since the zero-sequence currents cannot pass from the delta into the high-voltage lines, this refinement is not necessary, and the line currents are determined directly from the positive- and negative-sequence currents as indicated in the figure.

$$I_B=I_C=I_F/2n, \text{ and } I_A=0 \tag{12}$$

Three-Phase Short-Circuit Analysis

Transformers Connected in Delta on Low-Voltage Side

Although three-phase short circuits are of infrequent occurrence on distribution circuits, they occasionally occur on open bus structures or in other equivalent locations. The fundamental equation for three-phase short-circuit current is

$$I_{3\phi}=\frac{E_s/\sqrt{3}}{z_{TL}''+z_{(s-P)}'+z'} \tag{13}$$

in which

z_{TL}'' = the impedance of the transmission line and other series equipment in ohms referred to the secondary voltage to neutral. For transformers connected in wye-delta

$$z_{TL}''=Z_{TL}\bigg/\left[\frac{E_P}{E_s/\sqrt{3}}\right]^2=Z_{TL}/3n^2$$

For transformers connected in delta-delta

$$z_{TL}''=Z_{TL}\bigg/\left[\frac{E_P/\sqrt{3}}{E_s/\sqrt{3}}\right]^2=Z_{TL}/n^2$$

$z_{(s-P)}'=z_{(s-P)}/3$, the equivalent wye, or line-to-neutral impedance of the transformer bank, in low-voltage ohms.

z' = the line-to-neutral impedance of the external circuit to fault in low-voltage ohms including conductor impedance and fault impedance, that is, the impedance of one of three assumed equal arcs to their common meeting point.

Line-to-Line Short-Circuit Analysis

Transformers Connected in Delta on Low-Voltage Side

Line-to-line short circuits frequently occur on exposed wires and in open bus structures. This type of fault is probably most frequent on distribution systems where one corner of the secondary delta is connected to ground. Analysis is made by using the method of symmetrical components.[3,4] In terms of the open-circuit secondary voltage, the low-voltage fault current is

$$I_{L-L}=\frac{E_s}{2[z_{TL}''+z_{(s-P)}']+z} \tag{14}$$

in which the quantities have been previously defined. For this case z equals the total external impedance of the external circuit to fault in low-voltage ohms (in contrast to z' used for the three-phase analysis).

Short Circuits on Single-Phase Transformer Secondary Circuits

Transformers Supplied From Two High-Voltage Lines

The problem of determining short-circuit currents on single-phase transformer secondary circuits is so important that it deserves mention. If the transformer and total external impedance to fault is referred to the high-voltage side, the equation is obtained from elementary methods by inspection:

$$I_{HT1\phi}=\frac{E}{2Z_{TL}+Z_{(P-S)}+Z} \tag{15}$$

in which

$Z=n^2z$, the impedance of the external circuit to fault in equivalent high-voltage ohms

Or, the low-voltage secondary current equals:

$$I_F=\frac{E_s}{2Z_{TL}/n^2+z_{(s-P)}+z} \tag{16}$$

Equations 15 and 16 give correct results for symmetrical subtransient fault currents. The line-to-line fault analysis developed by using the method of symmetrical components is a better approach from the strictly technical viewpoint. This gives the same equations but has the advantage that the proper generator constants may be included in the transmission-system impedance term and

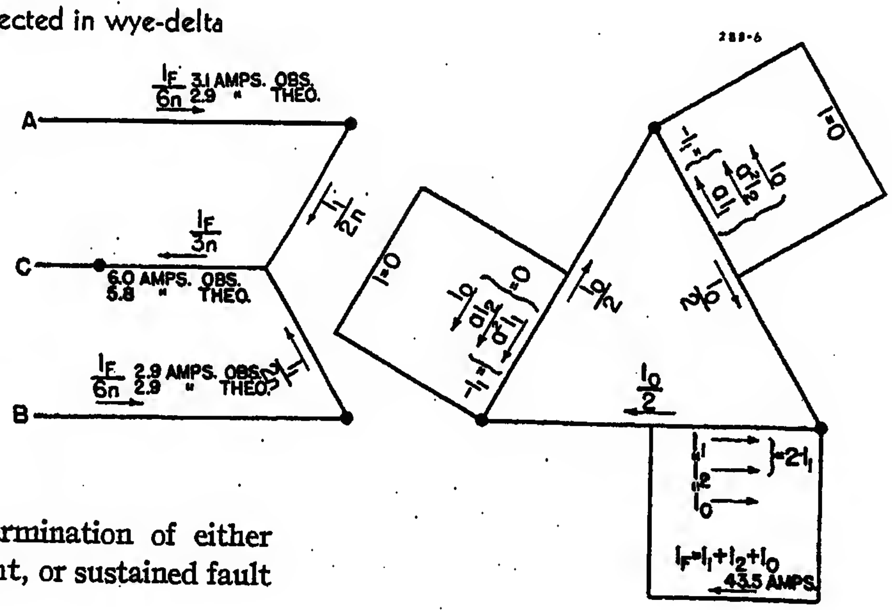

Figure 6. Detailed current distribution for a light-leg-to-ground short circuit

Transformers connected in wye-delta. Experimental values inserted

thereby permit determination of either subtransient, transient, or sustained fault current.

Transformers Supplied From One High-Voltage Line and Neutral

Analysis for this case is similar to the preceding analysis, and from the method of symmetrical components

$$I_{HT1\phi}=\frac{3E/\sqrt{3}}{2Z_{TL}+Z_{0TL}+3Z_{(P-S)}+3Z} \quad (17)$$

or the low-voltage secondary current equals

$$I_F=\frac{3E_s}{(2Z_{TL}+Z_{0TL})/n^2+3z_{(S-P)}+3z} \quad (18)$$

in which Z_{0TL}= the zero-sequence impedance of the transmission system in high-voltage ohms.

The equations for line-to-ground faults on three-wire systems supplied from single-phase transformers having the mid-tap of the low-voltage secondary winding connected to ground are the same as the above with the following modifications: The voltage effective in producing short-circuit current is now $E_s/2$, the ratio of transformation is $2n$, and the transformer impedance is $z_{(S/2-P)}$.

Short-Circuit Currents on Distribution Systems Resulting From High-Voltage Transformer Failures

During the initial stages of an internal failure between the high-voltage and low-voltage windings of a transformer, that is, before any of the conductors have been opened due to arcing, the high-voltage fault current flowing through the low-voltage secondary windings induces compensating currents in the high-voltage windings which circulate back through the high-voltage circuits. Also, under these conditions the transformer saturates because of high-voltage impressed on the low-voltage windings. Saturation neglected the requirement of equal and opposing ampere turns is met, and the current limiting effect of the transformer is due to leakage impedance. Actually, because of saturation, the effective impedance may be somewhat less than the leakage impedance. For purposes of illustration consider a three-phase distribution transformer supplied from a transmission line of reasonable length and assume that short circuits occur between each high-voltage terminal and the corresponding low-voltage terminal. The impedance limiting the fault current is equal to the transmission-system impedance up to the transformer terminals in high-voltage ohms, plus the impedance of the transformer in low-voltage ohms. Thus, the additional impedance opposing the high-voltage short-circuit current flowing in the secondary winding equals the transformer impedance in high-voltage ohms divided by the ratio of transformation squared (that is, n^2).

For most practical distribution systems n^2 is large, and the additional current-limiting effect due to the transformer is small. For 2,400 delta 240-volt transformers $n^2=100$, and the additional impedance is one per cent of the transformer leakage impedance (saturation neglected).

Where the windings have been opened, and compensating currents cannot flow, the current-limiting effect of the transformer is due to exciting impedance. Very high saturation results, and it has been suggested that the exciting impedance may approach leakage reactance in magnitude. Analysis for this case is similar to that in the preceding paragraph. The saturated exciting impedance in high-voltage ohms is reduced by the square of the turn ratio, and the effect of the transformer may be neglected as a first approximation.

For unsymmetrical transformer failures, such as a breakdown near the end turns or between the high- and low-voltage bushings, the effect of transformer impedance is likewise small. The voltage effective in producing the fault current equals the vector sum of the voltage of the high-voltage system and the induced voltage of the secondary winding. In cases where the ratio of transformation is small, this effect may

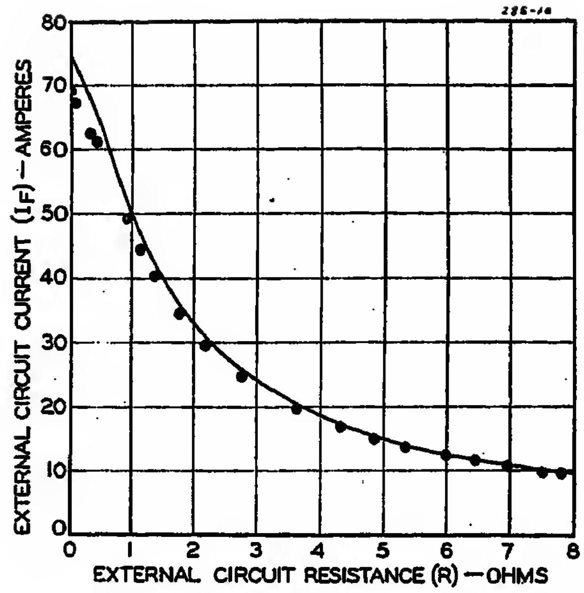

Figure 10. Power-leg-to-neutral experimental short circuits

Transformers connected in delta-delta

be important. However, for cases where the ratio is 10/1 or greater, this effect is also small and may be neglected for approximate work. An internal failure between the windings introduces additional complications, but it is unlikely that the fault current would be greater than that caused by breakdown near the extremities of the windings. Since the effects due to the transformer are relatively small, they may be neglected in estimating the high-voltage short-circuit current flowing to ground in low-voltage distribution circuits due to high-voltage transformer failures. Figure 13 gives a few of the laboratory connections used in the study of high-voltage transformer failures. The arrows represent the detailed current distribution and indicate the compensating primary currents induced by the high-voltage fault current flowing in the low-voltage secondary windings.

It is believed that the total high-voltage short-circuit current produced in low-voltage distribution circuits due to a distribution transformer failure can be determined with an accuracy sufficient for most practical purposes by neglecting the effects of the transformer itself. Additional impedances, such as the resistance of ground return circuit, must be included. It is obvious that the errors due to the approximation decrease as the impedance of the transmission system up to the transformer is increased, and conversely. It is believed this procedure is satisfactory for cases in which the feeder impedance is at least equal to 50 per cent of the transformer leakage impedance in high-voltage ohms. This analysis permits study of the effects of grounding resistances for distribution systems. It gives an approximate method of estimating the voltage to which a distribution system may rise above

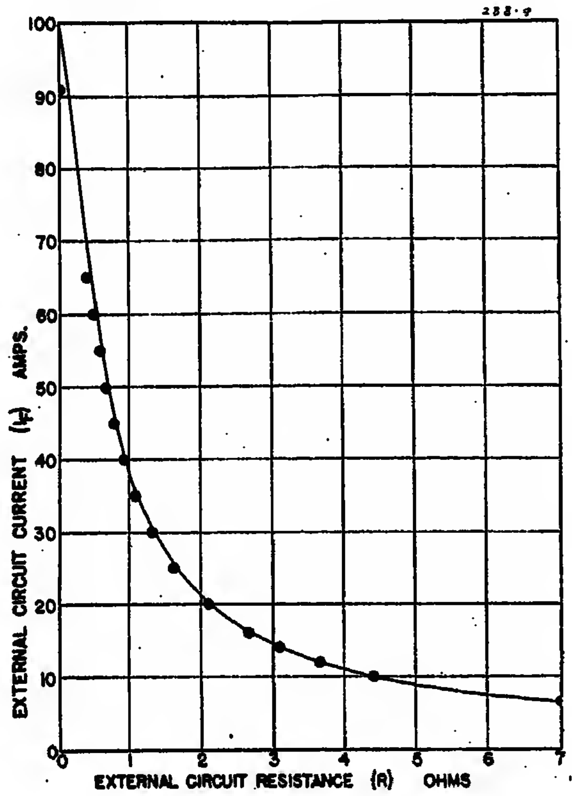

Figure 9. Power-leg-to-neutral experimental short circuits

Transformers connected in wye-delta

ground because of transformer failure, and it is important in the study of protective measures and shock hazard. Experience shows that the number of high-voltage failures in modern distribution transformers are relatively small in comparison to the number in service. However, breakdowns occasionally occur, and a mathematical approach to the problem is of value.

The total fault current in the low-voltage distribution circuit due to a high-voltage transformer breakdown is obtained from the conventional line-to-ground analysis, neglecting the effect of the transformer:

$$I_G = \frac{\sqrt{3}E}{2Z_{TL}+Z_{0TL}+3z} \tag{19}$$

The voltage rise of the secondary neutral above ground potential due to

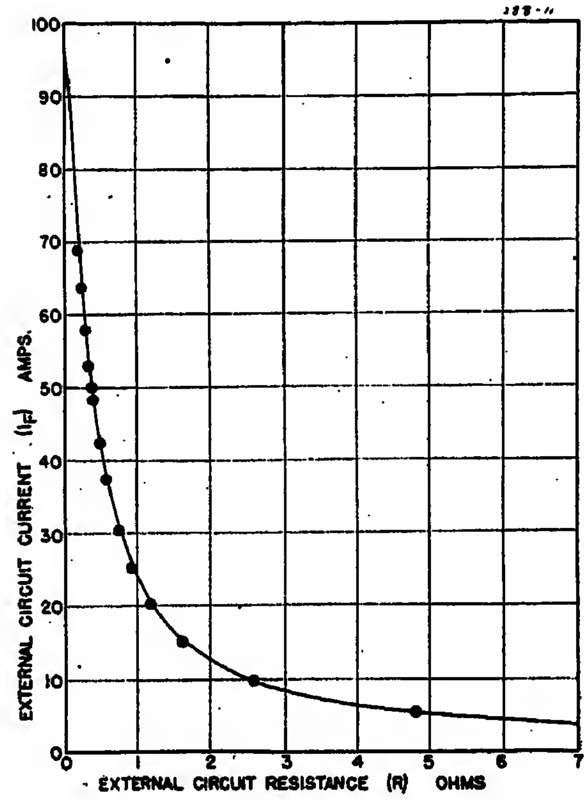

Figure 11. Light-leg-to-neutral experimental short circuits

Transformers connected in wye-delta

this fault current flowing through the impedance to ground equals:

$$E_{LT\ \mathrm{neutral}} = \frac{\sqrt{3}Ez}{2Z_{TL}+Z_{0TL}+3z} \tag{20}$$

in which z represents the grounding impedance (that is, resistance of driven ground in ohms), and other quantities as defined previously.

Experimental Results

Experiments were made on a laboratory model consisting of three reactors connected to simulate a short transmission line and four ten-kilovolt-ampere transformers having two tapped primary and secondary windings, rated 500/100 volts. The experimental points and theoretical curves for power-leg-to-neutral and light-leg-to-neutral short circuits are given in

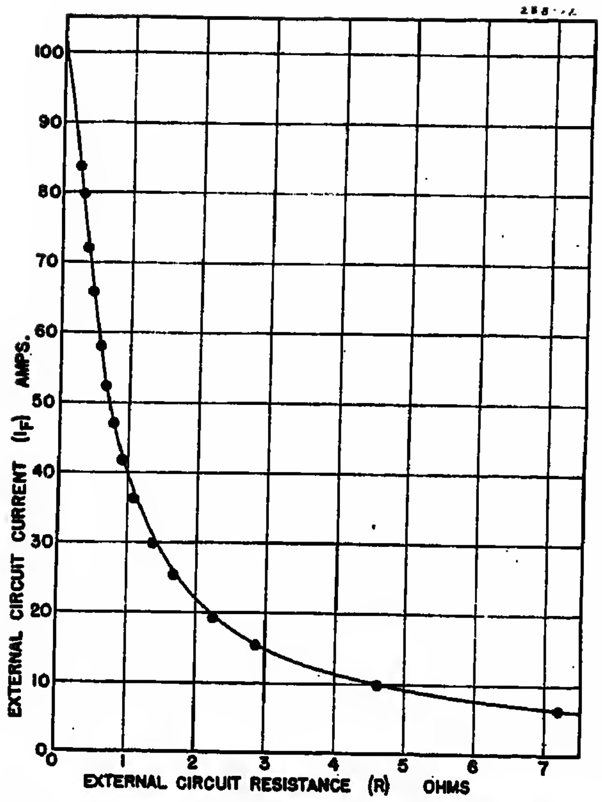

Figure 12. Light-leg-to-neutral experimental short circuits

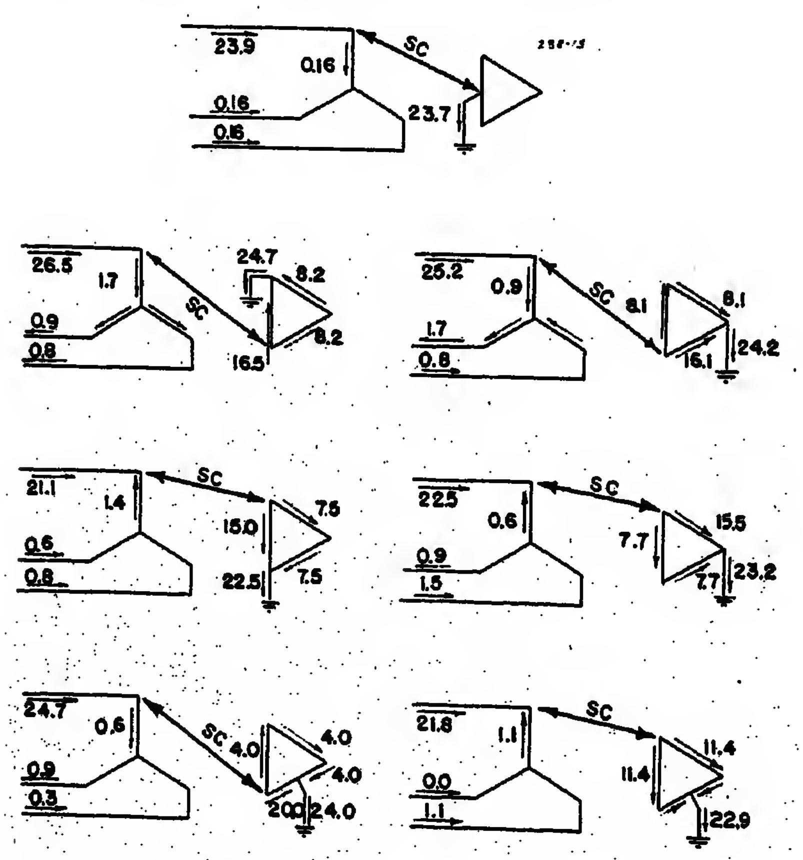
Transformers connected in delta-delta

Figures 9 to 12 inclusive. The fault or current in the external circuit was plotted against external circuit resistance. The calculations included all known resistances of the circuit, including the resistance of a water-box load connected to simulate the fault, conduit return, and arc resistance. Theoretical and observed currents have also been inserted in Figures 3A, 4A, 6, and 8, to check the determination of high-voltage line currents. The transformers were connected 500 to 200 volts for these tests, and for Figures 11 and 12 three transformers were used. For the tests of Figures 9 and 10 four transformers were used; two transformers were connected in parallel to simulate the practical case where the lighting transformer had twice the capacity of the power transformers. The agreement between observed and theoretical values was believed satisfactory and is offered as substantiating the analysis. It was noted that the experimental values were slightly less than the computed curves, the discrepancy increasing for smaller values of resistance. The error was believed to be due to the resistance of the many leads and split-terminal socket connections which obviously could not be included in the analysis, to the fact that the system was not entirely symmetrical since the transformers and reactors did not have identical impedances respectively, and to slight unbalances of the supply voltages. The poorest correlation was obtained for the power-leg-to-neutral short circuit with the transformers connected in delta-delta. It should be noted that the discrepancies were on the safe side, as the measured values were low.

Several experiments were made to check the conclusions given in the discussion of high-voltage transformer failures. Short circuits with the transformers energized at reduced voltage were made to simulate primary to secondary failures using three transformers connected 1,000/100, 1,000/200, and 500/500. Typical results for various fault locations for the 1,000/100-volt connection are given in Figure 13. If the winding currents are multiplied by factors proportional to the turn ratio, primary and secondary ampere turns are in close agreement. The slight discrepancies from theoretical values are attributed largely to the effects of saturation and exciting current. This substantiates the statement that as long as compensating currents flow, transformer leakage impedance rather than exciting impedance, is the most important factor in limiting the fault current. As was expected, the effects due to the transformer decreased as the ratio of transformation was increased. The greatest observed error for the 1,000/100-volt connection was five per cent. For these tests the artificial transmission-line impedance was equal to 43 per cent of the transformer leakage impedance, and the ratio of Z_{0TL} to Z_{1TL} was varied between 1.0 and 5.5/1. From this it was concluded that the effects of the transformer may be neglected in approximate determination of the total short-circuit current in low-voltage circuits of practical distribution circuits because of high-voltage transformer failures for ratios of transformation of 10/1 or greater.

Figure 13. Study of effect of transformer in limiting short-circuit current for typical high-voltage transformer breakdowns



Application

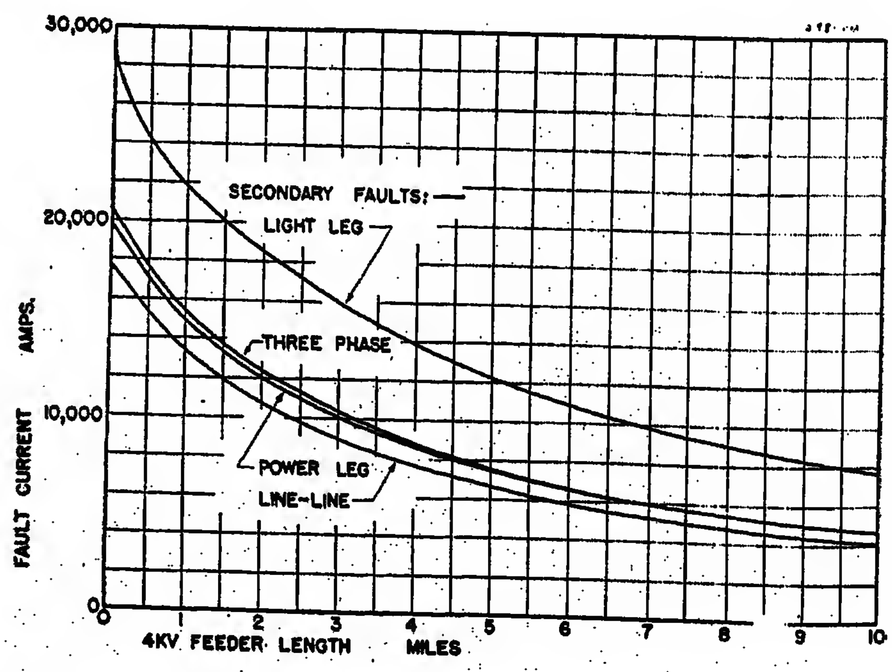
For purposes of illustration, the results of this investigation were applied to a typical installation consisting of three 100-kva 2,400/240–120-volt distribution transformers supplied from an infinite bus over a four-kilovolt feeder. The feeder was three-conductor 4/0 copper having the common horizontal spacing of 23–30–53 inches, and $Z_{TL}=0.303+j0.622$ ohm per mile. It was assumed that $X_{0TL}=3.5X_{TL}$. The following constants were obtained from tests on one 100-kva unit.

$z_{(S-P)} = 0.00691+j0.01895$ ohm or $0.012+j0.0329$ per unit

$z_{(S/2-P)} = 0.00277+j0.00528$ ohm or $0.01925+j0.0366$ per unit

Figure 14. Short-circuit currents for 300-kva, 2,400-wye/240-120-volt transformer and four-kilovolt feeder

Fault resistance assumed zero



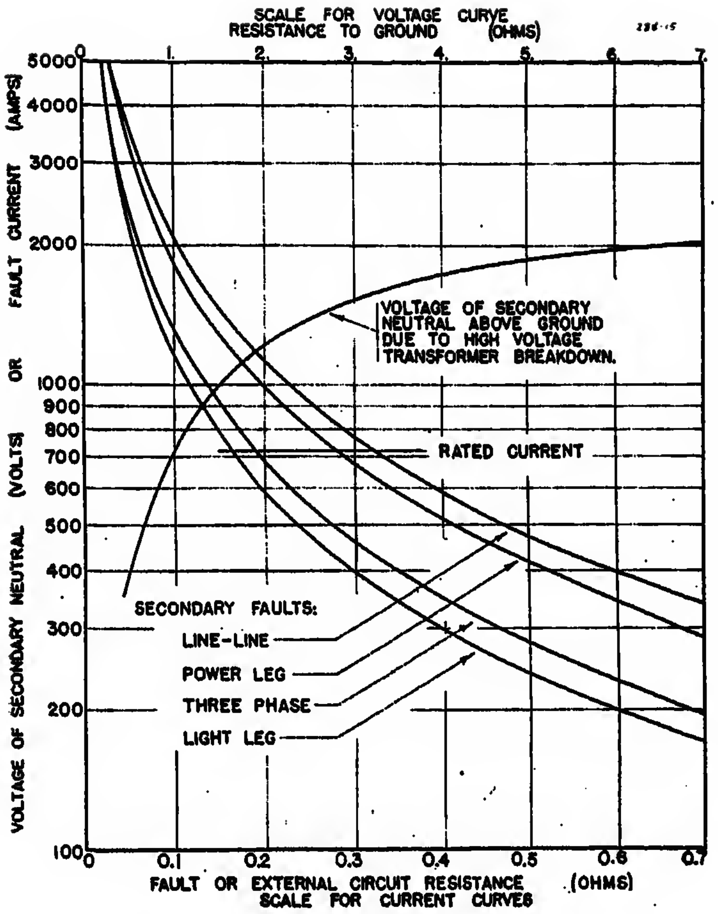


Figure 15. Short-circuit currents and voltage of secondary neutral for 300-kva 2,400-wye/240-120-volt transformer and 2.5 miles of four-kilovolt feeder

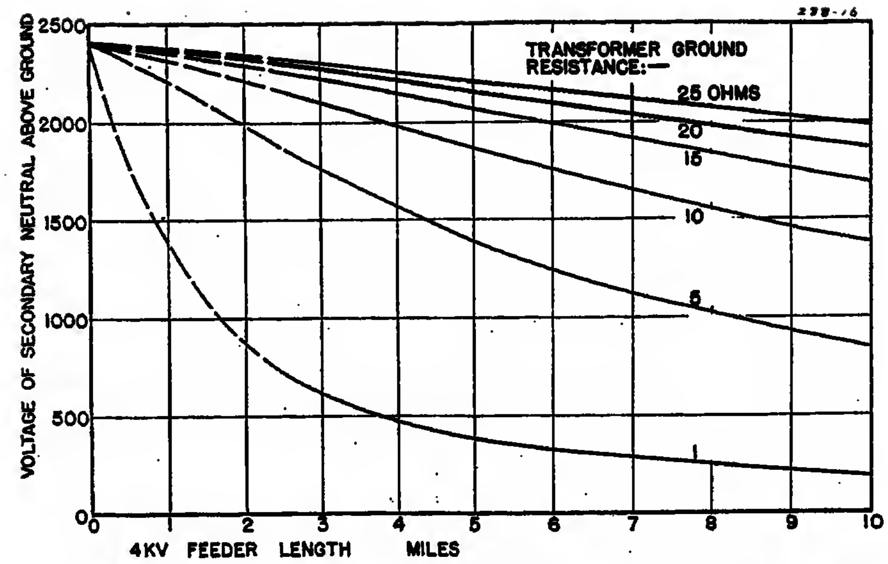

Figure 16. Voltage of secondary neutral above ground due to high-voltage transformer breakdown for 300-kva 2,400-wye/240-120-volt transformer and four-kilovolt feeder

$z_{(S/2-S/2)} = 0.00355 + j$ nil ohm or
$0.0246 + j0.000$ per unit

The transformers were assumed connected in wye-delta with the mid-point of one secondary winding connected to a ground having a variable resistance (R) ohms.

Figure 14 gives results for three-phase line-to-line power-leg-to-ground and light-leg-to-ground short circuits for various lengths of feeder up to ten miles. The fault or ground resistance was assumed zero for this case. It was noted that the light-leg-to-ground fault developed the greatest current, whereas the three-phase and power-leg short-circuit currents were approximately equal. Line-to-line short-circuit currents were the smallest and were equal to the three-phase value multiplied by 0.866.

The effects of fault resistance and resistance to ground are shown in Figure 15. For this case the feeder length was assumed to be $2^1/_2$ miles, and the fault currents were determined for external circuit resistances of 0 to 0.7 ohm. The power-leg-to-ground fault current decreased less rapidly than the light-leg fault current, the latter decreasing from its predominating value for zero resistance to values consistently below that of the other curves. It was interesting to note that if the line-to-line short-circuit current values are sketched in as a function of one-half the fault resistance, the curve practically coincides with the light-leg fault-current curve over the range covered in the figure. The important point brought out by the curves is the large current-limiting effect due to relatively small values of resistance.

The relatively large effect of small impedances in limiting low-voltage short-circuit currents has economic importance. The impedance of current transformers, resistance of joints, and the reactance due to bends in busses and connections may result in a material decrease in the interrupting duty of auxiliary circuit breakers or fuses in comparison with the main circuit breaker. Consideration of these factors in choosing the location of circuit breakers may point to improvements in plant layout with significant savings for large capacity low-voltage installations. Another aspect of this problem concerns the positive operation of circuit breakers or fuses. The protective devices would probably be set to clear for 150 to 250 per cent rated current. Entering the curves with these current values indicates that an external circuit resistance in excess of only 0.06 to 0.10 ohm would prevent proper clearing of faults. The advantage of several subfeeders with low trip values instead of one or two main circuits with high trip values or large fuses is self evident. In cases where high current-rating fuses are required, some form of ground protection (at the main circuit breaker) may be desirable.

The curve showing voltage rise of the low-voltage neutral above ground, due to a high-voltage transformer breakdown, was computed for resistances to ground of 0 to 7.0 ohms. It was found that the fault current would be limited to the rated low-voltage current of the transformer for a ground resistance of about 1.0 ohm. Hence, it was concluded that most transformer failures would be cleared only by the protective devices on the high-voltage side. During the time required to actuate the protective device, the voltage of the distribution system will be subjected to relatively high potential above ground. For example, the voltage above ground reaches 1,500 volts (the minimum dielectric strength of code rubber when new) for a ground resistance of three ohms, whereas a grounding resistance of five to seven ohms provides small protection indeed. The voltage rise of the secondary neutral above ground due to transformer failure for various resistances to ground is plotted as a function of four-kilovolt feeder length in Figure 16.

The results of the study emphasize the importance of securing low resistance to ground and low return-circuit resistances for distribution systems. It is realized that it is often difficult if not impossible to obtain driven or buried grounds having resistances low enough to provide satisfactory protection for low-voltage distribution circuits. This is particularly important for 240-volt three-phase three-wire installations where the mid-tap of one transformer is grounded and the neutral is not run into the plant. The author knows of one such installation consisting of a large transformer bank supplied over a regulated four-kilovolt feeder only a relatively short distance from the substation. The single driven ground at the transformer structure measured about 100 ohms. Although the plant conduits and equipment were apparently well grounded to the water system, little protection was actually afforded against either transformer breakdown or short circuits involving a ground return within the plant. Although the above remarks refer to the examples chosen for study, somewhat similar conclusions might result from analysis of many commercial installations.

Theoretical Possibilities in an Internally Heated Bimetal Type of Thermal Watt-Demand Meter

EDWARD LYNCH
MEMBER AIEE

Synopsis: There are two generally recognized methods of measuring demand. The block-interval type has been used extensively where great accuracy is desirable, a simple explanation necessary, and a quick testing method essential, but the "logarithmic" type has received increased attention in recent years, and a greater dissemination of knowledge of its characteristics is desirable.

A mathematical expression for "logarithmic" average is given which can apply to a variable load as well as to a uniform load. It is shown that a meter with a simple exponential time-deflection characteristic will indicate this "logarithmic" average, but that meters with characteristics obtainable in present commercial thermal meters will theoretically differ from it except when used with certain loads.

The accuracy of commercial meters has increased in recent years. So besides indicating that the various types of characteristics available in commercial meters have apparently been satisfactory on normally encountered loads, it is shown that sturdiness and high torques are desirable features to sustain these accuracies.

The internally heated thermal watt-demand principle is discussed, and the conclusion is reached that by its use high torque can be obtained using the time tested bimetal type of meter. In addition, the rapid diffusion of heat in the bimetal where it is generated theoretically allows shorter "heat-up" time when the meter is being tested and results in a time-deflection characteristic much closer to the ideal simple exponential.

Paper 42-110, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 13, 1942; made available for printing May 20, 1942.

Edward Lynch is thermal device engineer, West Lynn works, General Electric Company, Lynn, Mass.

Demand measurements when combined with watt-hour-meter readings have been recognized as giving a practical basis for electricity charges.[1,2] In the United States demand meters operating on the block-interval principle have been extensively used, and their operating principle and characteristics are well understood.

There is another recognized method of measuring demand which has been used to a limited extent for the same purpose. It is the method utilized by thermal demand meters, and the resulting indication has been called the "logarithmic average" demand. A general explanation of meter design considerations which enter into this demand indication and the operating characteristics which they affect will be covered in the following discussion.

Time Deflection Characteristic

The block-interval meter indicates continual arithmetic average maximum demand. The thermal meter obtains its average in a different manner, and it indicates a slightly different quantity which can be designated as continuous logarithmic average maximum demand. On a constant load its reading changes rapidly at first and then more slowly until, in the case of a meter which reaches 90 per cent of its indication in 15 minutes, which by definition makes it a 15-minute demand interval meter, it would be within about one per cent of its ultimate in 30 minutes. From this characteristic we see that any load on the meter during the 30 preceding minutes may have a readable influence on the demand pointer indication, but that the longer time that has elapsed, the less effect this load has on the reading. The indicating pointer on these meters is therefore continuously changing its position as load changes occur according to what has been called a "logarithmic" average.

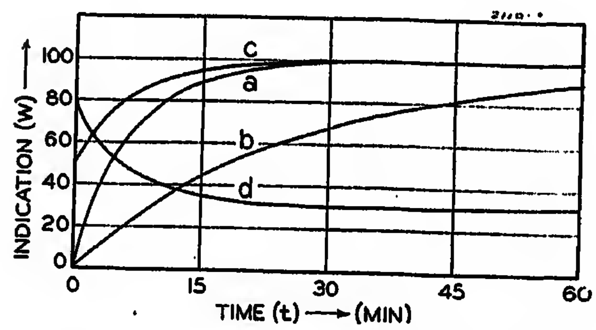

Figure 1. Curves of $W = W_1(1-\epsilon^{-kt}) + W_0\epsilon^{-kt}$

	W_1	W_0	K
a	100	0	0.1535
b	100	0	0.0384
c	100	50	0.1535
d	30	80	0.1535

This average for a theoretical meter can be expressed as follows (see appendix B):

$$W = k\int_{-\infty}^{t} w\epsilon^{-k(t-t_1)}dt_1 \tag{1}$$

where

W = instantaneous deflection of pointer
k = a design constant
w = load (which may vary with time)
t = time at which deflection is W
t_1 = time at which load is w

On constant loads after about three demand intervals this "logarithmic" average is identical with the arithmetic average as given by a block-interval type of meter.

This study would hardly be complete without one or two constructive suggestions. The goal must be as low a resistance to ground as possible. The resistances of the ground circuit must be maintained sufficiently low to insure positive operation of the protective devices in case of transformer failure. In addition, it would appear that considerable protection would result if, in addition to providing the best ground that can be reasonably obtained at the transformer installation, the low-voltage neutral be carried along with the phase wires (regardless of whether or not it is to be used for power) and connected to the plant conduit system and grounded as effectively as possible on the customer's premises. The common neutral system of grounding would appear to provide an alternate method of accomplishing the same result.

Simple Exponential Is Ideal

However, time-deflection characteristics of commercial thermal meters are not identical, and they differ from the characteristics of block-interval meters so that on fluctuating loads they can theoretically give slightly different readings. The following discussion of theoretical and practical time-deflection curves will indicate the desirability of a simple exponential characteristic for the thermal meter.

Figure 1 shows typical theoretical time-indication characteristics of thermal meters when a constant load is applied. Curves *a* and *b* differ by the fact that the demand interval or time to reach 90 per cent indication is 15 minutes (k is 0.1535) for *a*, and 60 minutes (k is 0.0384) for *b*. Curves *c* and *d* have 15-minute demand intervals but start with an initial indication. Each curve can be expressed by the "exponential" equation:

$$W = W_1(1-\epsilon^{-kt}) + W_0\epsilon^{-kt} \qquad (2)$$

(See appendix A)

where

W = instantaneous deflection of pointer
W_0 = deflection of pointer at zero time
W_1 = ultimate deflection for load involved
ϵ = 2.718
k = a design constant
t = time

(W, W_0, W_1 must be expressed in the same units, and k must be in units the reciprocal of the units for t.)

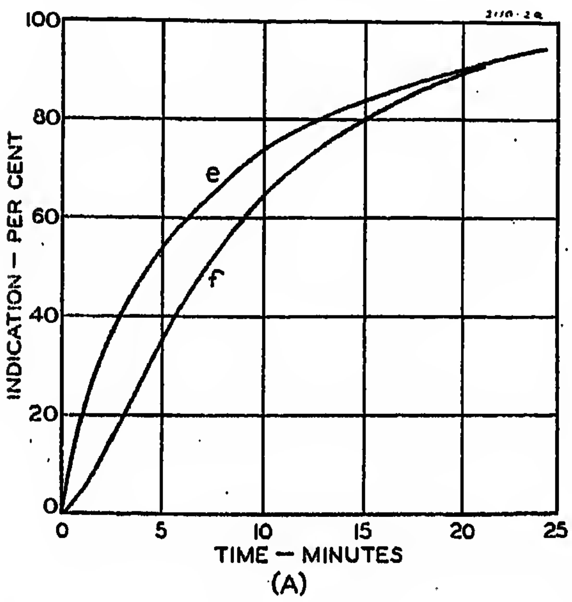
The well-known expressions $W = W_0\epsilon^{-kt}$ and $W = W_1(1-\epsilon^{-kt})$ for the transient return of the indication to zero when power is cut off, and the rise to ultimate deflection when a constant load is applied from zero deflection, can be seen to be special cases of the above more general equation. Equation 2 holds for conditions of constant applied load, whether or not the indication starts or ends at zero, and whether the indication increases or decreases. It is interesting to note that the instantaneous deflection is equivalent to the sum of two hypothetical indications, one of which starts at zero and rises to the ultimate deflection of the meter, and the other of which starts at the initial indication of the meter and reduces to zero, both following the locus given by equation 2.

It is also interesting to note that k, which determines the demand interval has a dimension equivalent to the reciprocal of time and is a function of the heat insulation of the heated parts (increasing as the insulation decreases), and a function as well of the heat capacity of the heated masses (increasing as the capacity decreases). This same k represents in magnitude the reciprocal of the time that would be necessary to attain proper deflection if there were no heat escape. It also represents the reciprocal of the time necessary to accomplish a change in indication represented by the following fraction of the total change:

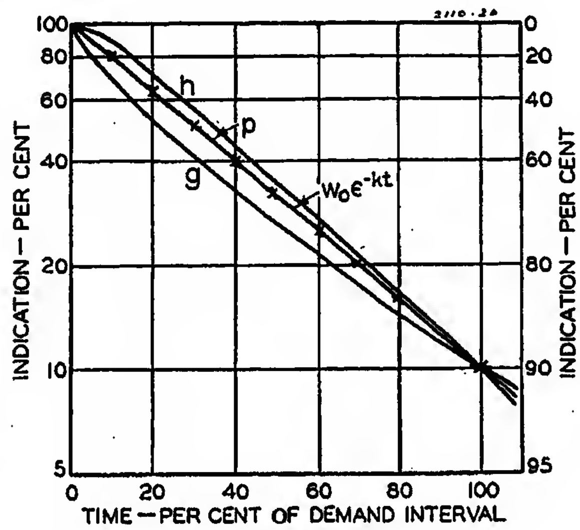
The fraction is:

$$\left(1-\frac{1}{\epsilon}\right) = 0.632 \text{ approximately}$$

If the load varies at a uniform rate (see appendix B), either increasing or decreasing, k has further physical significance because $1/k$ represents the time between the arrival at some particular watt load and the indication of that load by the meter, providing the rate has been uniform long enough (three demand intervals) for this time lag to become essentially constant. This time lag is independent of the rate of change of watts and the meter demand interval is directly proportional to it if we consider simple exponential characteristics.



A. Load cut to zero after equilibrium temperature is reached



B. Constant load applied from zero

Figure 2. Time-indication curves of typical thermal watt-demand meters

Time-Deflection Curves in Meters

No commercial meter in the past has, to the writer's knowledge, attained exactly an indication given by equation 2. Curves *e* and *f* in Figures 2A and 2B represent typical time-deflection curves of actual meters which have been converted to equivalent demand intervals in *g* and *h* and are plotted decreasing from an initial value on semilog co-ordinates in order to easily compare them with the straight line *p* of $W_0\epsilon^{-kt}$.

An investigation of time-indication curves on any particular type of thermal meter indicates that there are small variations from meter to meter in the demand interval due to limitations in manufacturing control. We find also that in the same meter there are differences depending on the conditions of load and ambient temperature. We can reason from this that for a "15-minute demand interval" meter the actual demand interval should not be less than 15 minutes under any normal conditions of use in order not to read high on certain conditions of load, and we find practically all meters on the market which are considered satisfactory today for use as 15-minute demand interval meters fall within limits from 15 to 21 minutes interval.

When we consider differences in the curves in Figures 2A and 2B, we find another fundamental characteristic which although small might appreciably affect the meter readings in certain isolated conditions. This effect is easily demonstrated by applying a load which would give about full-scale deflection in 40 minutes and cut the load off at the end of five minutes. If we consider the "exponential" characteristic as shown in *p* as a standard of comparison, we find that a meter with a characteristic similar to *e* may read high by eight per cent of full scale, and a meter similar to *f* may read low by eight per cent at the instant the power is cut off. These should not be considered as errors as the definition of the time-deflection characteristic determines these differences. The meter following the *d* curve will continue to rise for a

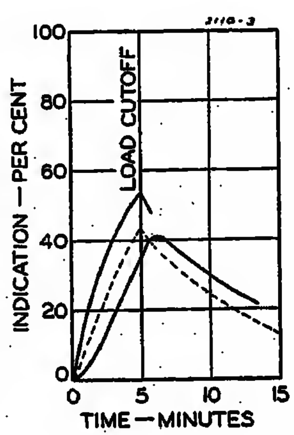


Figure 3. Time-indication curves for typical thermal watt-demand meters

Uniform load cut to zero before thermal equilibrium has been attained

little time after the power is cut off but will not quite reach the maximum value reached by the "exponential" characteristic. Figure 3 shows this characteristic graphically. It will be noted that meters with the f characteristic lag behind changes in load, while meters with the simple "exponential" or the e type of characteristic will change direction immediately in the direction of the new load value.

Simple Exponential Curve Desirable

From this brief discussion we can reason that as far as thermal meters are con-

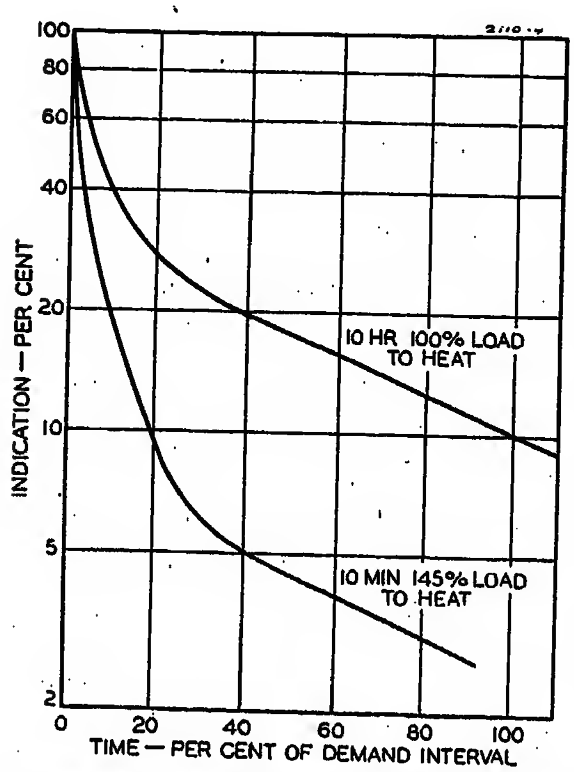

Figure 4. Time-indication curves of special thermal watt-demand meter

Cooling curves after loads as shown

cerned, subject, of course, to any considerations which rate engineers may find of importance, the simple "exponential" time-indication curve published as characteristic of thermal meters is desirable. It is desirable if an acceptable time-indication curve is to be defined, for it allows a relatively simple mathematical definition of the shape of the curve. And more important is the fact that it is the only characteristic which will indicate "logarithmic" average for all types of loads.

Multibranch Thermal Circuits

The reason for the divergence of commercial-meter characteristics from the simple exponential has been attributed to diffusion.

Figure 4 shows performance curves of a 60-minute-interval thermal wattmeter illustrating an exaggerated condition of this diffusion which appeared in a paper presented by P. M. Lincoln before the Institute. The design constant, k was treated as a variable to account for the results. A slightly different treatment of the curves may be of interest and offers some advantages from a mathematical point of view in determining their shape.

The analogy shown in Figure 5 illustrates that multiple-branch thermal circuits may be expected to cool in a constant ambient according to the exponential:

$$W = W_0(A_1\epsilon^{-k_1t} + A_2\epsilon^{-k_2t} + A_3\epsilon^{-k_3t} \ldots + A_n\epsilon^{-k_nt}) \quad (3)$$

We can use the following expression to predict changes in indication when any constant load is applied:

$$W = W_0(A_1\epsilon^{-k_1t} + A_2\epsilon^{-k_2t} \ldots + A_n\epsilon^{-k_nt}) + W_1(1 - A_1\epsilon^{-k_1t} - A_2\epsilon^{-k_2t} \ldots - A_n\epsilon^{-k_nt}) \quad (3a)$$

In these equations A_1, A_2, k_1, k_2, and so forth are complicated functions of the storages and heat-transfer coefficients of the various branches. The form $W_0\epsilon^{-kt}$ referred to in various literature on thermal demand meters has been referred to above as a special case of equation 2, and equation 2 can be seen to be a special case of this more general equation 3a.

P. M. Lincoln has shown that the simplified expression is inadequate to explain the results of his tests unless we treat k as a variable. However, the results shown in Figure 4 can be predicted approximately from an equation such as 3, carried out to three terms as below:

$$\text{Indication} = W_0(0.19\epsilon^{-0.921t} + 0.51\epsilon^{-0.2302t} + 0.3\epsilon^{-0.019t}) \quad (4)$$

This curve is plotted in Figure 6 where the first term is given as a dotted line, the second term as a dash line, and the third term as a dot and dash line, and the total as a full line. This curve checks reasonably with the per cent indication versus time curves (after ten-hour heating). Another group of curves (Figure 7) shows the heating curve for ten minutes at 145 per cent load and the following cooling curve when the load is removed, as given by constants in equation 4. Crosses indicate points calculated by considering the multiple-branch circuit as used in equation 4, and the circles represent points taken from Doctor Lincoln's meter data. The correlation is considered reasonably good for a first approximation of coefficients and exponents in the above equation. This allows us to think of meters of this nature as if they were the equivalent of multiple-branch thermal circuits with more than one constant k. Thus although such a meter reaches about 90 per cent of its final indication in 60 minutes, its final indication within reading limits will depend on the coefficient and power terms of one or more of the terms in equation 3. This may result in an extremely long time when considered from a testing point of view. In the above equation 4 for the 60-minute characteristic shown in Figure 6, k_1 corresponds to a demand interval of about 2.5 minutes and k_2 to an interval of about ten minutes and k_3 to an interval of about two hours. Doctor Lincoln has shown that meters with performance closer to the simple expression $W = W_0\epsilon^{-kt}$ can be built.

Time-Indication Curves of "Square" Scale Meters

When we consider the time-indication curves of a demand meter with a "square"

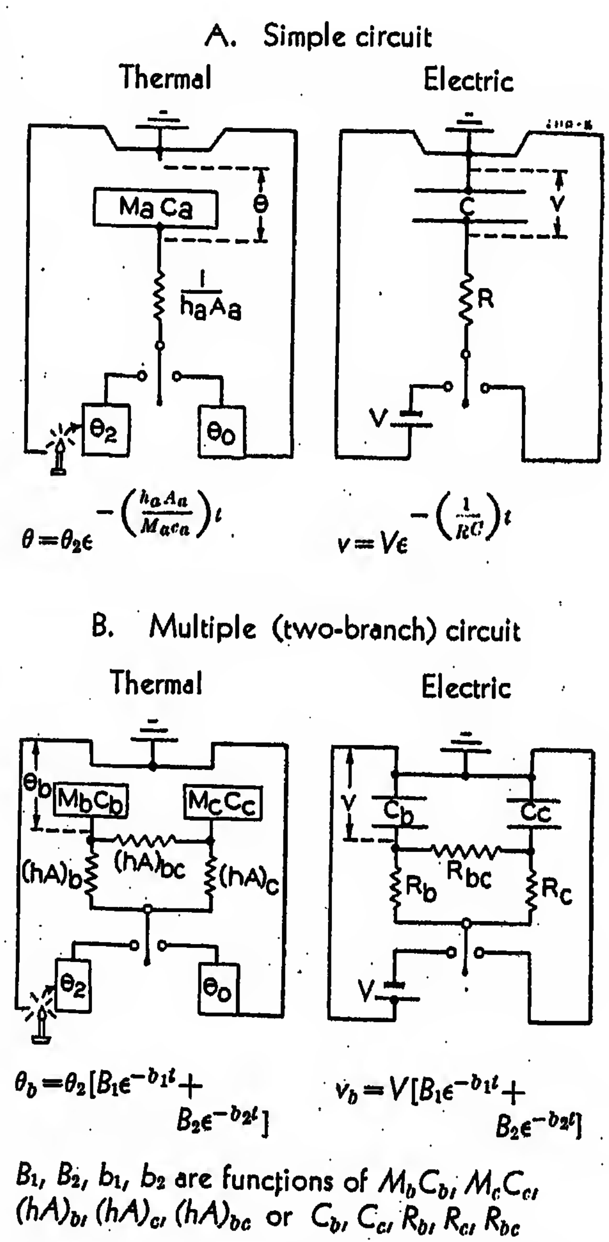

Figure 5. Comparison of thermal and electric circuit

M = mass
c = specific heat
C = capacitance
h = heat transfer coefficient
A = area
R = resistance
θ = temperature difference
v = voltage
θ_2 = initial temperature difference
V = initial voltage
θ_0 = ambient temperature

scale such as those used for ampere demand, we encounter further characteristic differences. The time-deflection characteristic of the wattmeter (as a simple thermal circuit) in general form has been given in equation 2 for constant applied loads. The time-deflection characteristic of a "square" scale meter can be expressed similarly, but since the indication is not proportional to the deflection but is proportional to its square root, we find the expression for indication:

$$A=\sqrt{A_0^2\epsilon^{-kt}+A_1^2(1-\epsilon^{-kt})} \tag{5}$$

where

A = instantaneous indication on a "square" scale (constant load)
A_0 = initial indication on a "square" scale
A_1 = final indication (constant load)

This reduces $A_0\epsilon^{-k/2\,t}$ when load is cut off. This has the same form as $W_0\epsilon^{-kt}$, and the cooling curve of time-indication will have the same general shape as the wattmeter, but since the exponent is $k/2$, it will take twice as long to cool to any percentage indication.

If the load starts at zero indication equation 5 reduces to

$$A=A_1\sqrt{1-\epsilon^{-kt}}$$

It can be seen that this does not have the same form as $W=W_1(1-\epsilon^{-kt})$, which is the equivalent on a uniform scale. These curves are shown graphically in Figure 8.

It may seem desirable to keep the shape of the time-indication curves of "square" scale and uniform scale meters on increasing loads (starting at zero) as nearly alike as possible. It has been proposed to decrease k for the ammeter to half the value for a wattmeter. This gives curve n shown in Figure 8 (as compared to curve j). It also gives a cooling curve m which is indeed slower (compared to i). Such a meter not only will differ in basic construction but also will theoretically differ on varying loads when compared to the uniform scale meter.

Another alternative suggested is to utilize the design and construction of the wattmeter, which requires changing the definition of demand interval so that the fraction of final indication of a "square" scale meter is the square root of that of a uniform scale meter. Thus, if the wattmeter is kept at 90 per cent for the demand interval definition, the ammeter would then be $\sqrt{0.90}=0.95$ or 95 per cent. Such a meter does not have the same characteristic as a uniform scale meter, and its reading will differ on varying loads when compared to the uniform scale meter. (See k and l of Figure 8.) However, if the basic characteristic of interest is the heating effect, then the characteristic of this meter favorably compares with that of a uniform scale wattmeter. Perhaps in such a case, the scale marking should be in terms of amperes squared.

It is interesting to note that differences of watt- and ampere-demand meter readings on normally encountered loads have been sufficiently small to allow the use of meters with many of the varying characteristics described above with satisfactory results.

Operating Characteristics

With a knowledge of the fundamental operation characteristic of thermal meters, let us consider how it is affected with time or with changing conditions of load power factor, ambient temperature, and so forth. One of the important considerations in reliability of a meter of this kind is mechanical stability in which sturdiness of construction and constant friction are important factors. These factors are especially significant in meters which are to be maintained with a minimum of skilled servicing and equipment. Most meters with maximum indicating pointers have friction clutches to hold one pointer in the position of its maximum indication. Experience over a long period of time has shown that there is a more or less definite range of optimum friction in such cases. This is due to the fact that over the range that is normally used, the friction becomes more constant, the greater the magnitude of the friction. However, at the higher values of friction, its magnitude is objectionable, and at the very low values its variation with time, temperature conditions, and so forth, is equally objectionable. A value from 30 gram-millimeters

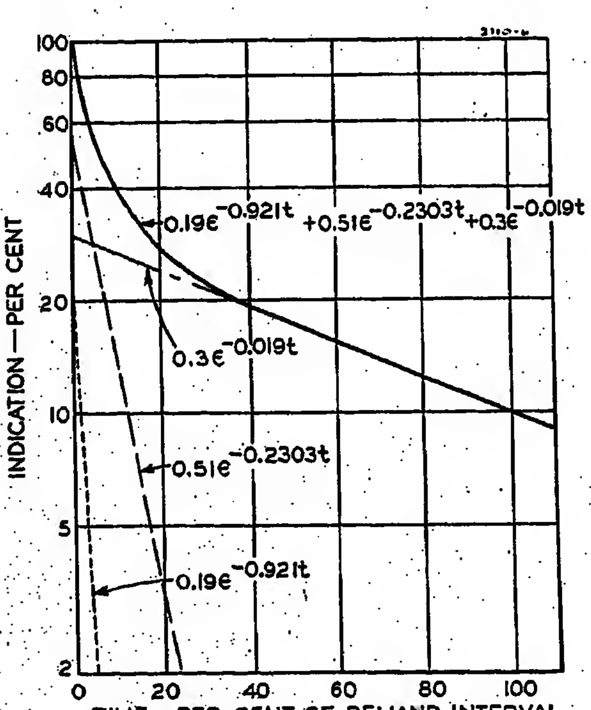

Figure 6. Time-indication curve including components

up, in a design which has been used for many years, has proved very satisfactory as far as consistency is concerned.

High Torque Desirable

To utilize frictions of this order of magnitude and still have them only approximately $1^1/_2$ or 2 per cent of the full-scale meter torque requires a meter torque of 1,500 to 2,500 gram-millimeters or a torque gradient of about 20 to 35 gram-millimeters per degree. Most thermal meters on the market today of the bimetal type do not utilize such high torques and rely on the lower friction torque remaining as constant as is required. The limiting features in obtaining higher torques are:

1. The amount of bimetal that is used, which is limited by other considerations such as space requirements, and so forth, and which has a definite influence on the demand interval of the meter.

2. The temperature at which the radiation or convection becomes an appreciable factor and the maximum temperature that the structure can stand.

To increase the operating temperature of the temperature-sensitive element without raising the temperature of the insulating parts of the heater requires better efficiency of heat transmission from the heater to the heated element. In recent years progress has been made toward greater efficiency and at the same time toward limiting convection and radiation by resorting to a bourdon tube actuating element with its bulb covered by a thermos bottle. This has gone a long way toward the achievement of high torque with low watts input. Inherent in a bourdon-tube design, however, is the hazard of leakage, one that must be eliminated by proper design, taking into consideration the long ranges of loads, power factors, and ambient temperatures over which modern meters are expected to function, and realizing the pressures that are set up in the tubes to meet these conditions. Added to this problem is one of choosing the best liquid for the bourdon tube. The problem is to obtain one which will not cause difficulty at lower temperatures and, at the same time, will have satisfactory temperature-expansion characteristics over the range required. With the use of demand meters in outdoor installations, this limiting feature assumes importance for temperatures below 32 degrees Fahrenheit and more especially, for temperatures as low as −40 degrees Fahrenheit, which although perhaps not common, might certainly be encountered in some installations. Many liquids are available and much experimental work has been done in this direction.[3]

Internally Heated Bimetal System

But when we consider difficulties of this nature together with others such as the hysteresis effects in bourdon-tube springs, and so forth, we realize the desirability of finding another method of attaining better heat-transmission efficiency which can be used with the time-tested bimetal spiral construction. Such a method is available if we heat the element by current through the bimetal itself. Here no loss is encountered, because the heat is generated where it is wanted. We thus get the highest possible efficiency of transmission and can limit radiation by means of controlled surfaces and convection by means of limited air spaces which, because of research work done in recent years, offers a practical solution.

If this arrangement is utilized to obtain the maximum efficiency of heat transmission possible, full-scale torques of the order of 2,000 grams-millimeters are readily obtained, and we can continue to use the time-tested bimetals as the activating element, where past experience and the vast amount of work that has been done by bimetal companies and meter manufacturers on heat treatment and the aging process insures stability of the bimetal characteristics. Moreover, uniformity of bimetal characteristics has recently been the subject of intensive investigation and has resulted in closer perfection of bimetal spirals with far more consistent characteristics than have been obtainable in the past.

Effect of Temperature Coefficient of Bimetals

One of the interesting phases encountered in taking advantage of the internally heated principle is occasioned by the fact that all suitable bimetals have a positive temperature-resistance coefficient. This has led to the following equations from a simple mathematical solution of Figure 10 giving the indication of such a meter:

$$W=4I_BI\cos\theta\left[\frac{R_1R_2}{R_1+R_2}\right]+I_B{}^2[R_1-R_2]-I^2\left[\frac{R_1R_2(R_1-R_2)}{(R_1+R_2)^2}\right]$$

Since

$$I_B=\frac{E}{R_1+R_2}$$

Therefore:

$$W=4EI\cos\theta\left[\frac{R_1R_2}{(R_1+R_2)^2}\right]+E^2\left[\frac{R_1-R_2}{(R_1+R_2)^2}\right]-I^2\left[\frac{R_1R_2(R_1-R_2)}{(R_1+R_2)^2}\right]$$

If:

$R_1=aR_2$ where a may be a variable as load conditions vary

$$W=4EI\cos\theta\left[\frac{a}{a+1}\right]+\frac{E^2}{R_2}\left[\frac{a-1}{(a+1)^2}\right]-I^2R_2\left[\frac{a(a-1)}{(a+1)^2}\right] \quad (6)$$

This general equation enables us to make a selection of a value for a when the meter is not excited and a value for the ratio of I to I_B which will give satisfactory values for W when $EI\cos\theta$ is kept constant, and ambient temperature, voltage, power factor, or load is changed through limits ordinarily met in service. These are two design constants which the design engineer can vary to obtain the optimum condition for this sort of meter.

When a is equal to 1.0, the last two terms of this equation disappear. However, if a differs slightly from 1.0 we can take advantage of the changes in these last two terms with temperature, power factor, and so forth, to obtain some slight compensation for small inherent errors.

An important bimetal characteristic which enables a simple mechanical construction to meet these requirements is the fact that the torque per degree temperature rise is independent of the length of a bimetal coil. We can therefore buck two bimetal coils on a single shaft to obtain complete temperature compensation at no load, and at the same time get the required ratio in resistances by using coils of different lengths. Modern bimetal-coil manufacturing procedure has made possible the satisfactory matching of coils of this nature.

Data on Actual Meter

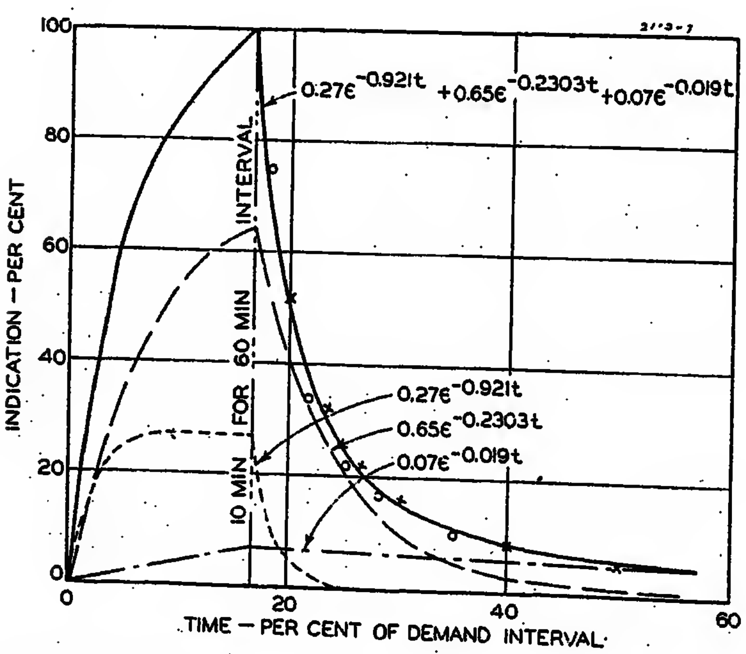
It is interesting to note how these observations are confirmed in a sample meter built to take advantage of this high efficiency heat generation thus giving a high torque bimetal meter. Figure 9 illustrates such a meter and Figure 10 gives its wiring diagram. The most important operation characteristics are tabulated in Table I and indicate the possibilities which may be utilized in development along these lines. Important is the fact that generation of heat in the bimetals allows such rapid diffusion of heat that there are possibilities that the necessary voltage heat-up before test can be shortened and that the time deflection curves actually will follow the desirable simple exponential curve.

Conclusions

A great deal must be discussed in elaborating on the various time-deflection characteristics obtainable in thermal watt-demand meters but experience has indicated that since demand is not an exact quantity, and since rate structures must vary for different classifications of load,

Figure 7. Time-indication curves

Constant load cut to zero before thermal equilibrium has been attained (showing components)



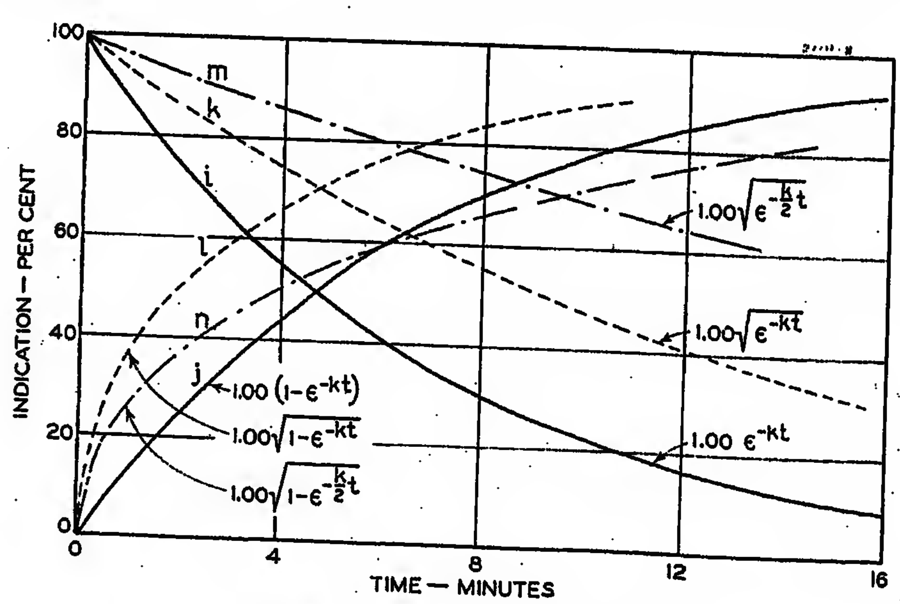


Figure 8. Time-indication curves

Two types of "square" scale meters compared to a uniform scale meter

the various kinds of characteristics discussed above all seem to be satisfactory for most demand measurements.

Accuracy of thermal meters today is considerably better than it was several years ago, and sturdiness, together with high torque, are desirable qualities to sustain this greater accuracy.

This high torque is obtainable with the time-tested bimetal type of thermal watt-meter by taking advantage of the "internally heated" principle which gives maximum heat transfer efficiency and gives a time of response characteristic much closer to the ideal simple exponential than has been attained in commercial meters in the past.

The preceding data of a typical meter developed to give high torque by means of internally heated bimetal construction indicates that a superior all-around meter has been designed, and that this principle of operation is worthy of consideration as the basic design of thermal watt-demand meters.

Appendix A[6]

The general time-deflection response equation is developed here for a device indicating the difference in temperature of two similar bodies connected by a thermal shunt when constant heat inputs (or zero input) is applied to each body, the bodies starting at any initial temperature or temperature difference.

Let

H_1 = rate of heat applied to A (gram calories per second)

H_2 = rate of heat applied to B (gram calories per second)

h = thermal conductivity from A or B to ambient (gram calories per second per degree centigrade)

Q = thermal conductivity of shunt (gram calories per second per degree centigrade)

θ_{01} = initial temperature of A (degrees centigrade)

θ_{02} = initial temperature of B (degrees centigrade)

θ_1 = instantaneous temperature of A above θ_{01} (degrees centigrade)

θ_2 = instantaneous temperature of B above θ_{02} (degrees centigrade)

M = heat stored in A or B per degree centigrade (gram calories)

The conservation of energy equations become

$$H_1dt-Q(\theta_1-\theta_2+\theta_{01}-\theta_{02})dt=h(\theta_{01}+\theta_1)dt+Md\theta_1$$

$$H_2dt+Q(\theta_1-\theta_2+\theta_{01}-\theta_{02})dt=h(\theta_{02}+\theta_2)dt+Md\theta_2$$

Let

$$\theta_{01}-\theta_{02}=W_0 \text{ and } (\theta_{01}+\theta_1)-(\theta_{02}+\theta_2)=W \text{ and } \theta_1-\theta_2=W_2$$

$$d\theta_1+d\theta_2=d(\theta_1+\theta_2)=dW_2$$

The time-deflection response of thermal meters is proportional to the temperature difference W.

Then by subtraction and substitution

$$(H_1-H_2)dt-2Q(W_2+W_0)dt=h(W_2+W_0)dt+MdW_2$$

$$\frac{dW_2}{dt}+\frac{h+2Q}{M}W_2=\frac{H_1-H_2}{M}-\frac{h-2Q}{M}W_0$$

Let

$p=d/dt$, and 1 = Heaviside's unit operator (see reference 4)

$$\left[p+\frac{h+2Q}{M}\right]W_2=\left[\frac{H_1-H_2}{M}-\frac{h+2Q}{M}W_0\right]1$$

$$W_2(t)=\left[\frac{H_1-H_2}{M}-\frac{h+2Q}{M}W_0\right]\times\left[\frac{1}{p+\frac{h+2Q}{M}}\right]1 \quad (1)$$

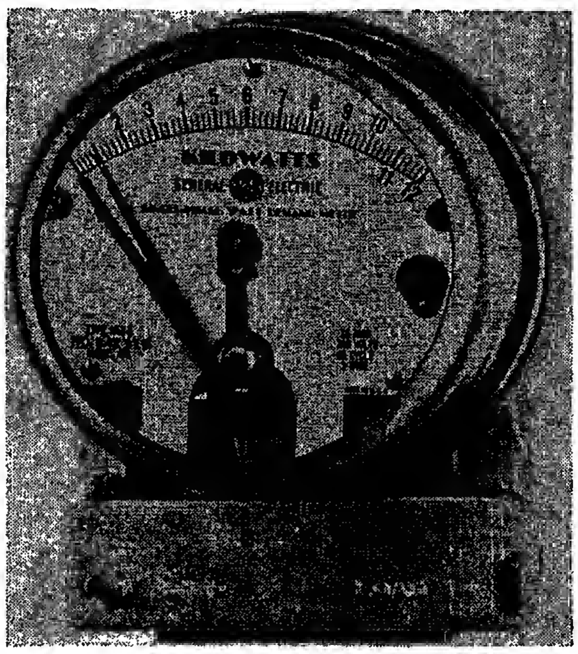

Figure 9. Single-phase watt-demand meter

15 amperes, 240 volts, 60-cycle, three-wire

From simple operational calculus

$$W_2=\left[\frac{H_1-H_2}{M}\right]\left[\frac{M}{h+2Q}\right]\times\left[1-\epsilon^{-\frac{h+2Q}{M}t}\right]-\left[1-\epsilon^{-\frac{h+2Q}{M}t}\right]W_0$$

By definition above

$$W=W_2+W_0$$

$$W=\left[\frac{H_1-H_2}{h+2Q}\right]\left[1-\epsilon^{-\frac{h+2Q}{M}t}\right]+W_0\epsilon^{-\frac{h+2Q}{M}t}$$

Let

$$\frac{H_1-H_2}{h+2Q}=W_1 \text{ and } \frac{h+2Q}{M}=k$$

Then

$$W=W_1(1-\epsilon^{-kt})+W_0\epsilon^{-kt} \quad (2)$$

Appendix B

The response of an object such as a theoretical thermal watt-meter is developed here for three conditions of loading:

(*a*). Where the load is any function of time.

(*b*). Where the load is constant.

(*c*). Where the load increases at a constant rate.

The response is of such a nature that it is directly proportional to the temperature of a mass where the mass is supplied with a heat input proportional to the load; and this input is utilized both in raising the temperature of the mass and in supplying the heat escape which is proportional to the temperature of the mass.

Let

h = thermal conductivity from mass to ambient (gram calories per second per degree centigrade)

Table I. Characteristics of a 15-Ampere 240-Volt Three-Wire Single-Phase Thermal Watt-Demand Meter

(Typical Average Values for an Experimental Internally Heated Design)

Torque (full-scale)		2,200 g-mm
Scale length		Approximately 4 inches
Power factor influence (7.2 kw) referred to pf 1.00	0.5 pf lag	Less than 2%
	0.5 pf lead	Less than 2%
Frequency influence referred to 60 cycles		Negligible
Temperature influence (12.0 kw, 1.0 pf) referred to 25 C	+50 C	Less than 2%
	−20 C	Less than 2%
Voltage influence (10% change in voltage) referred to rated voltage		Less than 2%
Rising time-deflection curve shape		"Simple exponential" (Figure 2B, curve p)
Demand interval		Approximately 17 minutes
Watts loss	Potential (240 volts)	2.5
	Current (12 kw, pf 1.0)	9.0
Size		Standard single-phase watt-hour meter size

$hf(t_1)$ = rate of heat applied (gram calories per second)

θ = temperature (instantaneous) of mass which is proportional to meter deflection (degrees centigrade)

t = time (minutes)

W = angular deflection

The conservation of energy equation becomes

$$hf(t_1)dt = h\theta dt + Md\theta$$

Then

$$\frac{d\theta}{dt} = \frac{h}{M}[f(t_1) - \theta] = k[f(t_1) - \theta] \text{ where } k = \frac{h}{M}$$

Let

$\frac{d}{dt} = p$, and $\mathbf{1}$ = Heaviside's unit operator (see reference 4)

$$(p+k)\theta = kf(t_1)\ \mathbf{1}$$

$$\theta = \frac{k}{p+k}[f(t_1)]\mathbf{1} = k\left[\frac{1}{p}\right]\left[\frac{p}{p+k}\right][f(t_1)]\ \mathbf{1}$$

From Borel's theorem:

$$Y_1(p) = \frac{p}{p+k}\mathbf{1} = \epsilon^{-kt_1}$$

$$Y_2(p) = f(t_1)\ \mathbf{1}$$

$$\theta = k\int_0^t \epsilon^{-k(t-t_1)} f(t_1)dt_1 \qquad (1a)$$

This shows that the temperature θ of the indication W is proportional to the sum of all the instantaneous values of $f(t_1)$ each multiplied by a factor, $\epsilon^{-k(t-t_1)}$, which decreases exponentially as the time, t_1, of the instantaneous value of $f(t_1)$ is taken backwards from the time, t. The value t is the time of the instantaneous value of the indication W or temperature θ being considered.

(*a*). This function,

$$\kappa\int_0^t [f(t_1)][\epsilon^{-k(t-t_1)}]dt_1$$

can be designated by definition as the logarithmic average of $f(t_1)$ at any time, t, and is the value a simple theoretical thermal watt-demand meter indicates.

(*b*). If $f(t_1)$ is a constant such as W_1 after starting from zero indication, the expression becomes

$$W_1(1-\epsilon^{-kt})$$

When the transient ϵ^{-kt} becomes small, the meter will read W_1 or the equivalent of a block interval type of meter.

(*c*). But if $f(t_1)$ is directly proportional to time such as At the expression reduces to

$$At - \frac{A}{k} + \frac{A}{k}\epsilon^{-kt}$$

This indicates that after the transient $A/k(\epsilon^{-kt})$ becomes small (about three demand intervals), the meter will have approached a constant increase in deflection:

$$\frac{d\theta}{dt} \text{ when } \epsilon^{-kt} \text{ is small} = \frac{d}{dt}\left(At - \frac{A}{k}\right) = A$$

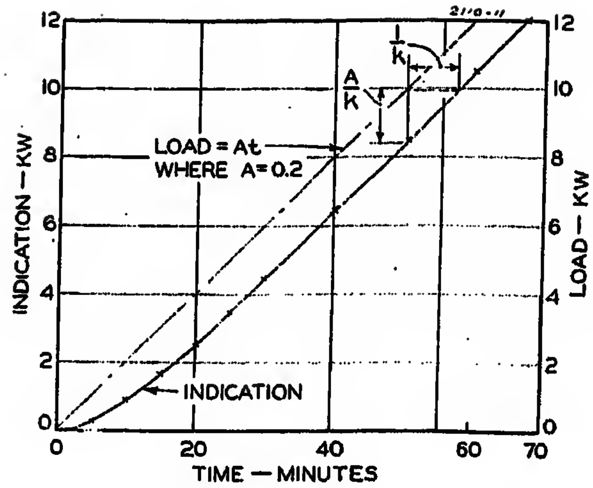

Figure 11. Indication lag of a thermal watt-demand meter on a constantly increasing load

x—points for curve

$$At - \frac{A}{k} + \frac{A}{k}\epsilon^{-kt}$$

where $A = 0.2$
$k = 0.135$

(demand interval = 17 minutes

Also since the deflection, if it followed watts input, instantaneously would be proportional to At.

And since the deflection, after the transient term becomes small, is $At - A/k$; therefore the reading will lag in deflection by A/k, and since the rate of change of deflection is A, the reading will lag in time by $1/k$.

WHILE there have been a number of papers on recovery voltage and its effect on the operation of circuit-interrupting devices, and although the transient recovery voltage and its characteristic are assuming a more important place in the design and application of circuit breakers with the growth and increasing capacity of power systems, there has not been available to the average power-company engineer a convenient method for determining this characteristic. The present paper offers such a method and also tabulates capacitance data for the more important circuit elements.

This method was developed in connection with a survey conducted by the Association of Edison Illuminating Companies to obtain a comprehensive picture of existing circuit recovery-voltage conditions. In order to review the characteristics for practically all breaker locations on the six power systems studied, it was necessary to develop a method that could be applied with minimum effort and time. The results of this survey are given in the companion paper, "Transient Recovery-Voltage Characteristics of Electric-Power Systems," by H. P. St. Clair and J. A. Adams.[11]

For different locations having the same voltage and short-circuit current duties, the transient recovery characteristic may vary with high-voltage values of approximately the same magnitude occurring over a time range of almost one hundred to one. From one end of this range to the other considerable differences may occur in the performance of some types of breaker. However, a moderate change in time to the first high peak usually produces a comparatively small change in breaker performance; a change in this time of ten to one, for instance, might produce a two-to-one change in arc length. In this situation it will be obvious that high accuracy is not required in the determination of the recovery transient, so that approximations which might be intolerable in some other applications become here quite permissible. This is very fortunate, for the circuits involved are far too complex for precise mathematical analysis and in many cases do not lend themselves well even to miniature system analysis. With a certain amount of approximation, however, these circuits may be simplified to the point where a mathematical solution is not too arduous. It is believed that the method outlined below will give results with an error of less than 20 per cent, which is considered quite reasonable. Tests have shown that in some cases much greater accuracy can be expected. Only sufficient discussion is given to explain the method of calculation and for a more complete analysis of the problem reference should be made to the various papers listed in the bibliography.

Definitions and Basis of Calculation

The circuit recovery voltage is the voltage that appears across the contacts of a circuit-interrupting device immediately after it opens the circuit. Just before interruption the voltage across the contacts is limited to the arc voltage, and at the instant the arc is extinguished the voltage attempts to recover to the generated value. Since most short circuits are limited principally by reactance, in the usual case of a symmetrical current wave, the generated voltage is near its peak value when the circuit is interrupted at current zero and, therefore, the voltage recovery is from practically zero to peak voltage. This recovery is prevented from taking place instantaneously by the capacitance of the circuit and, because of the circuit characteristics, it may oscillate at high frequencies to nearly double its final value. Usually the capacitances involved are very small, and the recovery occurs in a matter of microseconds. For

successful interruption the dielectric strength between the contacts of the interrupting device must exceed at all times the transient recovery voltage.

The method of calculation gives the *circuit* transient recovery-voltage characteristic and does not take into account any modifying action that the breaker may have on the characteristic. On an actual circuit the recovery-voltage characteristic may be modified by one or more of the following factors:

1. Asymmetry of the current wave.
2. Decay of flux in the generators during short circuit.
3. Arc voltage drop in the fault.
4. Arc voltage drop in the breaker.
5. Conduction current in the breaker after current zero.

These factors usually reduce the severity of the recovery-voltage characteristic. In order to compare calculated with test results, it is necessary to account for these factors when analyzing oscillograms obtained on test.

The calculation of the transient recovery-voltage characteristic involves the determination of the natural frequencies and voltages of the circuits affecting the recovery voltage from the inductances and capacitances of these circuits, and the combination of these values to obtain the voltage wave across the open breaker contacts. It is often not sufficient to obtain only rate of rise to the first peak, as this peak may be relatively low in comparison with some later peak which may be more important from the standpoint of breaker interrupting ability. Therefore, it is important to obtain a fairly complete voltage characteristic. The envelope over the wave is usually sufficient for this purpose.

Method of Calculation

The complete recovery-voltage circuit includes the inductance and capacitance of each piece of apparatus and of each line and connection. The mathematics is considerably simplified if distributed capacitances such as occur in transmission lines and cables are replaced by lumped values. Figure 1 shows a representative circuit resulting from this simplification. This circuit might correspond to that for a feeder breaker with a reactor on the feeder side of the breaker and a fault immediately beyond the reactor. Between the breaker and the feeder reactor is a capacitance to ground which is contributed by half of the breaker, half of the reactor, and the conductor between them.

On the bus side of the breaker is the capacitance of the bus and connected

Table I. Capacitance for Circuit 1

	Micromicrofarads

Total capacitance	355

equipment. There are shown lumped reactances corresponding to generator, transformer, and feeder reactors. Transformers themselves are also represented here since they constitute substantially lumped reactances with a comparatively small amount of capacitance. Beyond these lumped reactances will be found the relatively large capacitances of generators, transmission lines, and cables, and, finally, completing the circuit, the additional reactances of the sources themselves.

The circuit shown in Figure 1 is too complex for convenient treatment and so by paralleling reactances and capacitances in the source circuit and also in the outgoing feeder circuit, it is reduced to the circuit of Figure 2. This involves an approximation which would not be permissible in very precise work but will, in general, be satisfactory for the present purpose.

In a similar manner the circuit of Figure 2 is reduced to that of Figure 3.

It is possible to go immediately from the circuit of Figure 1 to the circuit of Figure 3 by means of the following procedure.

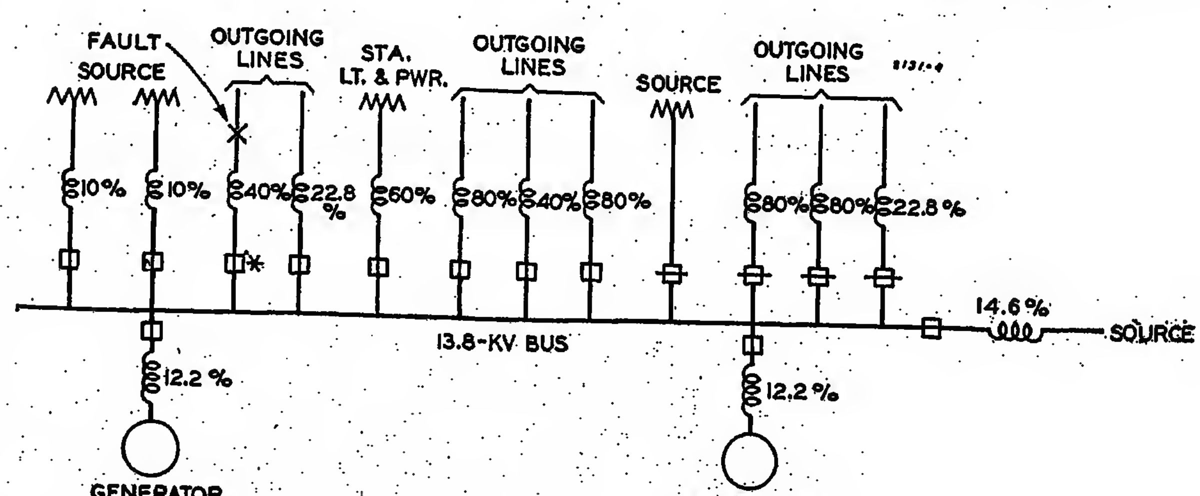
1. Determine the parallel reactance of all reactors connected to the bus except the one on the faulted line. Use the corresponding inductance as L_2.
2. Add together all the capacitances connected on the left side of these reactors. The resulting sum is C_3.
3. Determine the inductance corresponding to the reactance limiting short-circuit current on the bus. Subtract L_2 from this inductance. The result is L_3.

The transient corresponding to each of these circuits consists of a number of oscillations of different voltages, different frequencies, and different damping factors. Each of these oscillations considered by itself starts from zero and leaves a certain voltage across the breaker when it has died down, oscillating in the meantime between zero and twice that voltage value as shown in Figure 19. Figure 11 shows a transient in which a number of these oscillations are combined. The equation for such a transient is

$$E = e_1(1-\epsilon^{-a_1 t}\cos 2\pi f_1 t) + e_2(1-\epsilon^{-a_2 t}\cos 2\pi f_2 t) + e_3(1-\epsilon^{-a_3 t}\cos 2\pi f_3 t) + \ldots$$

Figure 4. Station single-line diagram

*Breaker for which calculation is made



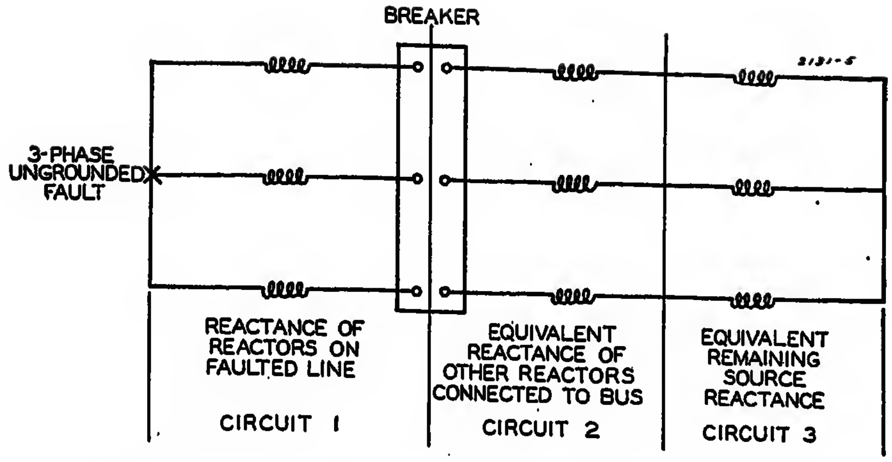


Figure 5. Reduction of system to three circuits

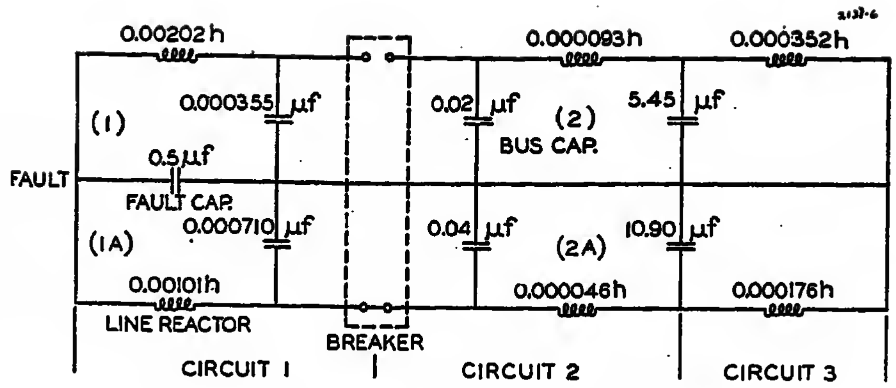

Figure 6. Equivalent circuit—three-phase

where e_1, e_2, e_3 . . . are the voltages associated with the various oscillations, f_1, f_2, f_3 . . . are the corresponding frequencies, and a_1, a_2, a_3 . . . are the respective decrement factors. Each of these oscillations may be considered to be associated with one inductance–capacitance pair (sometimes modified by the presence of the remainder of the circuit), and the voltages and frequencies are determined from the inductances and capacitances of these pairs.

Where an inductance and capacitance stand by themselves, as do L_1 and C_1 in Figure 3, the frequency associated with them is given by the well-known formula

$$f=\frac{1}{2\pi\sqrt{LC}}$$

and the voltage is equal to normal crest voltage times the ratio of the particular inductance concerned to the total inductance of the circuit. Where two adjacent circuits are coupled inductively or capacitively, however, they will react on each other, and this must be taken into account in determining frequencies and voltages. Boehne[8] has developed a method for doing this with two circuits so coupled.

Quite often with two adjacent circuits, the frequency of the first circuit is much higher than that of the second circuit, and the coupling capacitance is so high that it offers negligible impedance to current in the first circuit. In such a case fairly accurate results may be obtained by solving the two circuits independently. This is particularly helpful, where there are three or more adjacent circuits, in reducing the number to two so that Boehne's procedure can be applied.

Table III. Voltage Distribution

Circuit	Inductance	Per Cent Voltage	Volts
3A	0.000366 (L_R)	10.0	1,690
1A	0.000865 (L_S)	23.5	3,970
1	0.002020	54.5	9,210
3	0.000445	12.0	2,030
	0.003696	100.0	16,900

The decrement factors involve the resistances associated with the circuits. Since it is difficult to carry resistance values through these reductions, and fairly wide variation in decrement factor introduces comparatively small variation in the initial part of the curve, an approximate value for the decrement factor can be used for all circuits. In the survey referred to above, a factor which gave a decrement to 85 per cent of the initial value at the end of the first half-cycle was used for each oscillation. This factor gives a decrement to 20 per cent of the initial value in five cycles. This was based on observation of the decrement indicated in a number of cathode-ray oscillograms taken on actual circuit interruptions. Figure 19 shows a wave with this decrement.

This method must be considered to be a very much simplified one which will give results with reasonable accuracy in a great many cases. While it would be more accurate to consider both positive- and zero-phase-sequence values for all circuits, this will introduce additional complication which does not seem to be warranted except in special cases. Caution should be exercised, particularly where a higher degree of accuracy is desired, in simplifying circuits by the method suggested to avoid introducing unnecessary errors.

Inductances for circuits and equipment can be obtained from the reactance data used for short-circuit calculations. Capacitance data can be obtained by direct measurement when the circuit can be isolated, and when measuring equipment is available. However, if this is impractical, sufficient accuracy can be obtained by summation of the capacitances of the various circuit elements. Capacitances of equipment can be obtained from the manufacturers, the capacitances of cables and wires can be determined from standard formulas given in most handbooks, and those of copper connections in cells can be estimated by graphical methods.[3] Some data are given in the appendix for the more important circuit elements. It is extremely important that the capacitances of the higher-frequency circuits be estimated accurately, especially when the voltages associated with them are a relatively high proportion of the total voltage.

The following example illustrates the method of calculation. While there are various methods of simplification for circuits, only a few possibilities are illustrated. Various factors are brought out in the discussion of this example which have not been covered in the foregoing.

Example

This calculation obtains the transient recovery-voltage characteristic for the first phase of a breaker to open a three-phase ungrounded fault on a generating station feeder. The fault current is limited by reactors installed close to the breaker, with the result that the capacitance is low between the breaker and reactor, and the rate of rise of the transient recovery voltage for this portion of the circuit is extremely high. It will usually be found that circuits of this type give severe recovery-voltage characteristics.

The single line diagram of the station is shown in Figure 4 with breaker positions indicated and reactance values given on a

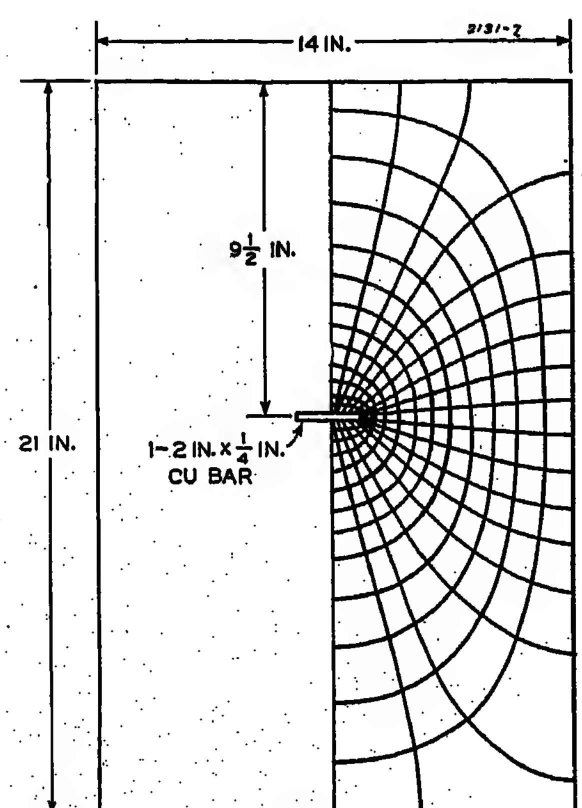

Figure 7. Flux plot for lead run in switch house

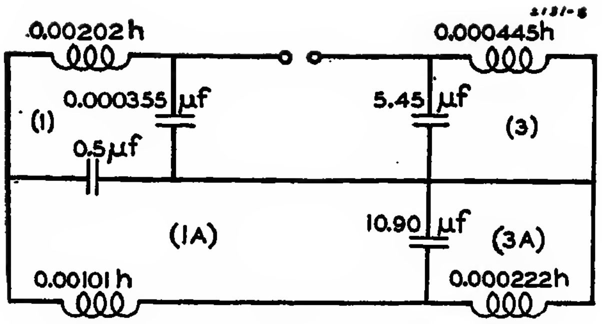

Figure 8. Equivalent circuit—reduced

100,000-kva 13,800-volt three-phase basis. In general, more severe recovery conditions are obtained when some circuits are disconnected, because this reduces the capacitance of the system. In analyzing the recovery characteristics of a system, it is advisable to consider probable operating connections for both normal and emergency conditions and to calculate the recovery characteristics for the one most likely to produce severe characteristics. This is analogous to the determination of short-circuit duty in applying circuit breakers.

The system can be reduced to three principal circuits limiting the fault current, Figure 5. These three circuits consist of:

1. A circuit from the fault to the breaker.
2. An equivalent circuit, the reactance of which is the parallel reactance of all reactors connected to the bus except the reactor on the faulted line.
3. An equivalent circuit representing the remainder of the system reactance.

The fault has been assumed to be a three-phase ungrounded short circuit, and the recovery characteristic is calculated for the first phase to clear, since this combination gives the most severe recovery-voltage characteristic. If it were considered impossible to obtain this type of fault, and, for example, only a phase to ground fault could occur, then the problem would reduce to a consideration of one phase only.

Phase-to-neutral capacitances are used for the three-phase ungrounded-neutral fault case. For most apparatus and for enclosed busses and connections these will usually be the same as phase-to-ground values.

At the time of clearing of the first pole, the second and third poles of the breaker are substantially closed circuits, and the circuit for the corresponding transient will be an outgoing circuit, consisting of the phase of the first pole to clear, in series with a return circuit consisting of the other two phases in parallel. Thus the return circuit will have just half the inductance and twice the capacitance of the outgoing circuit.

Introducing capacitances into the circuit of Figure 5 and paralleling the second and third phases, the circuit becomes that shown in Figure 6. The values of the constants are determined by the following method.

Circuit 1

The inductance will be that of the reactor in the faulted line. On the 100,000-kva 13,800-volt three-phase base, the reactance is 40 per cent, which is equivalent to an inductance of 0.00202 henry.

The capacitance will be that of the connections between the breaker and the reactor, including one end of the reactor and one half of the breaker. The capacitances of equipment are obtained from the tables in the appendix.

The capacitance of the connection was determined by means of the flux plot, Figure 7. This is a scale drawing of the conductor and the inside of the concrete cell with lines of flux and equipotential surfaces drawn in. The capacitance is calculated from the following equation:

$$C=2.7\frac{w}{l} \text{ micromicrofarads per foot}$$

where

w = number of tubes of flux = 34
l = number of cells per tube = 13

$$C=2.7\frac{34}{13}=7.06 \text{ micro-microfarads per foot}$$

The total capacitance for circuit 1 is obtained by summation of the capacitances of the various parts, as shown in Table I.

Circuit 2

The reactance is equivalent to the parallel reactance of all reactors connected to the bus, except those on the faulted line. This parallel reactance is 1.83 per cent, equivalent to an inductance of 0.000093 henry.

The capacitance includes that of one half of the breaker on the faulted line, the connections from this breaker to the bus, the bus, and the connections from the bus to and including one half of the reactors. This is obtained by the method used for circuit 1 and is 0.02 microfarad.

Circuit 3

The inductance of the equivalent source reactance can be obtained by determining the equivalent system reactance for a bus short circuit and subtracting the reactance of the equivalent reactor of circuit 2.

Table IV. Times to First Peaks

Circuit	Microseconds
3A	162
1A	67
1	2.6
3	155

From a short-circuit board study the bus fault current was determined to be 47,400 amperes, which is equivalent to a reactance of 8.8 per cent on a 100,000-kva 13,800-volt three-phase base. Subtracting the equivalent reactance of circuit 2

$$8.8-1.83=6.97 \text{ per cent}$$

which is equivalent to an inductance of 0.000352 henry.

The capacitance of this circuit is considered to be that from the reactors to the next large lumped reactance such as a transformer or generator. Actually in the case of a transformer there will be additional circuits beyond the transformer, but for practical purposes these usually need not be analyzed separately.

In this case the leads to the transformer banks consist of two 2,000,000 circular-mil lead-covered cables per phase which have a total capacitance of 0.584 microfarad.

The transformers are General Electric Company rated 20,000-kva 13,800–69,000-volt three-phase, and are delta-connected on the low-voltage side. From Figure 13, and the method explained in the appendix, the capacitance is 4,800 micro-microfarads.

The generators are General Electric Company, rated 75,000-kva 13,800-volt three-phase. Substituting in the equation given in the appendix:

$$C=0.0187\frac{75}{\sqrt{13.8(1+0.08\times13.8)}}$$
$$=0.26 \text{ microfarad per phase}$$

One half of this capacitance is considered concentrated at the generator terminals.

The lines are 3×350,000 circular-mil cable with an average length of two miles and a capacitance of 0.5 microfarad per mile. Since the lines are short, the total capacitance is effective, which for the

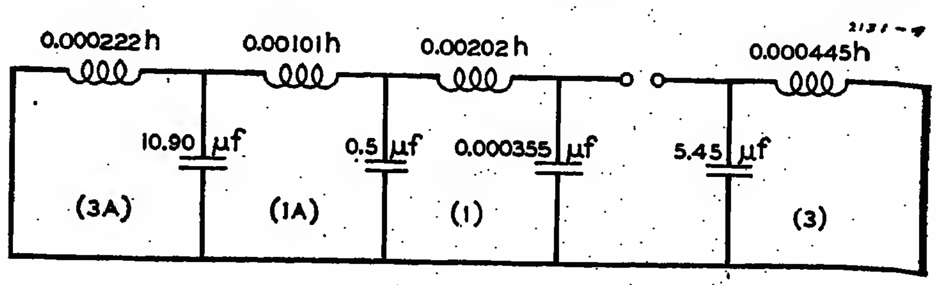

Figure 9. Equivalent circuit—rearranged

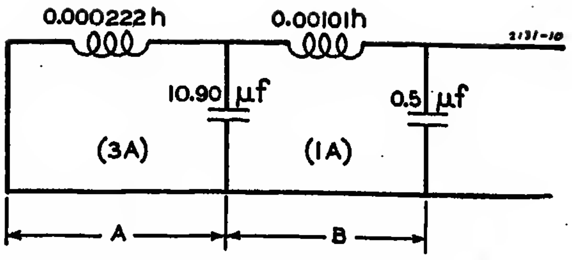

Figure 10. Circuits 1*A* and 3*A*

four lines is four microfarads. The capacitance of the station light and power section is negligible in comparison with that of the cables.

The total source capacitance is shown in Table II.

Fault Capacitance

Since the fault is ungrounded, there is a capacitance to ground at this point which consists of the three conductors of the open circuited line. Assuming the fault to be on a short line of 3,500 feet of 3× 350,000 circular-mil cable, the equivalent length of line to use for obtaining the fault capacitance can be obtained from the following equation which is explained in the appendix:

$$M=\left(\frac{\pi}{4}\right)^2\frac{L}{l}$$

where

L = inductance of the return circuit = 0.001232 henry

l = 1/3 zero-phase-sequence inductance per mile of line in henries = 0.00067 henry

therefore

$$M=\left(\frac{\pi}{4}\right)^2\times\frac{0.001232}{0.00067}=1.14 \text{ miles}$$

Since M is greater than the actual length of line, the total capacitance to ground of the line is used. For 3×350,000 circular-mil cable the zero-phase-sequence capacitance is approximately one half the positive-phase-sequence capacitance,[9] or 0.25 microfarad per mile. The fault capacitance is three times the zero-phase-sequence value, or 0.5 microfarad for 3,500 feet of cable.

Equivalent-Circuit Reduction

The upper part of the equivalent circuit, Figure 6, represents the first phase of the breaker to open, and the lower part represents the other two phases in parallel. The voltage will be distributed around the circuit approximately in proportion to the inductances, and the frequencies will be determined by the inductances and capacitances.

This diagram is simplified as explained below. Some of the reductions are approximations, but it is believed that they are sufficiently accurate for practical purposes.

Table V. Recovery Voltage

Time Micro-seconds	Circuit 3A 1,690 Volts π	Circuit 3A V	Circuit 1A 3,970 Volts π	Circuit 1A V	Circuit 1 9,210 Volts π	Circuit 1 V	Circuit 3 2,030 Volts π	Circuit 3 V	e Volts
2.6	—	—	0.04	—	1.0	17,000	—	—	17,000
67	0.41	1,250	1.00	7,350	25.8	9,210	0.43	1,620	19,430
100	0.62	2,230	1.50	3,970	38.4	9,210	0.65	2,840	18,250
120	0.74	2,700	1.80	1,550	46.0	9,210	0.77	3,370	16,830
140	0.86	3,000	2.10	1,270	54.0	9,210	0.90	3,700	17,180
155	0.96	3,120	2.32	2,460	59.5	9,210	1.00	3,760	18,550
162	1.00	3,120	2.42	3,260	62.3	9,210	1.04	3,740	19,530
180	1.11	3,000	2.69	5,400	69.1	9,210	1.16	3,500	21,110
190	1.17	2,870	2.84	6,120	73.0	9,210	1.23	3,280	21,480

Since the voltage across circuit 2 will be small compared with that of circuits 1 and 3, the error in adding the inductance of this circuit to that of circuit 3 will be negligible. Also, the error in neglecting the capacitance of circuit 2 and the capacitance of the two paralleled phases of circuit 1 will be small. By making these changes the circuit reduces to that shown in Figure 8. Figure 9 shows this circuit rearranged in a more convenient form for analysis. Since circuit 3 is separated from the rest of the circuits by the open breaker contacts there will be no interaction between it and the other circuits, and, therefore, its frequency will be determined directly by its inductance and capacitance.

By inspection of circuits 1 and 1*A*, it is evident that the frequency of circuit 1 is high and also that the 0.5-microfarad capacitance of circuit 1*A* is large compared with the constants of circuit 1. Therefore, circuit 1 can be treated as an independent circuit. This may be proved by the following method if desired.

For two interacting circuits with similar characteristics, the voltages and frequencies can be obtained by the method developed by Boehne.[3] Applying this method to circuits 1*A* and 3*A*, shown separately in Figure 10:

$$n_0=\frac{L_B}{L_A}=\frac{0.00101}{0.000222}=4.55$$

$$m_0=\frac{C_B}{C_A}=\frac{0.5}{10.90}=0.046$$

From Figure 20

$K_S=2.3$

$$f_A=\frac{1}{2\pi\sqrt{0.000222\times10.9\times10^{-6}}}= \text{3,240 cycles per sec}$$

$$f_B=\frac{1}{2\pi\sqrt{0.00101\times0.5\times10^{-6}}}= \text{7,100 cycles per sec}$$

$$f_S=2.3\times3{,}240=7{,}450 \text{ cycles per sec}$$

$$f_R=\frac{7{,}100}{2.3}=3{,}100 \text{ cycles per sec}$$

The true frequencies (f_S and f_R) for these circuits, therefore, differ five per cent from the individual circuit frequencies (f_A and f_B).

Determining the voltage distribution by Boehne's method, using the magnitude curves, Figure 21:

$J_S=3.9$
$J_R=1.65$

As a check on these values, J_S+J_R should equal n_0+1

$J_S+J_R=5.55$
$n_0+1=5.55$
$L_R=1.65\times0.000222=0.000366$ henry
$L_S=3.9\times0.000222=0.000865$ henry

These new inductances are 30 per cent and 70 per cent, respectively, of the total inductance of the two circuits compared with 17 per cent and 83 per cent for the original inductances.

These new inductances are used to

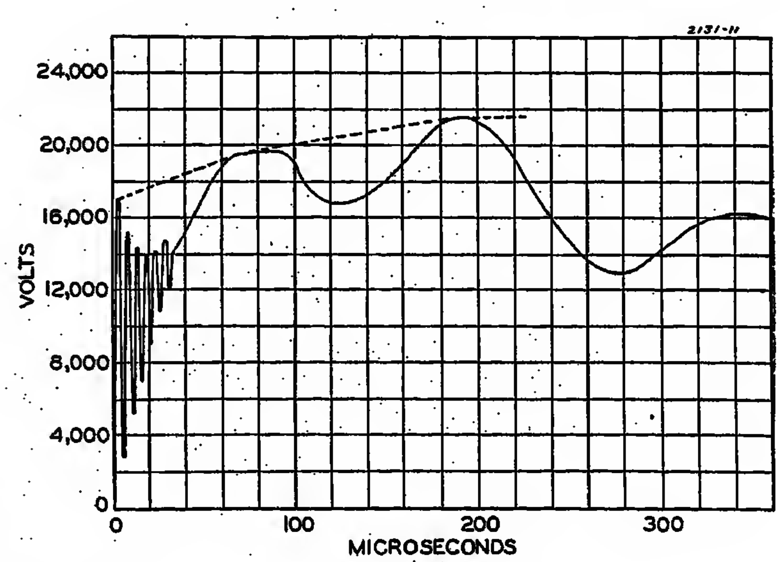

Figure 11. Recovery-voltage curve

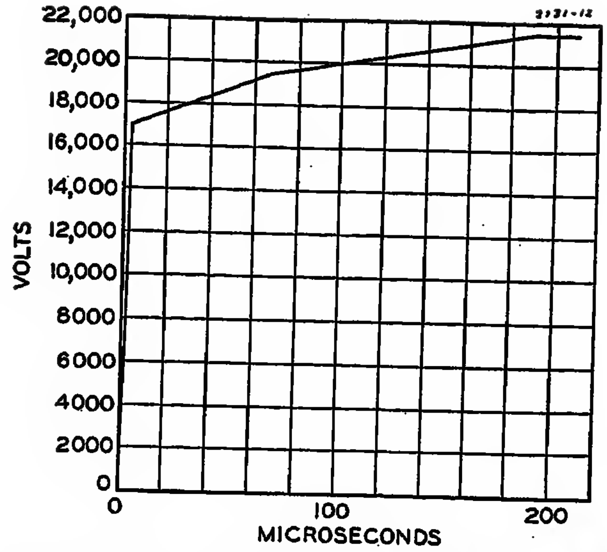

Figure 12. Envelope of recovery-voltage curve

determine the voltage distribution for circuits 1*A* and 3*A*.

Frequencies

The circuit frequencies are determined as follows:

Circuit 3*A*—3,100 cycles per second, from f_R above
Circuit 1*A*—7,450 cycles per second, from f_S above
Circuit 1

$$\frac{1}{2\pi\sqrt{0.00202\times 0.000335\times 10^{-6}}}=$$

194,000 cycles per sec

Circuit 3

$$\frac{1}{2\pi\sqrt{0.000445\times 5.45\times 10^{-6}}}=$$

3,240 cycles per sec

Voltage Distribution

The total voltage around the circuit for a three-phase ungrounded fault will be 1.5 times the phase-to-neutral voltage, that is, the crest value of the voltage of one phase plus the crest value of the mean of the voltages of the other two phases. For the system voltage of 13,800 volts:

$$e=13{,}800\frac{\sqrt{2}}{\sqrt{3}}1.5=16{,}900 \text{ volts}$$

The voltage will be distributed in proportion to the inductances as shown in Table III.

Recovery-Voltage Equation

Substituting the voltages and frequencies in the recovery-voltage equation gives the following for the transient recovery voltage of the circuit:

$$\begin{aligned} e=\;&1{,}690(1-\epsilon^{-a_1t}\cos 2\pi 3{,}100t)+\\ &3{,}970(1-\epsilon^{-a_2t}\cos 2\pi 7{,}450t)+\\ &9{,}210(1-\epsilon^{-a_3t}\cos 2\pi 194{,}000t)+\\ &2{,}030(1-\epsilon^{-a_4t}\cos 2\pi 3{,}240t)\end{aligned}$$

First Peaks

The first peaks of each of these waves occur when

$$2\pi ft=\pi$$

therefore

$$t=\frac{10^6}{2f} \text{ microseconds}$$

For these circuits, the times to first peaks are shown in Table IV.

Recovery-Voltage Curve

The method for the determination of points on the recovery-voltage curve is illustrated in Table V. The values under the heading π are time expressed as a fraction of time to the first peak of the corresponding wave. The corresponding voltages are obtained by using these fractions as abscissae for the decrement curve, Figure 19, and multiplying the corresponding ordinates by the voltage for the circuit as given in Table III. The total voltage at any time is the sum of the voltages of the individual circuits.

The recovery-voltage curve out to the maximum peak is shown on Figure 11. The labor involved in determining this entire curve is considerable, however, and most practical purposes will be served if the envelope consisting of the curve up to the first peak and the dotted line joining the peak with subsequent peaks are shown. This requires the calculation of only a comparatively small number of points as shown in the table. The curve is shown in Figure 12.

The rate of rise of the recovery voltage may be considered to be the rate of rise to the first peak. For this example it is:

$$rr=\frac{17{,}000}{2.6}=6{,}500 \text{ volts per microsecond}$$

Table VI. Total Capacitance to Ground of Single-Phase Core-Type Transformers

Westinghouse Electric and Manufacturing Company

	Capacitance in Micromicrofarads		
Kva	115 Kv	161 Kv	230 Kv
5,000	2,550	2,750	2,850
10,000	2,450	3,650	2,750
15,000	3,400	3,650	2,950
20,000	3,650	3,650	3,050

The maximum rate of rise is the slope of the line passing through zero and tangent to the first peak. This is:

$$rr_{max}=1.14\times 6{,}500=7{,}400 \text{ volts per microsecond}$$

As mentioned previously, the representation and simplification of this circuit exemplifies only one of a number of general methods. The representation of distributed constants by lumped constants sometimes requires more elements than at others, depending upon the circuit in which they are located. As the accuracy of the calculation depends upon the accuracy with which the circuit is repre-

Figure 13. Approximate trend of capacitance to ground of windings of single-phase core-type transformers with concentric windings (General Electric Company)

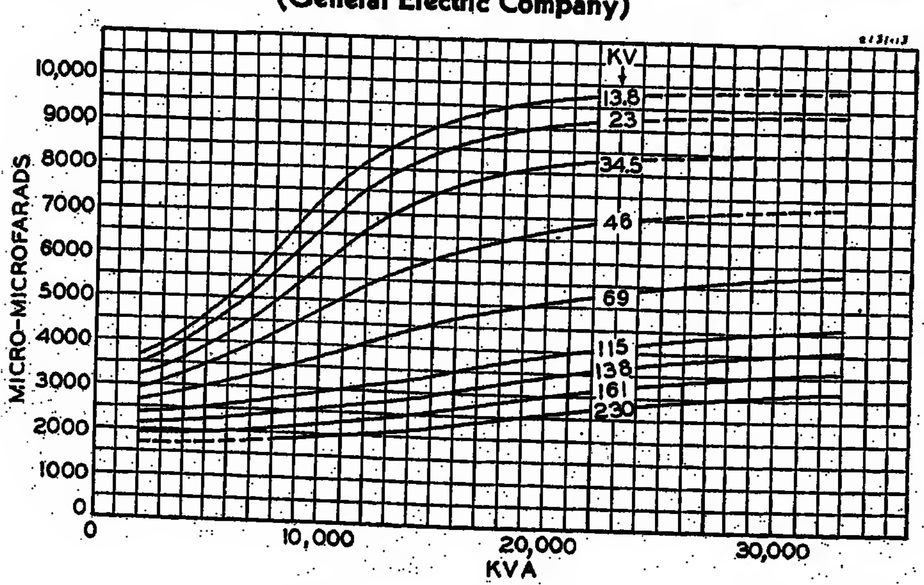

Figure 14. Capacitance of typical power transformers—high-voltage to low-voltage and ground, single-phase, 60 cycles—data from tests (Allis-Chalmers Manufacturing Company)

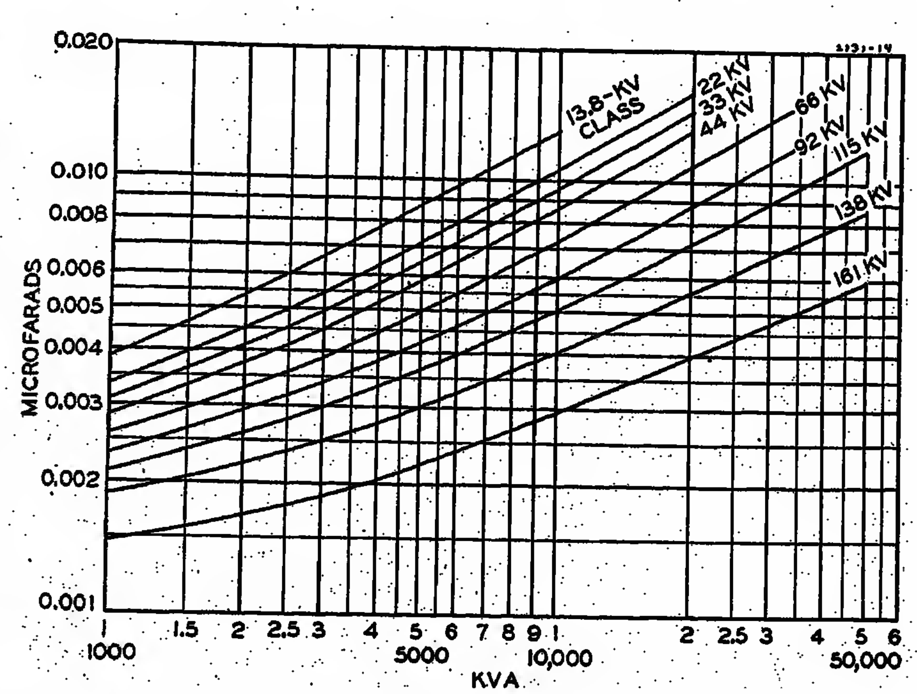

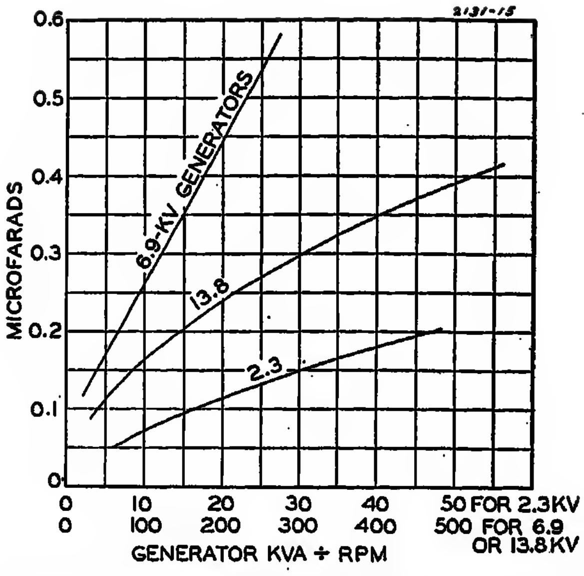

Figure 15. Effective capacitance to ground of salient pole generator stator windings—one-half capacitance of one phase to ground—all curves are the average of a large number of calculated curves (Westinghouse Electric and Manufacturing Company)

sented, as well as upon the assumptions made in simplifying it, both should be carefully studied.

Appendix. Capacitance Data

The following capacitance data are based on tests or computation by the manufacturer of the equipment unless otherwise noted.

Transformer Windings

General Electric Company. For single-phase transformers with concentric windings the total winding capacitance is given in Figure 13. These curves show only approximate trends. Individual transformers may deviate considerably from them. For capacitance of windings rated less than 13.8 kv, the 13.8-kv curve will apply.

The effective capacitance concentrated at each end of the transformer winding is one half of the curve value. The capacitance should be determined using the line voltage, whether the transformers are connected wye or delta, since the capacitance depends on the insulation thickness which is determined by the operating voltage of the transformer.

For a bank of transformers connected wye, one half of the capacitance of the transformer winding, as determined from the curve, should be used when considering each phase of the system. For a bank of transformers connected delta, the capacitance per phase is equal to the value obtained from the curve, because there are two transformers connected to each line.

Table VII. Total Capacitance to Ground of Single-Phase Shell-Type Transformers

Westinghouse Electric and Manufacturing Company

Kva	Capacitance in Micromicrofarads 115 Kv	230 Kv
10,000	5,500	5,900
20,000	7,100	7,700

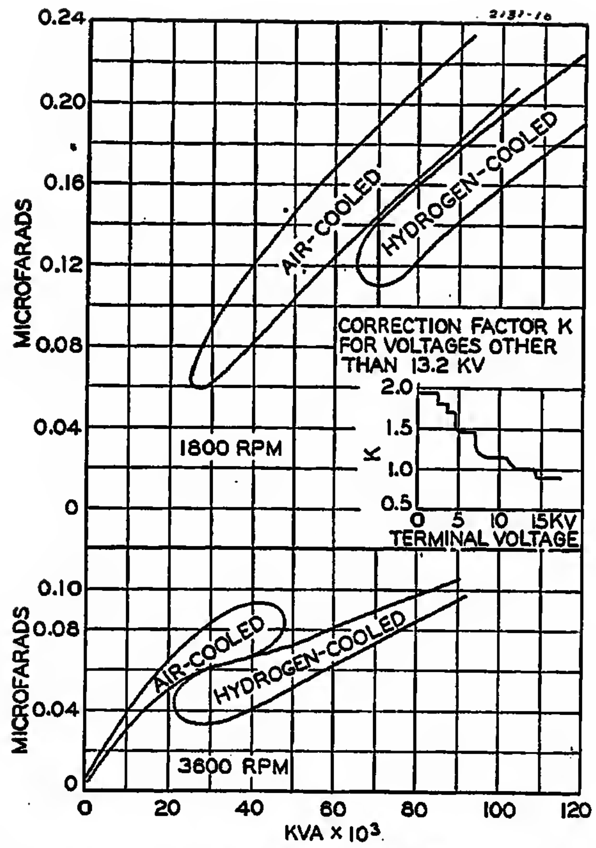

Figure 16. Effective capacitance to ground of turbine-generator windings—one-half capacitance of one phase to ground (Westinghouse Electric and Manufacturing Company)

Microfarad basis—13.2 kv; multiply capacitance by K for voltages other than 13.2 kv

For three-phase transformers, the capacitance per phase is approximately one half of the value given by the curve. The transformer kilovolt-ampere capacity to apply to the curves to obtain the capacitance is the three-phase kilovolt-ampere rating of the transformer.

For Pyranol transformers, the capacitance values are 1.6 to 1.7 times the curve values.

For a more complete discussion of these curves refer to "Equivalent Circuits of Transformers and Reactors to Switching Surges."[7]

Westinghouse Electric and Manufacturing Company. Table VI gives total capacitance to ground of single-phase core-type transformers. Table VII gives total capacitance to ground of single-phase shell-type transformers. The effective capacitance concentrated at each end of the transformer winding is assumed to be one half of the total capacitance.

Allis-Chalmers Manufacturing Company. The total winding capacitance for the high-voltage windings of various sizes of transformers are shown in Figure 14. The effective capacitance concentrated on each end of the winding is assumed to be one half the total value.

Table VIII. Effective Capacitance of Potential Transformers

Westinghouse Electric and Manufacturing Company

Kv Class	Ratio	Capacitance (Micro-microfarads)
25	23,000–115	180
34.5	34,500–115	175
46	46,000–115	185
69	69,000–115	310

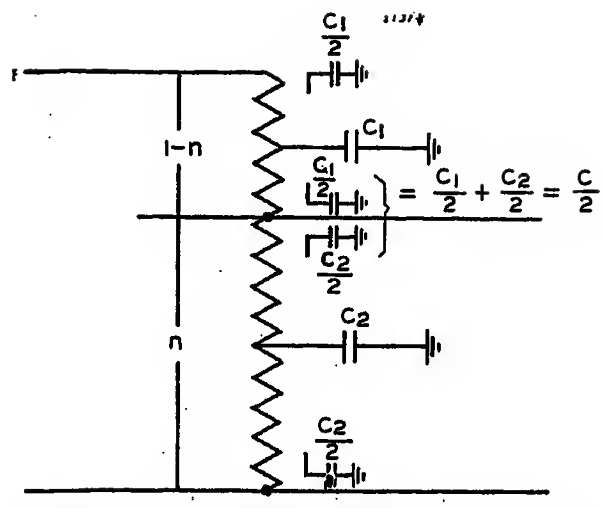

Figure 17. Capacitance distribution for autotransformers

Autotransformers

The capacitance of an autotransformer may be assumed to be distributed as shown in Figure 17.

C = total capacitance of autotransformer winding as determined from curve or tabulation (determine for transformer kilovolt-amperes, not circuit kilovolt-amperes)

n = ratio—low voltage to high voltage

$C_1=(1-n)C$

$C_2=nC$

Capacitance at high-voltage line end will be $C_1/2$

Capacitance at low-voltage end connected to tap will be $C/2$

Potential Transformers

Westinghouse Electric and Manufacturing Company. Effective values, that is, one half the measured winding capacitance, are shown in Table VIII.

Current Transformers

Average values for total winding capacitances are given in Table IX.

Induction Regulators

To determine the effective capacitance of induction regulators, it may be assumed that one half of each total winding capacitance is concentrated at each end of the winding as indicated in Figure 18.

C_P = total capacitance of primary winding
C_S = total capacitance of secondary winding

Table IX. Total Capacitance of Current Transformers

Kv Class	Type	Capacitance Micro-microfarads
General Electric Company		
7.5–15	Indoor	120
15	Outdoor	230
Westinghouse Electric and Manufacturing Company		
115	Oil-immersed / Self-cooled	433

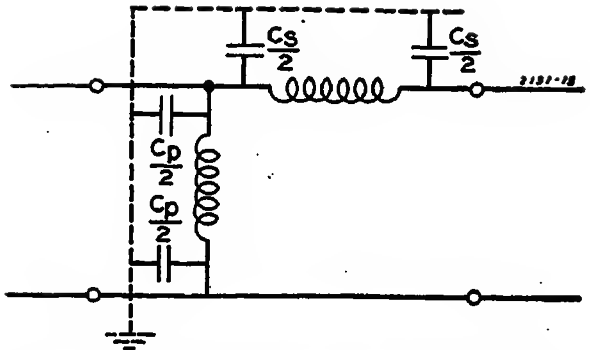

Figure 18. Capacitance distribution for induction regulators

Thus the effective capacitance at the source end is equal to $(C_P+C_S)/2$ while the effective capacitance at the load end is $C_S/2$.

Effective values determined from test readings obtained from regulators on the Philadelphia Electric Company system are shown in Table X.

Current-Limiting Reactors

An average value for the effective capacitance at each line terminal is approximately 100 micromicrofarads in the usual cell structure regardless of rating.

Generator Windings

General Electric Company. The following equation for the total capacitance per phase for generator windings has been taken from Park and Skeats' paper:[2]

$$C=K_c\frac{\text{mva}}{\sqrt{\text{kv}(1+0.08\,\text{kv})}}\text{ microfarads}$$

where the constant K_c has the following values:

Solid round rotors	0.0187
Salient-pole generators without amortisseurs	0.0347
Salient-pole generators with amortisseurs	0.0317

and

mva = rated capacity of generator megavolt-amperes

kv = rated line-to-line voltage of generator in kilovolts

One half of the value obtained from the equation should be considered concentrated at each end of the generator winding.

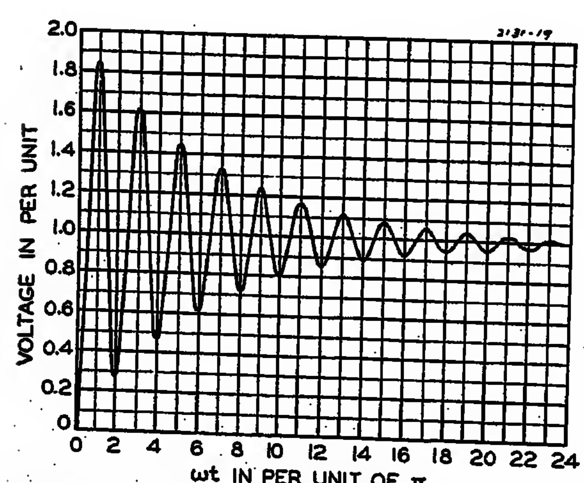

Figure 19. Curve for determining $1-\epsilon^{-\alpha t}\cos\omega t$ for decrement to 20 per cent in five cycles

$$1-\epsilon^{-0.051\omega t}\cos\omega t$$

π in microseconds for any frequency $=\dfrac{10^6}{2f}$

Westinghouse Electric and Manufacturing Company. The effective capacitance per phase (one half the total capacitance per phase) is given in Figure 15 for salient pole generators, and in Figure 16 for turbine generators.

Oil Current Breakers and Bushings

The capacitance of an oil circuit breaker consists principally of the bushing capacitances. The values given in Table XI are for one bushing or for one side of an open breaker and should be multiplied by two where the circuit passes through the breaker.

The capacitance of General Electric Pyranol-filled bushings is approximately the same as that of similar oil-filled bushings.

General Electric type H breakers—15-kv (including bushings)

One tank to ground	125 micromicrofarads
Both tanks to ground	150 micromicrofarads

Insulators

Suspension-Type

Standard duty (Westinghouse)	23 micromicrofarads
Higher strength (Westinghouse)	25–28 micromicrofarads

Locke Insulators

Rating and capacitance of Locke insulators are shown in Table XII.

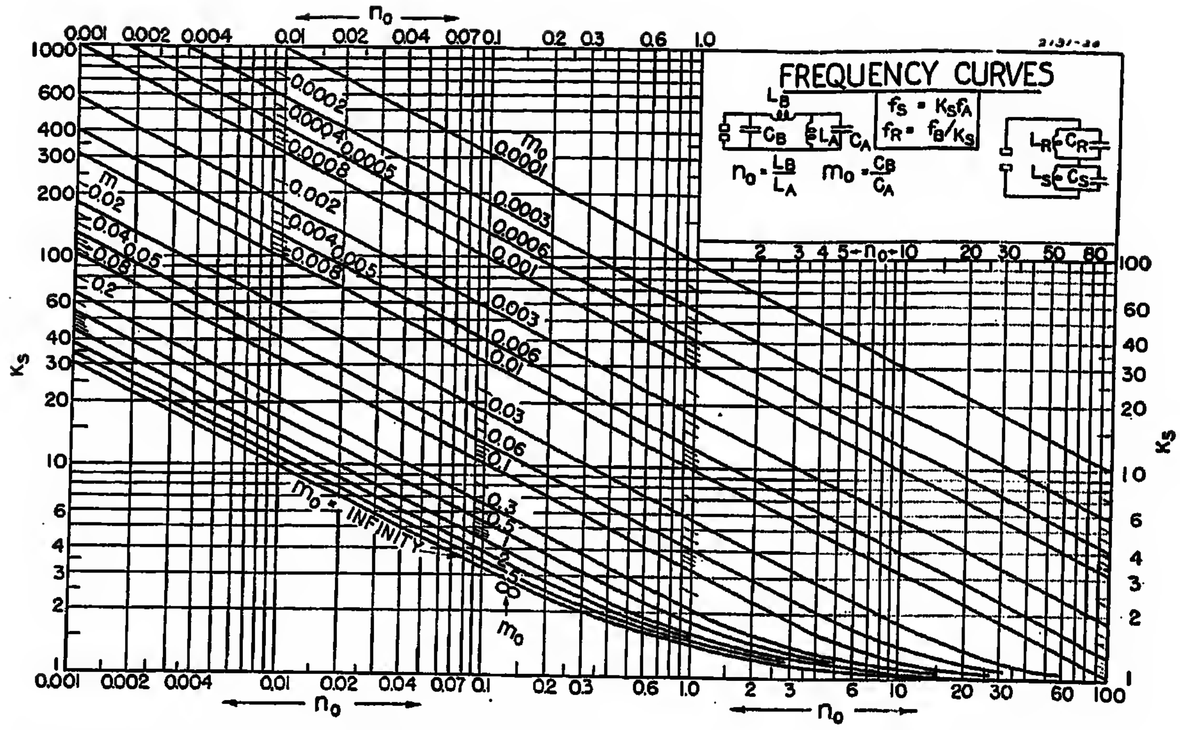

Figure 20. Frequency curves

Bus Supports and Wall Bushings

Indoor bus supports	12–25 micromicrofarads
Wall bushings	100–200 micromicrofarads

Lightning Arresters

General Electric Company. Approximately 20 micromicrofarads. However, this is subject to considerable variation depending upon design and voltage rating.

Determination of Capacitance by Flux Plots

In order to determine the capacitance of a bus or of a conductor by this method,[8] a cross section of the conductor in the cell should be drawn to scale. If there are any grounded parts running through the cell, the flux path will be from the conductor to these parts. However, if the conductor is surrounded by a concrete cell, the walls of the cell can be assumed as ground potential, and the capacitance calculated on this basis.

In the space between the conductor and the grounded parts or cell wall, draw equipotential surfaces and draw lines of flux

Figure 21. Magnitude curves

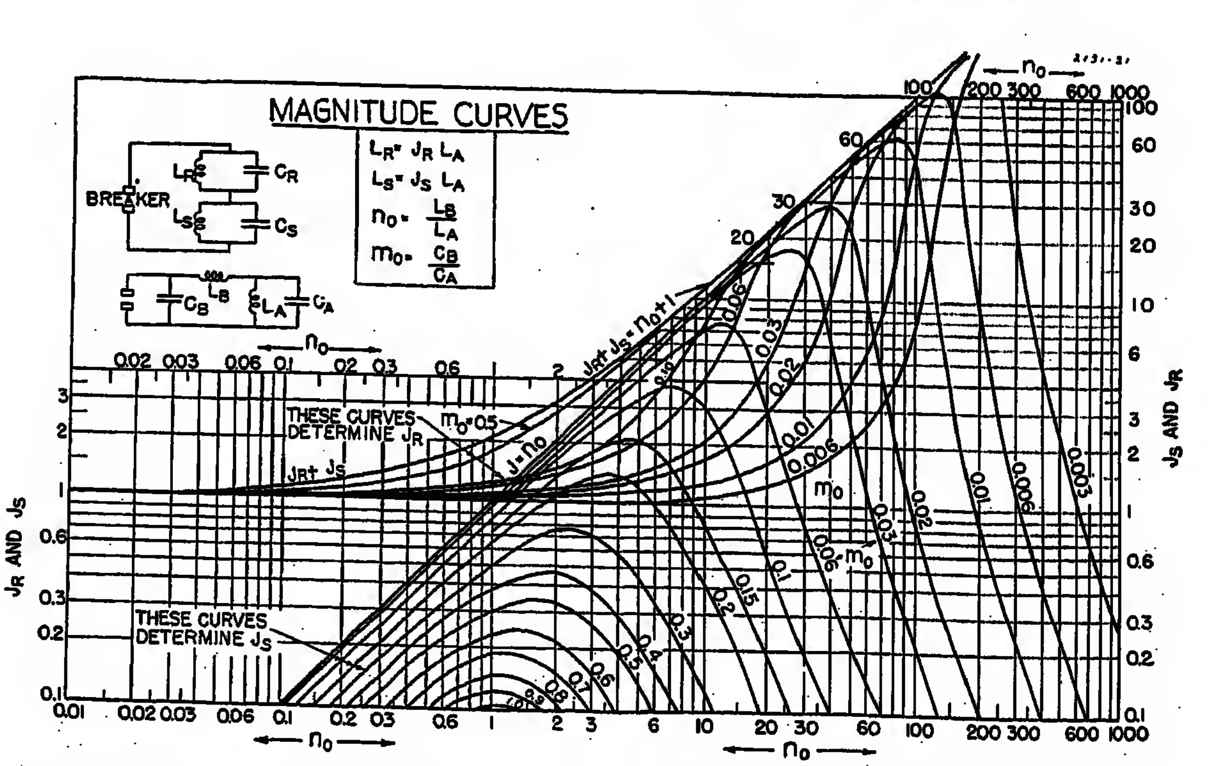

Table X. Effective Capacitance of Induction Regulators

287	1,200			400–500

* Values apply to present standard bushings but will serve as a reasonably accurate approximation for bushings which are no longer standard. The former standard 400- and 800-ampere bushings have the same capacitance as the 1,200-ampere bushings listed here.

† Capacitance increases with rated continuous current and rated interrupting capacity.

Table XII. Locke Insulators

Catalog No.	Rating Kv	Capacitance of 1 Unit Micro-microfarads
29,150	15	15
10,455	34.5	25
9,153	46	11
7,785	115 (3)*	56
9,473	7.5	61
23,070	15–23	60

* Three units of 7,785 are used for 115 kv. Above value is for one unit. Three units will have approximately one-half the capacitance of one unit

from the conductor to ground. These should be so drawn that the lines of force and equipotential surfaces cross at right angles, and so that the cells formed are approximately squares. The lines of force should leave the conductor and enter the grounded surface at right angles.

The capacitance of the section can then be determined by counting the number of tubes of flux between the conductor and ground and the number of cells in series in each tube and by calculating the capacitance from the following formula:

$$C = 2.7\frac{w}{l} \text{ micromicrofarads per foot of}$$

length of conductor at right angles to the paper where

w = the number of tubes of flux
l = the number of cells in series per tube

Fault Capacitance

The capacitance for a three-phase ungrounded fault consists of the capacitance to ground of the three conductors and of any equipment adjacent to the fault. Usually the capacitance of the cable or line will predominate and that of the apparatus will be negligible in comparison.

Any line or cable may be assumed, with little error, to be open at its far end. If such a line is short, it will behave substantially as if all its capacitance were lumped at the fault. If the line is long, on the other hand, it will behave for a considerable time like a resistance rather than a capacitance. Nevertheless, in the interest of simplicity, it is very desirable to represent the line as a capacitance; but if the entire capacitance of a long line is used, the resulting calculation gives an initial rate of rise which is much too low, and accuracy in this component is more important in the early part than later on. Consequently, an approximation has been adopted which consists in placing a limit on the length of line taken into consideration. This limit is set at a value such that the first reflection from the far end of the line, as limited, returns to the fault point after one-fourth cycle of the oscillation resulting from the corresponding value of capacitance in combination with the inductance of the return circuit.

This limits the error in the first part of the transient to a maximum of about seven per cent of the total circuit voltage. In general, this maximum error will not occur at the time of an important peak in the recovery transient, and hence the effect on the recovery rate from this source will usually be quite small. This limit in miles of line is given by the equation:

$$M = \left(\frac{\pi}{4}\right)^2 \frac{L}{l}$$

where

M = limiting line length in miles
L = inductance of the return circuit in henrys
l = $^1/_3$ zero phase sequence inductance in henrys per mile

If M as calculated is equal to or greater than the actual length of the line, the actual length of the line should be used in determining the fault capacitance. If M is less than the actual length of the line, this value should be used for the length of the line in determining the fault capacitance.

Electric Facilities and Operating Plan for the First Chicago Subway

CHARLES E. De LEUW
NONMEMBER AIEE

Synopsis: The $64,000,000 subway project now being completed will provide long-needed rapid-transit terminal facilities in the Chicago downtown district. The State Street subway will be completely equipped and in operation early in 1943 and will constitute a major contribution to the problem of handling additional traffic resulting from a decrease in the use of passenger automobiles.

This first subway route is five miles long and with fixed equipment will cost almost $34,000,000. The subways were built with track sections in tunnel—at low level. Platforms 500 feet long are provided at stations, except in the congested area where there is a continuous island platform 3,300 feet in length with access provided by mezzanine stations in each block.

All fixed equipment is being installed by the city. Despite the delay in securing equipment because of present scarcity of critical materials, the entire project will be built and equipped in a period of four years. This high-speed construction program required expeditious planning of locations for all electric facilities.

Power will be 600 volts direct-current. The 144-pound contact rail will be energized by existing substations and energy delivered by conventional positive and negative feeders, with contact rails reinforced with parallel feeders.

Adequate sectionalization of the entire system is provided largely by automatic operation. Centralized supervisory control of the all-relay type includes most modern accessories, such as an illuminated diagram board and remote-control dispatching equipment.

Train movements will be controlled throughout by a modern signal and electro-pneumatic interlocking system with automatic stops. Signals are spaced and timed for operation of 40 trains per hour on each track. Signals and other electric facilities, including lighting, pumps, fans, and escalators will have a-c power supply.

Fluorescent lamps will be utilized at all subway stations. Lighting intensities on mezzanine floors and station platforms will vary from six to eight foot-candles. Escalators are provided at all stations. At the downtown and heavier outside stations two four-foot escalators are provided operating at a speed of 90 lineal feet per minute.

The State Street subway will be operated initially by 455 steel cars now owned by the Chicago Rapid Transit Company. However, new equipment will be modern streamlined articulated units. The ultimate capacity of the State Street subway as thus equipped will be 80,000 passengers per hour.

Paper 42-137, recommended by the AIEE committee on land transportation, for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 20, 1942; made available for printing May 18, 1942.

Charles E. De Leuw is acting chief engineer, Chicago Department of Subways and Superhighways.

The author wishes to acknowledge the assistance of the following in the gathering of data for this paper and in the preparation of the text: C. W. Post, Wendell P. Monroe, and Walter W. Wenholz of the Chicago Department of Subways and Superhighways; Dwight L. Smith, and E. A. Imhoff of the Chicago Rapid Transit Company, and W. J. Clardy of the Westinghouse Electric and Manufacturing Company.

The Initial Subway Project

THE $64,000,000 subway now being completed, is the first step in a comprehensive plan for modernization and extension of all local transit in Chicago. The second step, now well under way, will be the consolidation of three separate and competing transit companies into a single unified corporation. This will result in economies in operation and the elimination of unnecessary and costly duplication of service.

The unification ordinance, granting an indeterminate franchise to the new unified company, has been passed, and virtually all of the preliminary steps taken, so that there now remains only the formal approval by the present security holders of the reorganization plan, the approval of the issuance of new securities by the Illinois Commerce Commission, and the final approval by the voters at a referendum to bring to its final culmination this objective which the city has sought for more than 25 years.

The third step will follow the granting of an indeterminate franchise to the new company and will consist of a thorough-going modernization of transit equipment, the substitution of trolley and motor busses for inefficient trolley-car service on about one third of the track mileage of the present surface-lines system, the extension of and improvement of service in intermediate and outlying areas of the city, not now adequately served with local transit, and the unification of all facilities through universal transfer between rapid transit and surface routes.

Function

An understanding of the function of the new Chicago subways requires a brief outline of the present local transit situation.

More than three quarters of the city's traffic is carried by the Chicago Surface Lines, operating a comprehensive network of street-car and, in more recent years, trolley-bus and motor-bus routes. During the last two decades, this surface transportation system has been supplemented by the operation of motor-bus routes, largely over the boulevards, by the Chicago Motor Coach Company, now carrying about seven per cent of the total traffic. The only form of urban rapid transit, other than that afforded by steam-railroad suburban roads, is that provided by the elevated railroad system operated by the Chicago Rapid Transit Company. However, unification of these companies will bring universal transfer and thus making rapid-transit facilities indirectly available to all.

For years engineers have realized the inadequacy of the downtown terminal facilities of this system. Thirteen elevated tracks, four on the north side, six on the west side, and three on the south side, deliver their loads to a two-track loop in the center of Chicago (except for a limited number of trains handled in stub terminals).

One of the principal objectives of the State Street subway is to provide terminal facilities for the rapid-transit lines to relieve the elevated loop. The loop, about two miles around, consists of two tracks both operating in the same direction. The cars using the inner loop must cross the outer-loop tracks at grade on both entering and leaving.

In spite of interference between all trains at two points, the outer loop now carries at the peak of service 208 cars in 35 trains during the maximum 30-minute period—see Figure 1. The inner loop now carries 167 cars in 36 trains. Commonly accepted practice to move trains expeditiously is a maximum of 40 trains per hour, and the heavily traveled New York subways operate at a lesser frequency than this. As a result of this congestion, speeds on the Chicago elevated loop lag down to six or seven miles per hour, and overcrowding of trains results—even under present traffic conditions.

The importance of additional terminal tracks for the Chicago rapid-transit system became vastly more important with the order rationing passenger automobile tires which became effective about the first of the year 1942. It has become evident that public transportation agencies will be required to carry, not only the additional traffic resulting from the accelerated pace of commerce and industry due to war activities, but also an ever increasing group of passengers who now use auto-

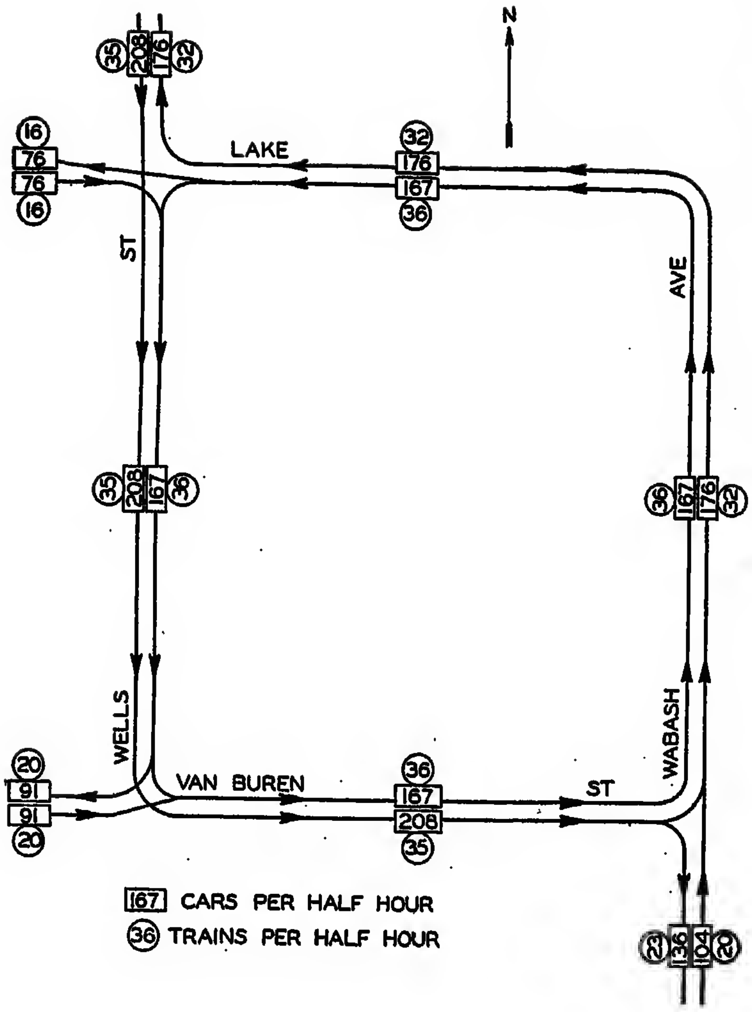

Figure 1 (left). Chicago rapid-transit car flow on the Union Loop during maximum half hour, 8:15–8:45 a.m., December 1941

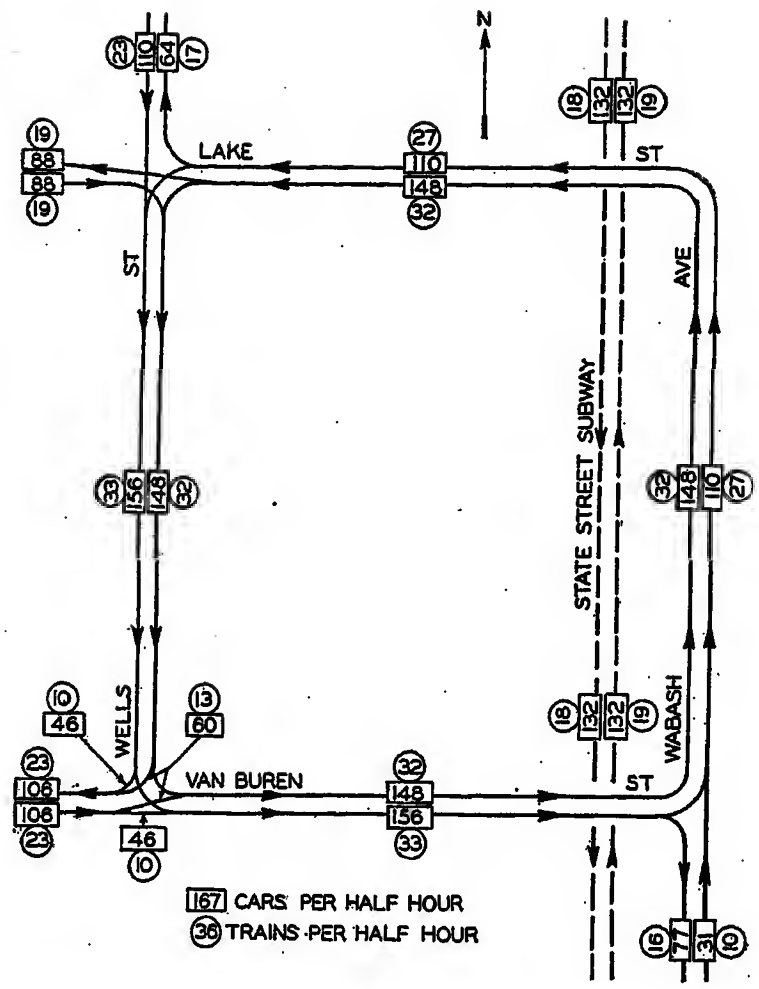
Figure 2 (right). Car flow on Union Loop and State Street subway during maximum half hour, 8:15–8:45 a.m., expected in December 1942



mobiles exclusively for their transportation.

Because most automobile traffic to and from Chicago's downtown district is long haul traffic, it is estimated that most of the present automobile passenger load will be transferred to rapid-transit trains. Our estimates indicate that unless relief is afforded by the operation of the State Street subway during the year 1943, it will be virtually impossible to operate enough cars over the existing union loop terminal to provide transportation with any reasonable loading standard. Figure 2 shows the estimated redistribution of present traffic after the start of operation of the State Street subway.

Description of Subways

The initial project consists of two terminal subways which will be operated with and become an integral part of the rapid-transit system. Route 1, the State Street subway, connects with the four-track north-side elevated route near Armitage Avenue, $2^1/_2$ miles to the north, and extends along Clybourn Avenue, Division Street, and State Street to a connection with the three-track south-side elevated route near 16th Street, $1^1/_2$ miles to the south. This subway has a total length of 4.9 miles and is estimated to cost $33,750,000 including fixed equipment.

Route 2, the Dearborn Street subway, is the first unit of an underground terminal system for west-side rapid-transit routes. The initial section extends from a downtown terminal loop to a connection with the Logan Square elevated route, $3^1/_2$ miles to the northwest of the downtown district. The total length of route is 3.9 miles, and the total cost, including fixed equipment, will be approximately $30,400,000. Except for short sections near the terminals, the entire project was built with track sections in tunnel at low level. Reinforced concrete tunnel sections were utilized throughout.

At each station platforms 500 feet in length are provided. At the three side-platform stations these structures consist of multiple arches—largely of reinforced concrete construction. Stations with continuous island platforms 22 feet in width were built in the loop district proper. This construction consists of a multiple three-arch section—two large bores on each side accommodating the trains and a portion of the platforms, with a smaller arch sprung from longitudinal steel girders supported by heavy steel columns. In general, stations are of the mezzanine type, constructed by cut-and-cover methods and located as close as possible to the street surface. Figure 3 shows an artist's perspective of the subway structure at a station.

All architectural features were designed with a view to providing attractive, light, and well-ventilated stations. A type of finish is planned which, in addition to being attractive, will stand wear and tear as well as the rigorous atmospheric conditions of downtown Chicago.

As finally developed the plans for the mezzanine stations provide for reddish-colored cement floors, scored in a tile pattern, light-colored structural glass walls, painted concrete ceilings, with dark (radio-black) marble column encasement, and metal doors and trim. Stairways have abrasive tile treads and glazed tile walls. The platforms are also to have colored cement floors, scored, with various colored paints on metal columns and all exposed metal—also on the arched ceilings.

Construction

Electrical Problems

Since the subways were tunneled through the soft clay underlying most of the city, air pressure was used during mining operations, and one of the first electrical problems confronting the subway department was the regulation of the contractors' electric facilities, including the service transformers, motor-driven air compressors, temporary electric lighting and hoists. The specifications were written to provide safety to the men working under air pressure in the tunnels. To insure reliability the power company was required to provide two entirely separate feeders from separate substations to each plant, each supplying a separate bank of transformers. Transfer switches were required as well as high-class equipment and wire throughout. Tunnel lighting and air compressors were especially safeguarded against failure.

The design of the permanent electrical work in the structure had to be made far in

advance of installation, because the conduit requirements for the feeders and branch wiring, as well as the space requirements of the equipment, had to be known before the concrete was poured. This subway is virtually free from all exposed wiring and cable.

Splicing chambers, circuit-breaker rooms, and machinery rooms all form a part of the underground structure. The space requirements of these rooms, therefore, is an important factor in the cost, and the electrical department had to be able to justify all space asked for. Arrangements had to be made with the power company for duct connections and transformer vaults, where necessary, so that these could be installed before the excavation was closed. Therefore, the electrical studies were intensive, even while the mining operations were just beginning.

Equipment Installed by City

Under the provisions of the unification ordinance passed in 1940, the new transit company is obligated to install all equipment in city-built subways. However, by the spring of 1941 it had become apparent that the seemingly interminable delays incident to completing all preliminary legal and financial negotiations might result in the first subway being completed before the reorganization was effected.

Therefore, the City Council, in May 1941, by ordinance directed the Commissioner of Subways and Superhighways to purchase and install the fixed subway equipment and to make arrangements with the trustees of the Chicago Rapid Transit Company for subway operation. Subsequently, the department proceeded vigorously with this work with the understanding that the city will be subsequently reimbursed for all equipment expenditures by the new transit company. In this task our engineers have had the full co-operation of the engineering staff of the Chicago Rapid Transit Company.

Progress

Basic subway construction on route 1 is complete. The elevated-to-subway connections at termini are now under construction. Station finish, much of which was redesigned to reduce the quantity of critical war materials, is now 50 per cent complete.

Anticipating some difficulty in securing the large quantities of steel, copper, and rubber required for fixed subway equipment, orders were placed and contracts let for furnishing most of the necessary equipment late in the year 1941. The last such contract, for signals and interlocking, was placed during April 1942; subsequently, contracts have been awarded for the installation of all traction power distribution equipment—work which is now under way.

The War Production Board has recognized the importance of completing the State Street subway by assigning a project rating of A-10 in February 1942. Higher ratings have been assigned various suppliers and manufacturers as required, so that the completion of the entire State Street project, including equipment, ready for operation early in 1943, now seems assured.

Power System

Trains operating in the State Street subway will be routed through the subway in the central area from the present outlying elevated terminals. The power for the subway trains will therefore be the same as that used on the elevated system, that is, 600-volt direct-current on the contact rails with paralleling feeders and with a return to the substations through running rails, negative feeders, and, to a limited extent, through steel elevated structures.

Substations and Feeders

Because the State Street subway is generally parallel to the present north and south elevated route, and because the downtown terminal traffic will be transferred from the elevated system to the subway, the subway power requirements will not be entirely in addition to the present system power requirements. Therefore, it is practicable to use existing substations now supplying the transit system. In most cases, these substations are actually adjacent to the subway structure, although one, the Sedgwick Street substation, is several blocks distant. New feeders will connect substations to the subway.

The substations are owned and operated by the Commonwealth Edison Company and under present plans this company will supply traction power to the subway. In general, the only new substation equipment required for the subway will be feeder circuit breakers and their automatic and control features.

The underground positive and negative feeders from the substations to the subway cable shafts will be paper-insulated, lead-covered cable. They will be spliced to water-resisting compound insulated feeders leading from cable shafts to circuit-breaker rooms in the subway structures. All power feeders in the subway will be insulated with water-resisting compound and finished with heavy asbestos braid. The subway circuit-breaker rooms at feed points will contain circuit breakers which will act as remote-controlled disconnect switches between these substation feeders and contact-rail feeders.

Contact-Rail System

A new contact-rail section has been adopted, similar in design but considerably heavier than that now used on the elevated system. This rail weighs 144 pounds per yard and will have a conductivity equivalent to 2,250,000 circular mils of copper. The rail will have a hardness somewhat greater than has been used for high-conductivity rails on other subways, to obtain longer life.

Since the contact rails are not generally of sufficient conductivity for the subway loads, it is necessary to reinforce them with paralleling feeders. These reinforcing feeders will be insulated with water-resisting compound and tapped to the contact rails at intervals of approximately 1,000 feet through disconnecting tap switches. The negative reinforcing feeders, in parallel with the running rails, will also be insulated with water-resisting compound and will be tapped to the running rails at intervals of approximately 400 feet. The positive and negative reinforcing feeders will be carried in a duct bench containing 12 asbestos-cement conduits along one side of each track in the train sections. The duct bench also serves as an emergency walkway—see Figure 4. Splicing chambers are located at 250- to 400-foot intervals.

The taps to the contact rails and running rails will be cables similar to the reinforcing feeders and are carried in asbestos-cement conduits in the concrete track ballast to pothead terminals, from which flexible bare bonds will connect to the contact or running rails. The location and gauge of the contact rail will be the same as that of the contact rail on the elevated system, so that the same collecting shoes can be used. This type of contact shoe is of the suspended overrunning contact type. The contact rails will be mounted on porcelain insulators on the track ties in the usual manner. Expansion and contraction will be taken care of by gaps at intervals of approximately 1,000 feet on level tangent track in the subways and at shorter intervals on curves and grades.

Sectionalizing

The contact rails with their reinforcing feeders are sectionalized at the substation feed points, interlocking plants, the emergency track crossovers, and at the tie points which are approximately midway between feed points. Short-circuit and overload protection on any section between substations is obtained by automatic opening of substation circuit

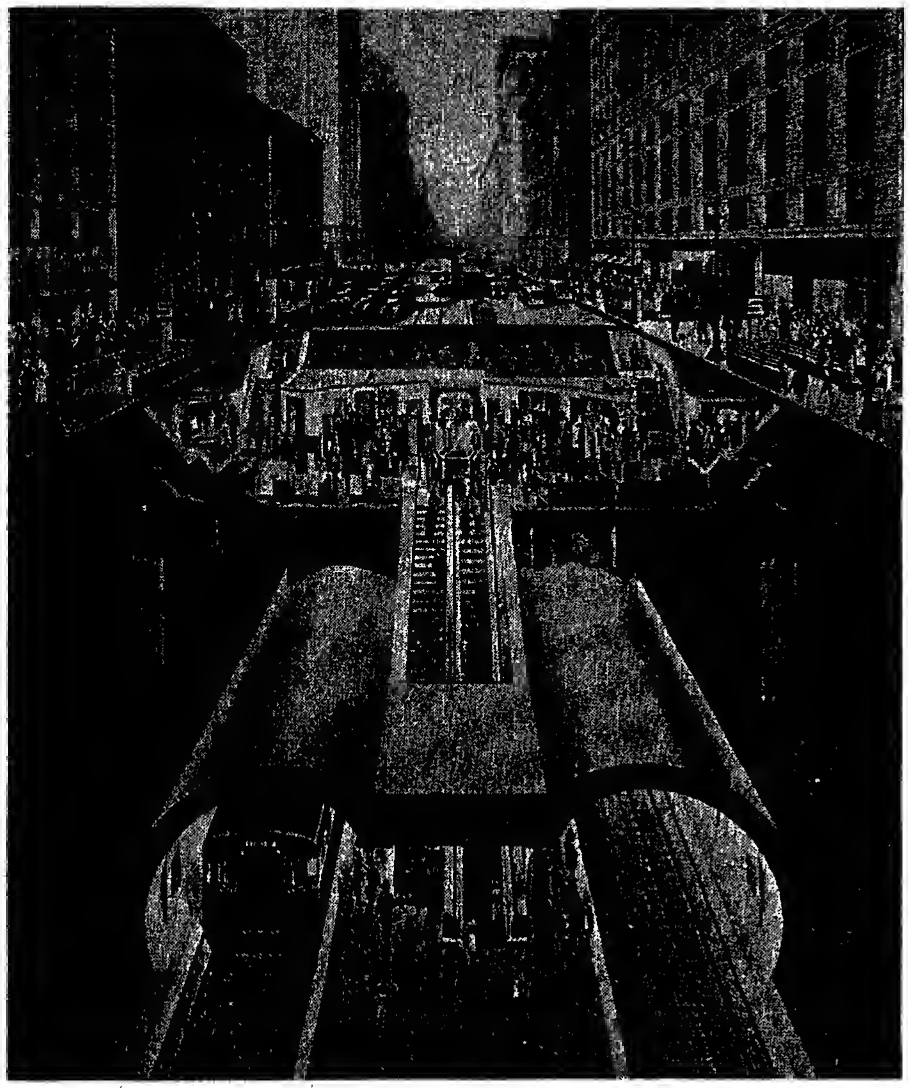


Figure 3. Artist's perspective of the subway structure at a downtown station

breakers and tie circuit breakers without affecting other sections. The other sectionalizing circuit breakers do not have automatic opening features but serve as remote-controlled disconnect switches with high interrupting capacities. The function of the automatic circuit breakers at tie points is to connect the contact rails and feeders of the two tracks together in order to utilize the conductivity of both for feeding distant loads.

The tie station circuit breakers, the substation circuit breakers and all sectionalizing and disconnect circuit breakers will be of the latched-in, air-break type and will be remotely controlled by the supervisory control system.

Return Circuit and Bonding

Since the block signal system of the subway tracks will be of the single-rail track circuit type, one rail of each track will be used exclusively for signals, leaving only one rail of each track available for the traction current to return to substations. Each running rail will have conductivity equivalent to approximately 1,000,000 circular mils of copper. This conductivity must be supplemented by the negative reinforcing feeders. Running rail joints will be welded, except at special track work where bonds will be required across joints. Bonds will be bare flexible copper cable with terminals suitable for welding to the head of the rail by the oxyacetylene welding process.

The contact-rail joints will not be welded, so they must be bonded. The contact-rail bonds will be short U-shaped cable bonds located underneath the rails with terminals welded to the flanges. There will be two 750,000-circular-mil copper bonds per joint.

Supervisory Control

Due to the physical extent of this project and the diversity of operations associated with power services for a subway, including ventilating and pumping systems, centralized control and supervision is essential. This is to be provided by supervisory control of the all-relay type.

The dispatching equipment of the supervisory-control system will be located in the power supervisor's office, two blocks from the State Street subway. Remote station supervisory-control equipment will be located at eight control centers.

A power supervisor's desk, an illuminated diagram board, and relay cabinets of the swinging panel type will comprise the principal elements of the dispatching equipment. Although these elements will incorporate dispatching equipment for all eight outlying centers, the equipment will function independently for each. Thus operations of any given center will not interfere with simultaneous functions of another center.

The functions to be performed include remote control and supervision of all feeder, sectionalizing, and tie-station d-c circuit breakers, as well as the operation of the two-speed station and tunnel ventilating fans. Additional functions will include supervision of the continuity of the normal and emergency a-c services, high water level and pump-motor overload, low supervisory-battery voltage, battery ground or ground on control wires to apparatus remote from the control center.

The supervisory-control system is an "all-relay" system using relays of the standard telephone type, having uniform mechanical construction, extreme simplicity, and established dependability. Operation of this system is based on codes of

Figure 4. Duct bench and walkway during construction

impulses suggestive of a simple telegraph system, but different from the telegraph in that the impulses are all of the same time duration. Several impulses in uniform sequence form a code, and the number of impulses in a code is varied to obtain various results. All codes are produced automatically, the dispatcher's action being limited to the simple twisting of a control key and the pushing of a button.

As an example of operation, assume that it is desired to close a circuit breaker. The dispatcher first operates the selection key on the escutcheon of the desired breaker. This sets the proper relays into operation to select the breaker. As soon as this selection is made, the fact is indicated by the lighting of the white selection lamp on the associated escutcheon, as well as the lighting of a similar selection lamp on the diagram board. The supervisory equipment now comes to rest, awaiting the will of the dispatcher. Then, to close the breaker, the dispatcher first places the twist-type control key in the closed position and then operates

the master control key. This results in the closing of the breaker. When the breaker closes, the auxiliary signal contact closes and energizes supervision relays which operate to change the indications of the red and green supervision lamps on the diagram board. The supervisory control equipment then returns to the normal rest position, ready for the next operation or change in indication.

The system is operated entirely from 48-volt storage batteries to insure against loss of control from loss of a-c power. A check-back feature is employed as a guard against the possibility of obtaining false indications or performing false operations. Multiconductor control cable will provide the necessary channels for operation of the supervisory-control equipment. Each of the eight remote supervisory centers will be controlled and supervised over a single pair of wires. In addition to the pair per station, there will be two standby pairs. One standby pair will be available to the five stations to the north of the dispatcher's office, and the second pair will be available to the three stations to the south.

Throw-over switches at all points will facilitate transfer to the emergency lines in case of trouble. An audible and a visual alarm will be given in the power supervisor's office in case any of the control lines are opened, grounded, or short-circuited. In addition, each line will be equipped with supervisory-control protectors which will function to clear any heavy surges which may appear on the line wires.

Emergency Alarm System

Adjacent to splicing chambers located at intervals of about 400 feet along each subway track, emergency alarm boxes will be located on the walls above the walkways. These alarm boxes will be similar to city fire-alarm boxes in that when the lever on one of them is pulled, an alarm is given at the power supervisor's office. The alarm will be audible and visible, and the number of the box on which the lever is pulled will be recorded on a tape together with the time and date. Also, the pulling of an alarm-box lever will immediately open all circuit breakers through which power is normally supplied to the contact-rail section where the alarm box is located. Thus, in case of an emergency, such as a train wreck or fire, the motorman of an affected train, or other employee, can quickly de-energize the contact rail and at the same time give the alarm at the power supervisor's office. A telephone will be located by the side of each alarm box to enable the person actuating the alarm box to give further information and ask for and receive instructions concerning the emergency.

The alarm circuit will be a single-wire loop connecting all boxes in series. Each alarm box, when its lever is pulled, will cause a spring-driven contactor to open and close this loop circuit automatically at intervals in a code corresponding to the box number. If levers on two to four different boxes are pulled at the same or nearly the same time, each will transmit its code in turn, and all signals will be received at the supervisor's office without interference. The loop circuit will have automatic line supervision which will cause a distinctive alarm signal to be transmitted and recorded, in case of a ground or open circuit on the loop. The source of current for the alarm circuit and recorder will be a 48-volt storage battery at the power supervisor's office.

The circuit breaker tripping circuits will be an individual series loop for each contact-rail section. The opening of one of these loops will effect the de-energizing of the contact-rail section by means of relays, causing the supervisory-control tripping relays to trip the breakers. The alarm-system tripping relays are so designed that the power supervisor can reclose the circuit breakers by supervisory control after a short interval. The source of current for the alarm system's tripping loops will be the storage batteries at the outlying supervisory-control centers.

Signal System

The signal system consists of wayside colored-lights, approach interlocking signals, home signals, and interlocking dwarf signals. All of these except the dwarf signals have automatic controls; the approach and home signals are also controlled manually to govern train movements to and through interlocking plants. Dwarf signals (sometimes called backup signals) are manually controlled.

Automatic Train Stops

Associated with each automatic block, approach, and home signal there will be a wayside electropneumatic train-stop mechanism which in the tripping position would engage trip arms on the train thereby applying brakes and enforcing obedience to the STOP indication of the signal. A stop-release contactor mounted on the signal when operated by the motorman will clear the stop arm and permit him to pass a red signal when it is necessary to close up to the train ahead, or when signal or car-equipment failure occurs—according to the "stop, then proceed" rule.

Timing Control

The tracks are divided into blocks with a signal and train stop at the entrance to each block. The minimum length of a block is equal to the emergency braking distance for the expected maximum speed of a train as it enters the block, plus an additional length as a factor of safety. Minimum-length blocks are used in station timing where a train is allowed to close in at restricted speed when the station section is occupied. An illuminated T sign informs the motorman of the train where to begin this restricted speed. Signals governing entry into a station have extended controls so that the train standing in the station is protected by three or four red signals or by a distance sufficient to protect it from a following train traveling at maximum speed. The approaching train, on entering a track section or block where the T sign is located, energizes a time-element relay which picks up at a predetermined time and cuts off the extended control of the next signal, allowing it to clear for the train now traveling at a restricted speed. If this train continues at restricted speed, the next signal will have its extended control cut off by a second timing relay and so on, to bring the following train up closer to the station. This station timing is necessary to provide for the 90-second headway for which the signal system is designed. With no train standing in a station, all closing-in signals will be green, and a train can then proceed at normal speed.

On descending grades the braking distance is greater, and therefore the blocks at high speed would be so long as to reduce the track capacity. Restricting the speed of trains on grades results in increased safety and increased capacity. To accomplish this, "grade timing" is used with one or more signals normally showing the stop indication. If the trains run at excessive speed, a caution signal will be displayed, together with an additional lunar white indication, which indicates that the next signal is at "stop", only because the allowable speed is being exceeded, and that it will clear if the train runs at the permissible speed as measured by a timing relay.

These timing relays will receive coded energy for the measurement of the time intervals controlled by contacts on the track relays. The code transmitter, consisting of a coil, a mechanically tuned oscillator, and contacts, will generate the desired code for a number of time relays as determined by the location and distribu-

tion of these timing relays. Timing relays are also used for the emergency release of approach and route locking at interlocking plants. The time intervals will vary from four seconds for station timing to a maximum of 120 seconds for emergency switch operation.

Interlocking

At interlocking plants, switches and signals are controlled by means of buttons on a control board, and electric relay interlocking, in lieu of the mechanical locking which formerly was standard with interlocking machines. The control board is mounted on a desk within easy reach of the operator and has engraved on its face a miniature diagram of the tracks and switches of the interlocking plant, backed with lights repeating the track sections, thus showing the presence of a train as it approaches and moves through the plant. The interlocking control circuits are designed so that to initiate a route the operator need only manipulate a knob or button on the control board at the beginning of a route and then a second button at the end of said route. This operation causes the various switches and signals of the route to be correctly positioned and indicates on the control board that these switches have responded. This operation further electrically locks other switches and signals so that no conflicting move can be set up. Circuits are also provided for approach and sectional-release route locking which is standard in interlocking practice. Each switch and crossover has a separate operating lever on the control board for independent manipulation. An indication is also provided for each switch or crossover to show when they are not free to move, either because of the electric locking, or because a conflicting position of the switch has been called for.

The entrance control button has a red and a green lamp within it. The red lamp will flash when a route is initiated, will become a steady red light when the route has been completed, and will change to a steady green light when the signal has cleared.

Relays and Track Circuits

All relays are of the plug-in type with terminal prongs at the back. These prongs fit into sockets set into bases that are permanently mounted on racks. The control wires are soldered to these sockets. A maintainer desiring to replace a relay pulls one out of a socket and plugs in a duplicate without disturbing the wiring.

All interlocking and signal-control relays operate on ten volts direct current. Track relays are of the a-c vane type and operate over single-rail track circuits, where one rail is given over to signal track circuits, and the other rail is used both for power return and for track circuits. A track relay is connected across the signal and negative rails at the entrance to a block, while the approximately four-volt secondary winding of an air-cooled track transformer is connected across these rails at the far end of the block of track section. The relay and transformers are protected from unbalanced propulsion current by means of a resistance unit inserted in the leads to the signal rail and also by 600-volt fuses. The resistance unit in the transformer lead further limits the flow of current with a train in its track section. The track transformer has another secondary winding which furnishes ten-volt energy for lighting all signal lamps.

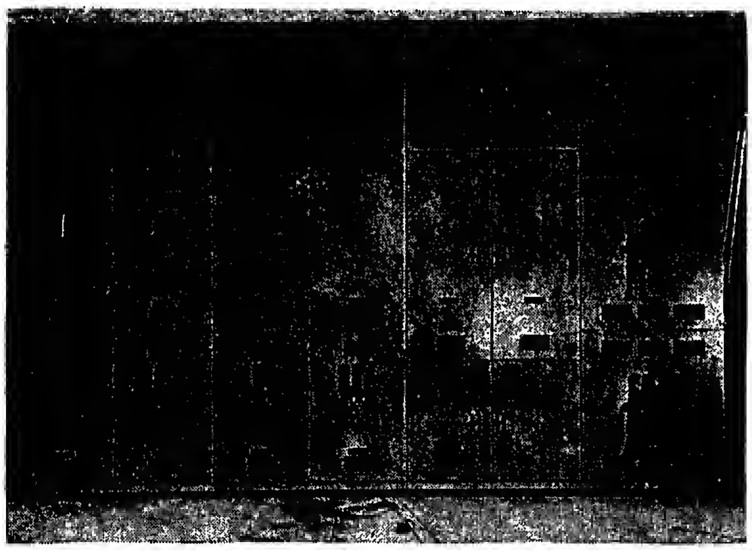

Figure 5 (left). Front of typical a-c switchboard

Figure 6 (right). Typical pump room

Signal Power Supply

The signal power-supply equipment is located in eight signal rooms in the State Street subway and at the north and south portal interlocking plants. Two liquid-cooled transformers at each location, one furnishing the normal supply and the other acting as a reserve source of power, receive energy at 60 cycles 208 volts in the subway and 240 volts at the two portals. The secondary circuits are interconnected by means of an automatic transfer switch and feed power to the a-c signal mains at 110 volts.

Two rectifiers of the copper-oxide type at each power-supply location are connected in parallel and feed power to the d-c signal mains at approximately 16 volts. These signal mains extend in each direction and in each tube from the power-supply source approximately half way to each adjacent supply location. The a-c signal mains feed the interlocking control-board lights, all signal lights, and track circuits. The d-c mains feed the relays at interlocking plants, all signal-line control relays, timing relays, and the electro-pneumatic valves.

Compressed Air

Air-compressor plants are located at the north-portal interlocking tower and at the 13th Street junction. Each compressor plant is equipped with two compressors connected to individual 600-volt d-c motors with automatic controls and fed from the propulsion current supply. The automatic controls are so arranged that either or both of the compressors may be cut in, depending on the drop in pressure. The compressed air is for operation of the automatic train stops and the track switches at interlocking plants.

The air distribution system consists of $1^1/_2$-inch air pipe extending the entire length of each subway tube and two-inch air mains on the elevated structure. Branch air lines feed compressed air at a normal pressure of approximately 65 pounds per square inch to the cylinders of the automatic stop and switch operating mechanisms.

Other Electrical Features

A-C Power Supply

The power for operating the a-c electric equipment will be supplied from frequent distribution centers along the subway by the Commonwealth Edison Com-

pany through 208/120-volt three-phase four-wire grounded neutral feeders. The total connected a-c load of the State Street subway and approaches (approximately ten track miles) is divided roughly as shown in Table I.

On this 4.9-mile two-track State Street route there are 21 a-c switchboard rooms in the subway, each supplied by duplicate service feeders from the Commonwealth Edison Company's transformer vaults. In the section outside of the central business district, the duplicate feeders are not merely parallel feeders; they come from normal and emergency sources, fed from different transformers. In the downtown area, the feeders come from transformer vault busses supplying the 208-volt three-phase network of the power company. These busses are interconnected with other vaults, and trouble in a vault supplying the subway would not interrupt services because of the network isolators. The reliability of the primary networks feeding transformers is well known.

Each a-c switchboard in the subway—see Figure 5—consists of a manually operated normal and an emergency service feeder main circuit breaker, on the load side of which is an electrically operated latched-in circuit-breaker type of automatic transfer switch to transfer the load from the normal to the emergency source in the event of failure of the former, and automatically transfer it back again on restoration of the normal source. In order to facilitate maintenance of the transfer switch there are by-pass and disconnect switches so arranged that the load can be by-passed around the transfer switch and the latter isolated, without interrupting the load. The remainder of the switchboard consists of the meter panel and branch feeder circuit breakers. The switchboards are all of dead-front steel construction with draw-out type of main service breakers. All circuit breakers are of the air-break type, main breakers having 50,000 amperes interrupting capacity, and the branch breakers in the switchboard 25,000 amperes interrupting capacity.

Table I

	Kva
Lighting	270
Pumps	360
Fans	350
Escalators	370
Miscellaneous	280
Total	1,630

Pumps

The drainage pumps are located in pump rooms over sumps constructed below track level—see Figure 6. Each installation includes two pumps, one acting as a standby normally, and each consisting of a submerged centrifugal pump driven through a long shaft by a 208-volt three-phase squirrel-cage splash-proof motor automatically controlled by float switches. At locations where the subway crosses below the Chicago River the motors are located at the ground surface, and they drive the pumps below by 80-foot shafts. The motors—ranging from 5 to 50 horsepower—are equipped with line-voltage starters. In the State Street subway, there is a total of ten pump rooms.

Ventilation

In general, it is proposed to depend upon the piston action of the moving trains for the normal ventilation of the tunnels, excepting in those portions of the tunnels which are at so great a depth as to make the cost of vent shafts to the surface prohibitive. These deeper sections of tunnel under the river will be ventilated by fans which can be operated continuously.

It is also proposed to depend upon the piston action of the moving trains for the normal ventilation of the stations, excepting the loop stations where the piston action will be somewhat ineffective.

Emergency fans will be installed midway between each pair of stations outside of the central district. In addition, small fans for the ventilation of toilet rooms and other service rooms will be provided in all of the stations. Vent shafts from train sections to the surface have been built on about 450-foot centers. The vent shafts near the stations have been located to serve a double purpose, namely, ventilation and blast relief for the station platforms. Without blast-relieving shafts at the tunnel entrances and exits of the stations, the high air velocities produced on the station platforms by the piston action of the trains would be intolerable. All of the openings in the tunnel walls to vent shafts will be equipped with power-operated louvers. These louvers will be interlocked with the emergency fans, so that when these fans are in operation, the louvers will be closed.

Two-speed reversible station fans will provide normal ventilation at the loop stations.

The horsepower of the fan motors ranges from $7^1/_2$ to 60. All of the fans except one will be of the propeller type, six to ten feet in diameter, and belt driven. The motors will be two-speed three-phase squirrel-cage motors with splashproof frames. One fan will be of the centrifugal exhaust type driven by a 60-horsepower motor and will be used to ventilate a deep tunnel section that does not have ventilating shafts. There will be a total of 26 fan rooms in the State Street subway including 13 in the downtown stations. The fans will be controlled by the supervisory control system of the railway.

Lighting

The normal illumination of the subway will be by fluorescent lamps in the stations and over station platforms, and by incandescent lamps in the train tubes. Forty-eight-inch, 40-watt white fluorescent tubes will be used in the stations. The tubes will be mounted in single-tube fixtures with single-tube power-factor correcting auxiliaries mounted in the base. Each tube will be entirely enclosed by a frosted glass globe covering the lower half of the tube, and a reflector and the fixture base covering the upper half. The lighting fixtures and lamps are planned to produce lighting intensities varying from six to more than eight foot-candles on mezzanine floors and station platforms.

Sixty-watt incandescent bare lamps will illuminate the tunnels between station platforms. They will be provided with opaque shields on one side to protect the eyes of the motormen. The lamps will be spaced at approximately 30-foot intervals on each of two lines of lamps per tunnel. Every fourth light in the tunnels will be on a 600-volt d-c circuit, with 56-watt railway-type lamps connected five in series in a group. Emergency 600-volt lights in the stations will be incandescent lamps.

The a-c lights will be remote-controlled from the cashiers' booths in the stations,

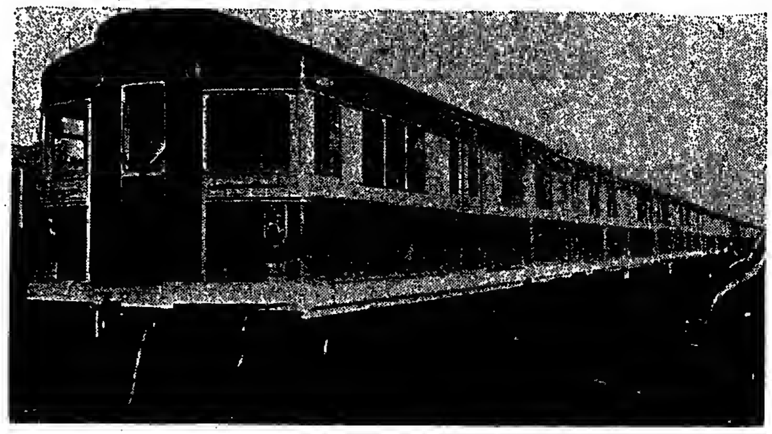

Figure 7. Streamlined and articulated subway-elevated cars of the type proposed for Chicago

single-phase latched-in contactors closing the lighting circuits. In general, there will be two degrees of a-c illumination in the tubes and the stations, with space sectionalization. The 600-volt emergency lighting circuits will always be energized from one of two sources, with an automatic transfer switch being provided at each station for both tubes and station. A special 600-volt lighting cable running the full length of the tubes will be one of these sources, and the nearest traction positive feeder will be the other source.

All lighting loads will have duplicate feeders, one of which will be exclusively for the lighting load, and the other may serve other loads or act as a standby emergency feeder for one lighting load, while serving as a normal feeder for a motor load. Manual transfer switches will be used for some lighting loads when near a switchboard, but the tunnel-lighting feeders will have automatic transfer switches. This duplication of lighting feeders will be in addition to the triple reliability of three-phase, four-wire lighting circuits with single-pole subbranch breakers serving the same area. Thus, the importance of reliable illumination in a metropolitan subway is recognized.

Provision will be made for more intense illumination at the portals during daylight hours, to permit adjustment of the motorman's eyes to the comparatively dark tunnels, by flood lights located near subway portals. Control of these additional lights will be from outdoor photoelectric cells.

Escalators

For the reason that the grade of the subway platforms is generally 40 feet or more below the sidewalks, the escalator installation in the State Street subway is exceptionally liberal. There will be two escalators connecting the mezzanine level with the platform level at almost all stations. Escalators are attractively finished and will operate at a speed of 90 lineal feet per minute. The downtown station escalators are four feet in width, while those in lighter outlying stations will be three feet. All the usual safety devices will be provided. The escalators will be reversible and will be controlled by push buttons located near the top and bottom of each escalator. The horsepower required to operate the various escalators will vary from 16 to 25 each when fully loaded. This equipment was purchased late in the year 1940 at the total cost of $1,174,000 for both subway routes.

Transportation Features

Train Equipment

It appears that the subway will be ready for operation prior to the time new rolling stock is available. The war is likely to cause an extensive delay in securing modern equipment for the proposed subway service. Therefore, operation will be initiated with trains of existing steel cars of the Chicago Rapid Transit Company.

There is a total of 455 of these units available—389 of which are equipped with two 170-horsepower motors each—and 66 trailers. The seating capacity is 52 passengers per car, and the total capacity 100. These rapid-transit cars were originally designed for use in a subway and are well adapted for the purpose. Trains will be composed chiefly of motor cars, insuring high free-running speeds and rapid acceleration.

The problem of new rolling stock was thoroughly studied by a committee of engineers, organized at the suggestion of the city, composed of representatives of the Illinois Commerce Commission, Chicago Department of Subways and Superhighways, the Chicago Rapid Transit Company, and the Chicago Surface Lines. The committee, after investigating the needs of the subway and the type of car best-suited to meet requirements of modern rapid-transit operation, drafted specifications for a modern lightweight high-speed rapid-transit unit.

A streamlined articulated unit, consisting of three compartment bodies on four trucks, and weighing approximately 82,000 pounds complete without load, was proposed. The general type of car is illustrated in Figure 7. The seating capacity is 106 passengers, and the total capacity 200. Propulsion would be with eight motors totaling 440 horsepower, and the free running speed 45 miles per hour on level tangent track. Such a car would start and stop at the rate of three miles per hour per second under average operating conditions.

In planning the new unit, the committee sought to utilize as many as possible of the favorable characteristics and equipment of the PCC street car. The latter vehicle, which obtains its alphabetical name from the Presidents' Conference Committee sponsoring its development, has been successfully used during the past six years for surface city transit. It embodies many "passenger-comfort" features, such as wide clear-view windows, plentiful illumination, adequate ventilation, uniform distribution of heat, smooth rapid starts and stops, noiseless operation, and the easy riding qualities resulting from rubber springs and resilient wheel construction. The operation of these new units over the welded running rails of the subway tracks promises an innovation in smooth-riding quiet subway-train operation.

The initiation of service on the State Street subway with the 455 steel cars now being specially equipped for subway use will provide three-minute service in each direction. When additional rolling stock is obtained, the number of trains will be increased with the demands of traffic up to a maximum of 40 trains per hour in each direction, the limit of the track capacity.

Operation

The maximum capacity of two-track rapid-transit subways is calculated by assuming the operation of 40 trains of five articulated units per track per hour. Units with maximum dimensions of 9 feet 6 inches in width and 90 feet in length, and weighing about 41 tons, are contemplated. With an average loading of 200 passengers per unit such an operation would develop a capacity of 40,000 passengers per hour per track. Thus the total capacity of the State Street subway would be 80,000 passengers, or 40,000 during the maximum half hour. This total capacity may be compared with the present total combined load for rapid transit, street cars, and motor busses of less than 90,000 in the maximum 30-minute period. Considering the fact that convenience requires the retention of some local bus and trolley-car routes at street grade, it is apparent that this terminal subway layout will provide adequately not only for present but for future traffic for years to come.

The 3,300-foot long platform planned for the State Street subway in the loop district will provide space for three double stops—each about 1,100 feet in length. Separate berths will be provided at each station stop for trains operating in different directions, thus providing the broadest possible distribution of incoming and outgoing passengers along the platform and through escalators, turnstiles, and stairways.

A New Multiple High-Speed Air Circuit Breaker for Mercury-Arc-Rectifier Anode Circuits and Its Relation to the Arc-Back Problem

J. W. SEAMAN
ASSOCIATE AIEE

L. W. MORTON
ASSOCIATE AIEE

Synopsis: Mercury-arc power rectifiers have been used increasingly to supply power to d-c utilization systems in the United States since the early twenties. War requirements, because they have multiplied the demand for aluminum, magnesium, chlorine, zinc, and copper, all of which utilize d-c current in their reduction, have tremendously increased d-c power consumption. It is estimated that $12^1/_2$ per cent of the kilowatt-hours generated in 1941 were consumed in such electrochemical processes. Since the mercury-arc rectifier is now the almost universally accepted form of conversion apparatus for this purpose, the attention of many more engineers has recently been focused on it.

Many advantages of the modern rectifier have led to its wide acceptance, but it is not within the scope of this paper to deal with these. One persistent factor in connection with the application of rectifiers which has claimed much attention is the phenomenon of arc-back. Various methods of attack have been employed successfully. High-speed anode switching appears to be the most satisfactory way to handle this problem. Such a solution is widely used in the aluminum industry.[1]

Part I of this paper includes an analysis of the arc-back problem and various means of protection from its effects. Reasons why high-speed anode switching *is* an improved type of arc-back protection are set forth.

Part II of this paper describes this multipole high-speed air circuit breaker. The requirements which the breaker must meet are discussed, and the electrical and mechanical features described. Performance of the breaker was checked in field tests. Oscillographic data are presented and prove that the performance is acceptable.

Part I. Analysis of Arc-Back Problem

Definition of Arc-Back

ARC-back may be defined as a failure of the insulating properties in an arc rectifier during the inverse half wave which results in the rapid reversal of current through the rectifier element. When such an event occurs, there are usually manifestations of this failure, such as high short-circuit a-c current and reversal of d-c current normally flowing from the rectifier.

Various theories have been developed to explain the reasons for this occasional failure of rectifying property or arc-back.[2–6] One commonly accepted explanation is the "particle theory" developed by Doctor Kingdon.[3–5]

In this theory an assumption is made that a minute particle of insulating material, perhaps as small as 10^{-6} centimeter in diameter, becomes accidentally attached to the surface of the anode. Under certain conditions this particle may become charged by positive ions from the surrounding ionized plasma, and a positive voltage built up. Since the distance between the particle and anode is infinitesimal, a high enough gradient may be established between particle and anode to draw electrons from the anode surface (one to ten million volts per centimeter). When the anode emits electrons, it becomes a cathode, and the rectifier is in arc-back. The chances of such particles or patches becoming charged sufficiently to create arc-back is a statistical study.

Engineering Approach to the Arc-Back Problem

Ever since the first commercial mercury-arc power rectifiers were installed, engineers have struggled with the arc-back problem. Constant research and developmental work have been and will continue to be conducted to minimize the occurrence. It has even been the subject discussed at several informal conferences under the sponsorship of the AIEE electronics committee at winter conventions.

Rating and Arc-Back Frequency

Much progress has been made. During the past 15 years, reliable rectifier ratings have been increased from 750 kw per vacuum system at the outset[4] until today there are many units in very successful operation supplying as high as 3,750 kw per vacuum system.

For d-c output voltages below 300 the arc-back problem has not been difficult. Absence of arc-backs has permitted the engineer to base the ratings on thermal limits of the rectifier element and associated transformer equipment.

However, at higher voltages, increases in rating have required progress in the art of reducing arc-backs. Usually, the rating is based on the level of load which the rectifier will carry with acceptable arc-back frequency rather than on the thermal limits of the apparatus.

Anode Shielding

One of the most powerful means available to engineers of reducing arc-back tendency is to increase the deionizing shielding which is placed near the anodes. The shielding may be increased by placing more deionizing surface in the arc stream below the anode, by reducing the area of the holes in the grid through which the arc passes, by changing spacing and configuration, by increasing arc length, or by multiplying the number of grids. It must be realized though that most of these measures also result in increasing the arc losses and lowering the efficiency.

In the modern rectifier a satisfactory compromise has been reached. Sufficient shielding has been provided to insure acceptable performance as regards arc-back frequency. On the other hand, it has not been increased to the point where it has endangered the attractive higher efficiency that the rectifier usually possesses, as compared to other types of conversion apparatus. Sufficient shielding to reduce arc-back near the vanishing point would likely sacrifice that margin of efficiency.

Reactance

Another factor, which bears on arc-back tendency, is the value of reactance in the transformer supplying the rectifier, and in the a-c system supplying the a-c power. Engineers have learned that a given rectifier may arc back frequently when connected to a transformer and a-c system having certain reactance characteristics, whereas, the same rectifier may be completely free from arc-back for other circuits and reactance characteristics, even though the d-c output voltages and loads are identical. Advantage is usually taken of this factor in the struggle to minimize arc back.

Paper 42-139, recommended by the AIEE committees on protective devices and industrial power application for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 20, 1942; made available for printing June 1, 1942.

J. W. Seaman and L. W. Morton are both with General Electric Company, Mr. Seaman as engineer in the air-circuit-breaker division in Philadelphia, Pa., and Mr. Morton as electrical engineer in Schenectady, N. Y.

Designing engineers, after having arrived at an economic balance between efficiency and shielding, have produced rectifiers which are relatively low in arc-back frequency. However, they know that they are unable to predict zero arc-backs. Therefore, they must depend upon protective equipment associated with the rectifier apparatus to eliminate the effect of arc-back, both on the electric equipment and on the continuity of service required.

Paths and Magnitudes of the Arc-Back Currents

In order to select protective equipment it is necessary to study the direction of current flow, its path through the various electric circuits, and the probable magnitudes involved. Figure 1 shows typical power circuits for two six-anode rectifiers operating in parallel on the same d-c bus, supplying a counter electromotive force load. Arrows indicate the direction of direct current in the various parts of the circuit when an arc-back occurs in one of the rectifying elements. Figure 2 indicates the behavior of current flowing in the important parts of the circuit shown in Figure 1 as they would be seen in an oscillograph. Steady-state values are typical of what would occur in many conventional rectifier installations if protective equipment were not provided. Current values shown are typical, being values measured oscillographically during representative tests on rectifiers rated 5,000 amperes 600 volts direct-current.

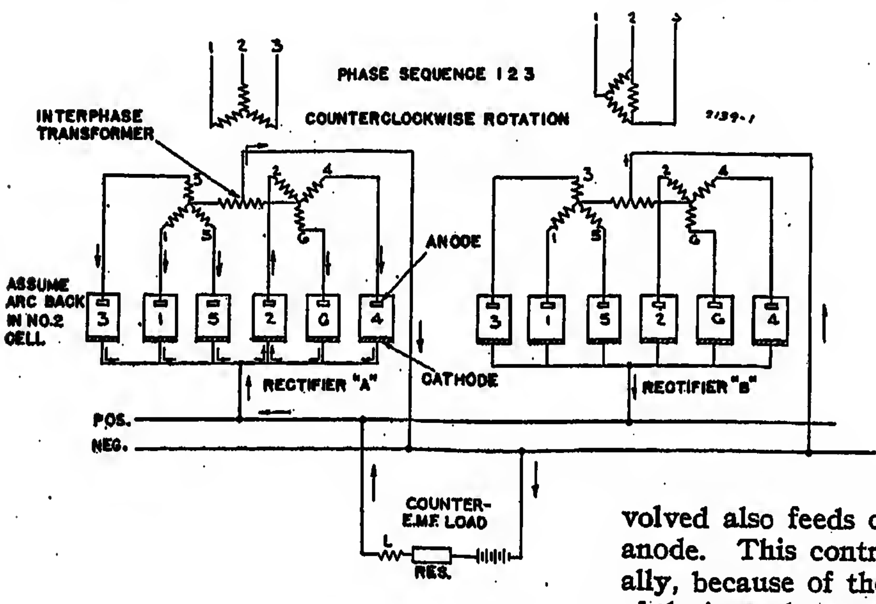

Figure 1. Direction of current in various parts of circuit when rectifier *A* arcs back

Accurate mathematical prediction of the current magnitude which would flow in a given circuit would be extremely difficult. The most important reasons for this are that reactance values in any transformer involved in an arc-back do not remain constant because of d-c saturation of the iron; and voltage drops in the arcs are not well known under the high current conditions obtaining. Usually such attempts give results in magnitude somewhat higher than test measurements. Therefore, studies of this sort are usually based on actual oscillographic tests. Certain general rules however, may be used to estimate the behavior of arc-back currents.

RULES FOR BEHAVIOR OF ARC-BACK CURRENTS

1. The reverse current flowing in the anode circuit of the rectifier element in arc-back consists of several components:

Contribution From Same Wye. The two other phases of the same transformer wye feed currents into the affected anode in turn as they commutate. Their magnitudes are limited by the commutating impedance of the rectifier circuit. This component is alternating or pulsating in character being displaced from the zero axis by action of the rectifier.

Contribution From Other Wye. The other wye of the rectifier transformer involved also feeds current into the affected anode. This contribution increases gradually, because of the initial high impedance of the interphase transformer. As the interphase transformer saturates due to undirectional current, its impedance decreases, and this contribution becomes greater. Its magnitude is determined by commutating impedance. This component is displaced from the zero axis by the action of the rectifying elements.

Contribution From Parallel Conversion Apparatus. Another component is fed from any parallel conversion apparatus such as other rectifiers connected in parallel to the same bus. This component is not pulsating being direct current in character. Its rate of rise is determined by the reactance due to air leakage fluxes throughout the circuit, both in the leakage spaces of the transformer windings conducting the reverse current and in the connections between the rectifiers. Final or steady-state magnitude of this component is limited only by the metal resistances of the station conductors in series, the resistance of one-half transformer secondary winding, the resistance of one-half the interphase winding, and the lumped or equivalent resistance of all contributing conversion apparatus in parallel.

Contribution From the D-C Load. If the nature of the d-c load is counter electromotive force, it too will feed current through the anode in arc-back. This component is d-c in character. Its rate of rise is determined by the air flux reactance of the circuits involved and its steady-state value by the total series metal resistance of the circuit.

2. All of these components add arithmetically to give the total reverse current at any instant carried by the anode in arc-back.

3. The effective voltage driving the short-circuit currents is reduced in proportion to the increase in arc drops caused by the higher currents passing through the arcs. Values for this increase in arc drop have been difficult to obtain, partly because of the transient and unpredictable nature of arc-backs and partly because of the instability of high-current arcs. Estimates of 50 to 100 volts are often used.

4. The effective driving voltage is reduced by a-c system regulation.

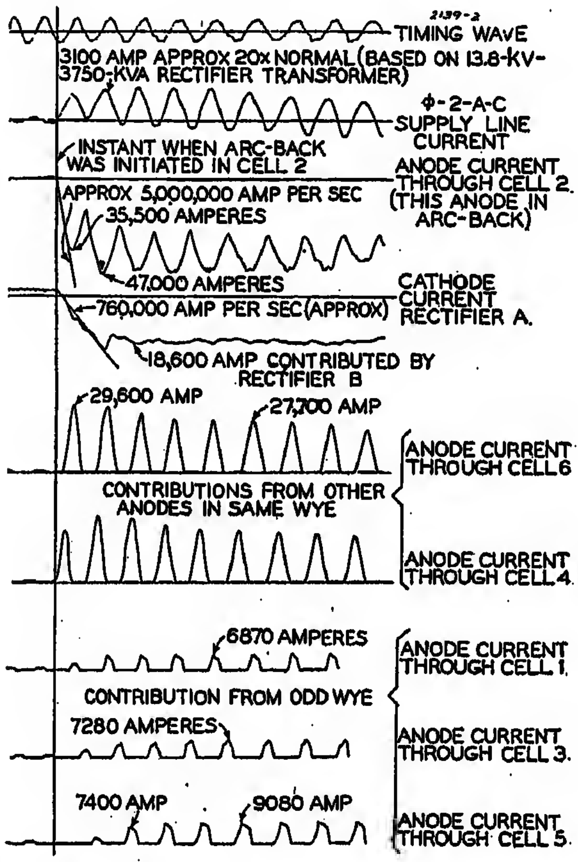

Figure 2. Behavior of current in various parts of circuit during arc-back

5. In practice it is found that the major contributions to the total reverse current are from the same wye and from parallel conversion equipment. The latter contribution is increased as the number and rating of paralleled conversion apparatus on the same d-c bus is raised. Such contribution theoretically reaches alarming proportions for many large electrochemical installations. It has been estimated that theoretical steady-state values of reverse current in an anode circuit might reach 600,000 amperes for certain large installations. (Anode reverse-current rates of rise for large installations have been measured and range as high as 10,000,000 amperes per second.)

6. Other anodes in the same rectifier unit or in other rectifiers on the same d-c bus are caused to arc back as a result of their high contributions to the first one in arc-back. It is doubtful if such theoretically possible high steady-state values as 600,000 amperes would be reached, and certainly they would not be maintained. Sympathetic arc-backs would always spread among the

associated rectifiers. End result would be that all rectifiers would become involved, and all contributions from parallel apparatus vanish.

7. Contributions from d-c loads usually are transitory. Rotating-type d-c loads come to a standstill quickly. Electrolytic loads are usually inductive, so that the current reversal is relatively slow, and rate of rise limited. Electrolytic-cell polarization voltages are usually only a fraction of the d-c applied voltage, and resistance drops are a large factor. Under short circuit such cells lose their polarity rapidly.

8. Current increases in the primary windings of the rectifier transformer corresponding (by transformer action) to the secondary currents. The values would be similar to those reached when all the secondary windings of such a transformer are short-circuited, except for the fact of the rectifying action and the higher-exciting currents due to d-c saturation in the iron. These factors increase the primary currents over the values that would obtain if all the transformer secondary windings were merely short-circuited.

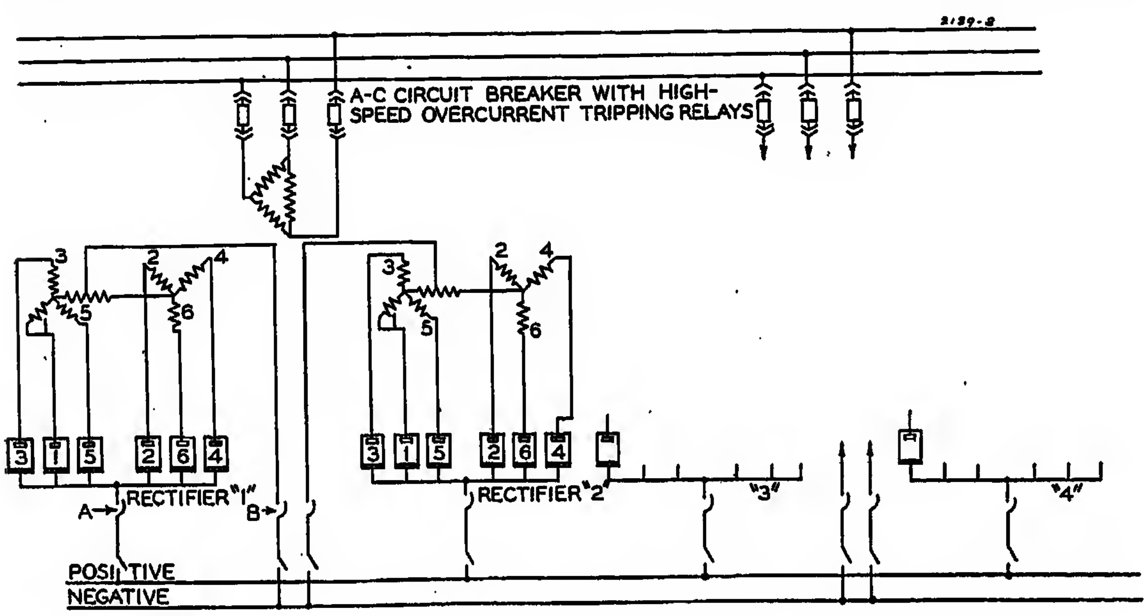

Figure 3. Cathode-switching arrangement of protective equipment

A—High-speed d-c circuit breaker with built-in reverse-current tripping action

B—Medium-speed d-c circuit breaker with time-delay overcurrent trip

Effect of Arc-Back Without Protection

The preceding analysis indicates that the high currents impose stresses on nearly all parts of the circuit. Various injurious results which could be expected if protective equipment were not provided may be listed as follows:

1. The a-c supply system may be overloaded. Increase in current supplied during arc-back often reaches 20 times the full-load current rating of the transformer.

2. The rectifier transformer would be damaged. Rectifier transformers are usually specially braced to withstand mechanical shocks due to arc-back. The duty caused by the high current in the windings connected to the anodes in arc-back would be particularly severe.

3. The rectifier element itself would be affected in several ways:

A. The higher currents would heat parts not previously degassed for such high currents and drive off gases which would impair the vacuum.

B. The high-current arcs would burn the metal walls of the vacuum chamber.

C. While the graphite anodes will withstand severe heating, continued presence of a cathode spot at the anode would remove material and roughen the surface.

4. Continuity of service would be interrupted, because other conversion apparatus on the same bus would be overloaded to the failure point.

Transients Which Signal Arc-Back

It is obvious that the sudden reverse and overcurrent conditions which appear in the circuits during arc-back offer ready means for signaling the event and actuating the protective equipment. A study of Figures 1 and 2 in the light of these requirements is worth-while. Current suddenly increases in the a-c supply lines and in all the anodes operating in normal forward-current fashion. However, these are symptoms of overload as well as arc-back. It is difficult by this means to distinguish arc-back from plain overload. If there is parallel conversion apparatus, a reliable indication of arc-back is the presence of reverse current in the cathode and negative connections. However, where a single rectifier feeds a purely resistance-type d-c load, no reversal occurs in these connections. The invariably present unmistakable evidence of arc-back is the presence of reverse current in the connection between the transformer secondary winding and the anode of the rectifier.

Four General Methods of Arc-Back Protection

Broadly there are four methods of protecting from arc-back. Three of these have been used in conventional large power installations.

Reactance

First is the use of large reactance values to limit the arc-back currents. Often if the resulting flow of current is limited to relatively low values by reactance, the condition causing the arc-back at the anode disappears, and normal rectifier action is automatically re-established. This can be true only where no other counter-electromotive-force apparatus is connected to the same d-c system. This method is sometimes used for such rectifier installations as those furnishing high-voltage d-c power to dust precipitators, oil-cracking processes, and laboratory apparatus.

Arc Suppression

Second is the so-called "arc-suppression" method. Arc suppression—in the case of multianode rectifiers—consists of grid action to prevent anodes from firing; in the case of ignitron rectifiers—it consists of ignitron action and grid action to prevent anodes from firing. Arc suppression does not have the ability to interrupt current passing from anode to cathode once it has been established.

"Arc suppression" accomplishes its purpose by preventing anodes—which would normally contribute current to the one in arc-back—from firing in turn as they become successively positive in voltage. In the case of a single rectifier, the anode reverse current consists entirely of contributions from other anodes, and it is possible quickly to starve the affected anode and eliminate the arc-back. It should be added that, if other conversion apparatus is connected to the same d-c bus, the current which they contribute must also be interrupted. One method is to interrupt the reverse current in the cathode line by means of a high-speed d-c circuit breaker. Another method, assuming all other conversion apparatus consists of rectifiers, is to apply "arc suppression" simultaneously to all other rectifier elements connected to the same bus during arc back.

"Arc suppression," by means of grids, is accomplished by suddenly energizing the grid with negative potential. With a negatively charged grid between the anode and cathode spot, electrons are repelled, and the anode is often effectively blanketed so that it cannot fire. In the ignitron, the anode is prevented from firing by suddenly cutting off the electric excitation of the igniter point which creates a new cathode spot each cycle. Without the existence or creation of the cath-

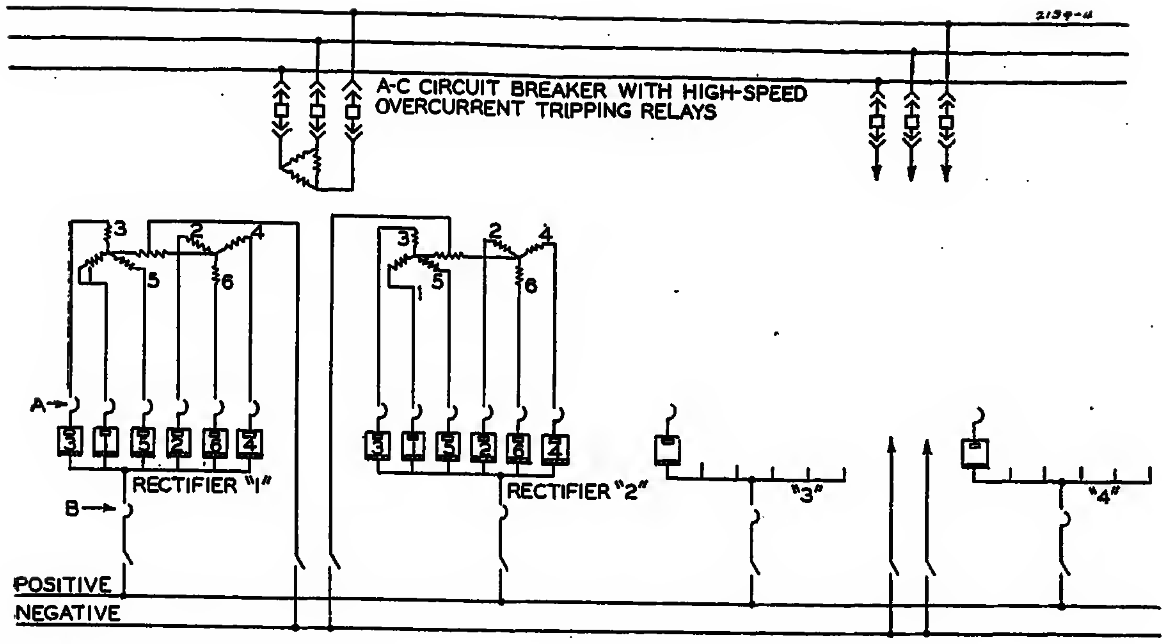

Figure 4. Anode-switching arrangement of protective equipment

A—High-speed multipole-anode circuit breakers with built-in reverse-current tripping action for each pole

B—Medium-speed d-c circuit breakers with time-delay overcurrent trips

ode spot in the mercury cathode pool, the anode should not fire.

Experience with "arc suppression," however, indicates that it is not always effective. Therefore, other backup protection in the form of protective switchgear is always provided to interrupt the overcurrents when "arc suppression" fails.

When it is successful, "arc suppression" is so rapid in action (one-half to two cycles) that it is not necessary for the a-c circuit breaker to open. The yardstick often used to measure the effectiveness of "arc suppression" is to record and compare the number of arc-backs accompanied by a-c breaker operations with those unaccompanied by a-c breaker operations. It is obvious that the relay or device which detects the presence of arc-back and actuates the "arc suppression" must be designed to operate in a small fraction of a cycle.

Experience indicates that "arc suppression" appears to be more successful in installations where reactance values are relatively high.

Cathode Switching

Third is the method most commonly employed until recently—that of disconnecting the rectifier and transformer from the system by means of circuit breakers. A typical arrangement is shown in Figure 3. In its best form it consists of an a-c circuit breaker with special high-speed induction-type a-c overcurrent relay protection, for each rectifier transformer, and a special high-speed reverse-current d-c air circuit breaker in the d-c side for each rectifier.

To illustrate the operation of the cathode-switching arrangement, assume an arc-back in cell 2 of rectifier 1—Figure 3. The following action takes place:

1. The d-c current reverses in the cathode line of rectifier 1. This action trips the reverse-current high-speed d-c breaker, which starts reducing the current in one-half to three-fourths cycle and interrupts the d-c circuit. Reverse current in the cathode line had been contributed by rectifiers 2, 3, and 4. This duty imposed overloads on these units and had started to operate the overcurrent tripping relays associated with the a-c circuit breaker supplying rectifiers 3 and 4 and all the negative d-c-line breakers. However, the high-speed action of the above reverse-current breaker usually should relieve the short circuit in time to prevent outages on 3 and 4, unless they too arc back sympathetically.

2. Even though the reverse-current contribution to cell 2 from the other parallel rectifiers is removed quickly by the high-speed cathode breaker, contributions from the other anodes in the same rectifier continue. Overcurrent relays associated with the a-c circuit breaker protecting the main transformer for rectifiers 1 and 2 therefore complete their operation, disconnecting the transformer and both rectifiers 1 and 2 from the a-c system.

3. Conventional a-c power-circuit breakers require a minimum of seven to ten cycles including relay time to interrupt an a-c short circuit. This means that the heavy duty imposed by the high arc-back current in both the rectifier element and the transformer winding continues throughout this time.

4. Two rectifiers connected to one transformer have been disconnected from service because of an arc-back in only one unit, as it was necessary to open the a-c power circuit breaker. Only rectifiers 3 and 4 remain in service.

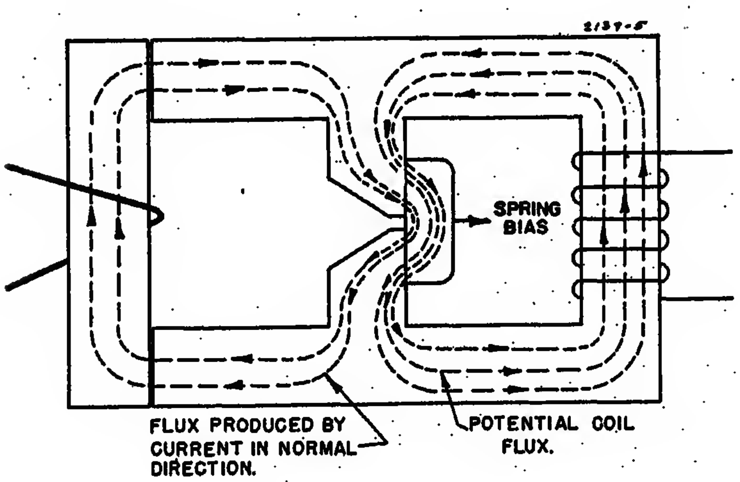
Anode Switching

Fourth is the latest method of dealing with the problem. A high-speed air circuit breaker in the anode line interrupts the fault current resulting from the arc-back.

Such an arrangement is shown in Figure 4. In its best form it consists of a power circuit breaker with standard inverse time a-c overcurrent relay protection for each transformer primary winding, a special high-speed multipole circuit breaker in the anode circuits with reverse-current tripping action, and a standard medium-speed d-c air circuit breaker in the cathode line for each rectifier. To illustrate the operation of anode switching and compare it with operation of cathode switching, assume an arc-back in cell 2 of rectifier 1, Figure 4. The following action takes place:

1. The d-c current reverses in anode line 2. This action trips pole 2 of the high-speed multipole-anode air circuit breaker, which starts to reduce the overcurrent in one-half cycle or less and interrupts the arc-back current in less than one cycle. Current contribution from rectifiers 2, 3, and 4, as well as the other anodes in the same rectifier unit, are all cut off. The common circuit path where they all add up and flow has been opened.

2. Since the short-circuit condition in the



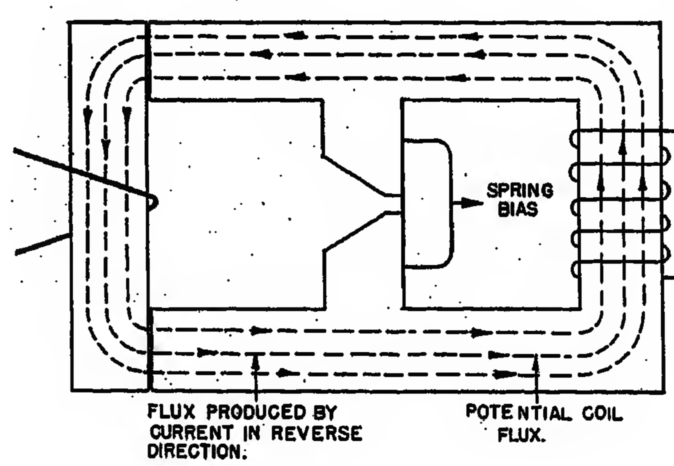


Figure 5. Magnetic circuit of high-speed trip mechanism, forward and reverse directions

transformer supplying rectifier 1 has disappeared in one cycle, its a-c overcurrent relay does not trip the main breaker. Therefore, the transformer remains energized, and rectifier 2 may remain in service.

3. High-speed action of pole 2 in interrupting the reverse current removed the overcurrent condition imposed on rectifiers 3 and 4 soon enough to prevent their outage.

4. Because the duration of short circuit does not last more than one cycle, only a small fraction of the same duty is imposed on both rectifier element and transformer winding of rectifier 1 as compared to the longer duty imposed with cathode switching when the overcurrent lasts 7–10 cycles.

5. The medium-speed cathode breaker can be interlocked with all poles of the anode breaker, so that the cathode breaker serving rectifier 1 would open, but without severe duty. Interlocking would be employed where it is inadvisable to allow a rectifier to remain in service without all anodes in operation.

Cathode switching for arc-back protection was adopted early in the history of rectifier application. It had wide acceptance, but "arc suppression" was later developed as recognition of some of the cathode-switching limitations, grew. Then when experience proved that "arc suppression" was not dependable under all conditions, and because wide use of rectifiers justified the effort, the high-speed anode switching was introduced. It now appears that the use of adequate high-speed anode breakers fulfills the requirements for arc-back protective equipment.

Part II. The High-Speed Air Circuit Breaker Developed

Basic Requirements

Before embarking upon the design of a new multipole high-speed breaker to satisfy the requirements of anode protection for mercury-arc rectifiers, a study was made to determine the prime requisites of this new breaker. These are as follows:

(*a*). The breaker should have a high opening speed. To clarify this it was determined that the breaker should start to reduce line current a half cycle or less (60-cycle basis) with maximum rates of current rise in the range of 2,000,000 to 6,000,000 amperes per second.

(*b*). Each pole of the breaker should be independently tripfree and be provided with a reverse-current tripping device, direct acting so that an arc-back on any anode would be removed independently of the other anodes.

1. A breaker should consist of six of such poles, closed simultaneously or individually.

(*c*). The breaker should remain closed on excessively high currents in the forward direction to insure that a rectifier not involved in an arc-back would remain in service.

(*d*). The proposed application required a breaker which could remain closed carrying load for long periods of time. It was therefore evident that existing switchgear standards should not be sacrificed in the interest of breaker opening speed.

There were other miscellaneous minor requirements attendant to the design of this new breaker, such as electrical closing, mounting, and so forth, which, while of interest to the designer, are not so pertinent to the discussion of this new high-speed breaker as the four preceding main requirements.

Design Problems

An analysis of the above requirements indicated that four major design problems were involved. These were as follows:

1. A high-speed current directional tripping mechanism.
2. A suitable breaker structure.
3. A current-interrupting device, compact in size, yet capable of coping with voltage in the order of 1,700 between phases.
4. A simple drive for operating a number of poles mechanically in parallel at a reasonably constant speed, regardless of the number of poles to be closed.

Trip Mechanism

The magnetic circuit of the tripping device selected is shown in Figure 5. The energy necessary for tripping the breaker on arc-back is stored in a compression spring restrained normally by the small armature. Flux provided by a potential coil normally holds the armature in the restrained position. A reversal of current caused by an arc-back quickly shifts the flux path of that portion normally holding the armature in the sealed position; therefore, upon current reversal the armature is released and allows the stored energy of the spring to dissipate itself in tripping the breaker latch. Figure 5 shows the flux path under normal operation and on arc-back. It will be noted that flux shifting is readily accomplished with this type of magnetic circuit.

The moving parts of the device were necessarily extremely light in order to reduce the effect of inertia and obtain a satisfactory operating time. The weight of these parts, excluding the spring, amounts to 2.4 ounces. The portion of the magnetic circuit in which the flux shifts, due to current reversal, was made of laminated silicon steel in order to facilitate the flux change. The magnetic circuit associated with the potential coil proper was made of solid iron and the iron surrounded with copper, so as to obtain a structure resistant to any sudden changes in applied voltage.

Since this device would be subjected to widely varying rates of current rise (in the order of 1,000,000 to 10,000,000 amperes per second), it was necessary to determine the effect of an extremely high rate of rise on its performance. It was conceivable that with an extremely high rate of rise of current in the tripping direction, the flux in armature would be reduced to zero and then built up in the opposite direction before the armature had moved sufficiently to be free of the influence of this flux. Such a condition would make the device inoperative and would prevent its functioning to trip the breaker. The level at which this would occur could be controlled by varying the inertia of the moving parts and by reducing the air gap of the poles bridged by the armature, the final air gap arrived at by test being in the order of $^{3}/_{32}$ inch.

A rather novel and interesting method was adopted to determine the effect of widely varying rates of current rise on the performance of the device. This consisted of testing the device in a low-voltage high-current a-c circuit. For a half cycle of current in the normal direction the tripping armature would not release, but on the following half cycle of current in the reverse direction this armature would release to trip the breaker. By simply changing the current magnitude, rates of current rise in the order of 23,000,000 amperes per second were readily obtainable, and the release mechanism was tested and operated satisfactorily at this rate of rise in a time of 0.002 second from current zero to point of release. A typical oscillogram of this performance is

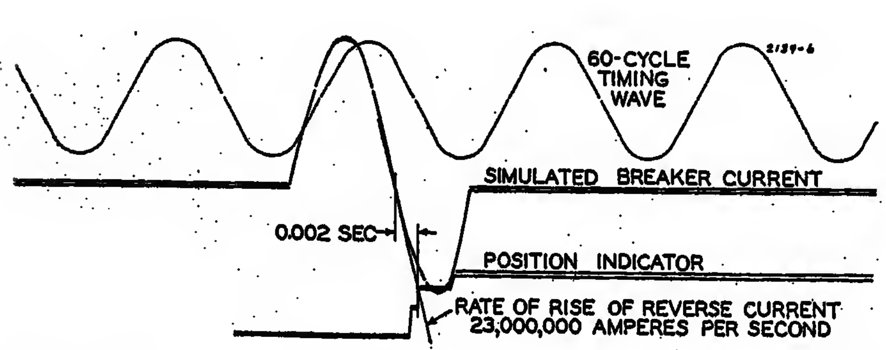

Figure 6. Typical oscillogram of low-voltage high-current a-c tests on high-speed trip mechanism

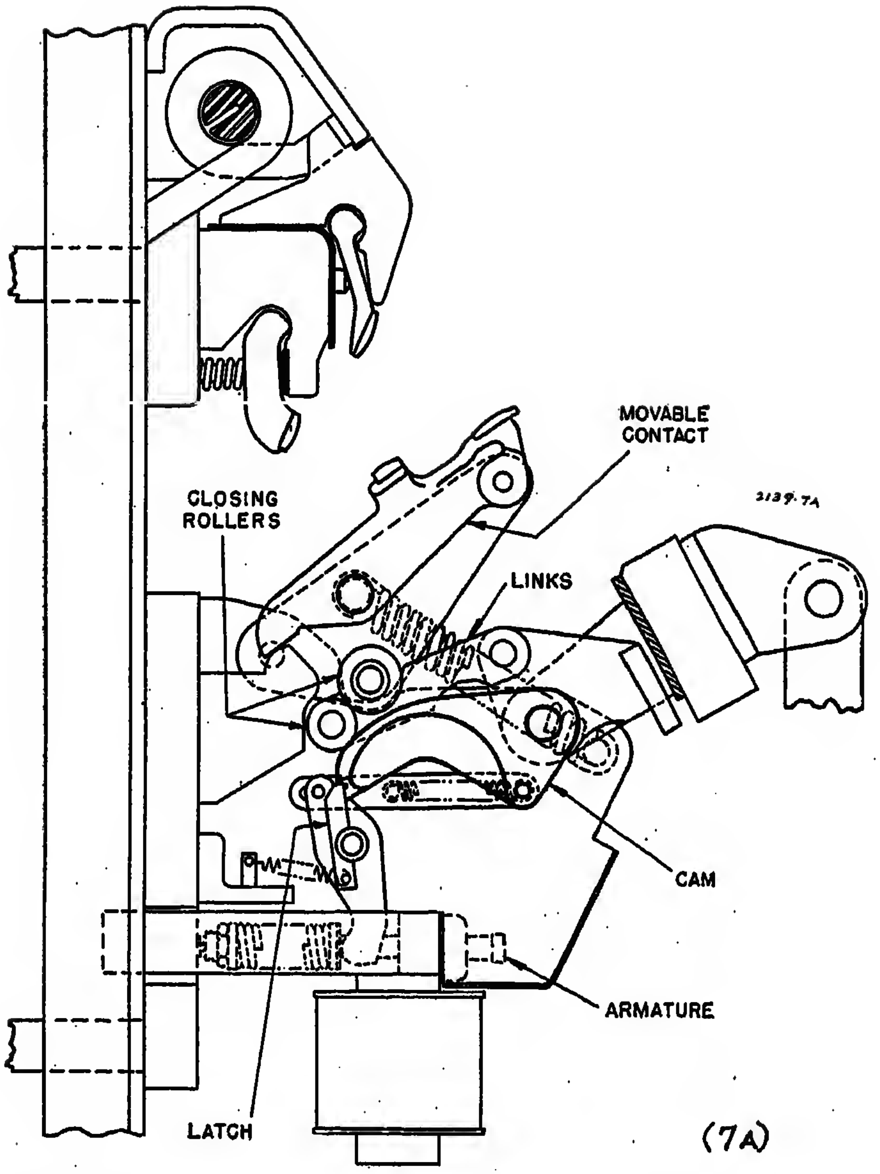

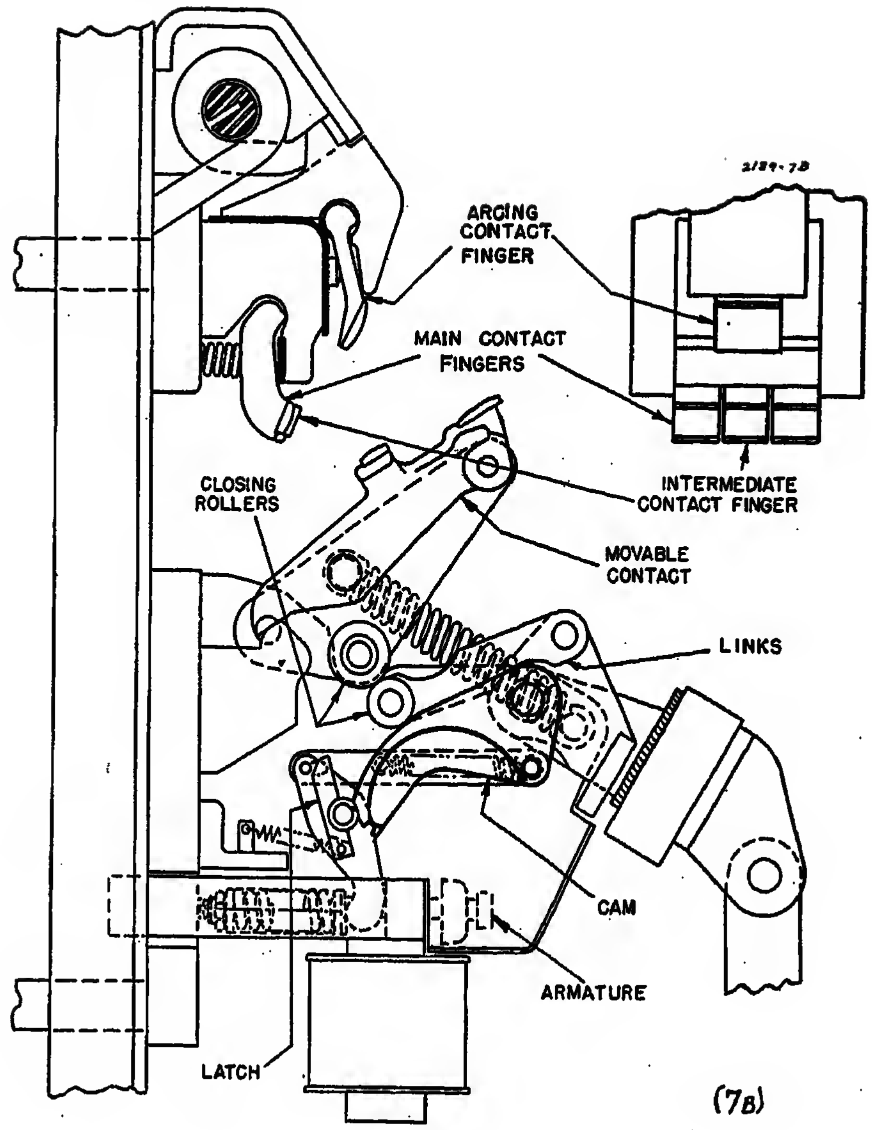

Figure 7A and B. Side views of breaker mechanism and contacts in open and collapsed positions

shown in Figure 6. Inasmuch as satisfactory performance was obtained at this rate of current rise, which is considerably above the rate of current rise obtainable in practice in d-c circuits, the design of the tripping mechanism was considered acceptable.

Breaker Structure

The tripping device just described was mounted on a breaker of conventional structure during the tests in the high-current circuit, both as a convenient method for testing the device itself, and also to observe the effects of high-speed operation on the mechanisms usually associated with more or less conventional circuit breakers.

As a result of these observations a novel breaker structure was evolved. Figure 7A illustrates the mechanism and contact arrangement designed for the application, with the mechanism reset ready to close. Positioned before the armature is a rotative latch normally supporting a cam-shaped member. The cam is so shaped that drawing a roller over its surface, by means of lever-actuated links, causes the movable contact to move to the fully closed position. Opening is equally simple to accomplish. Releasing the armature (Figure 7A) causes the latch to rotate from under the cam. The cam, closing rollers, and movable contact then collapse simultaneously. The opening speed is thereby dependent only on the applied opening force. Toggles with their hard-to-accelerate characteristics, under normal usage, are entirely eliminated. This mechanism represents a considerable departure from the usual toggle-activated circuit-breaker mechanism which does not lend itself so well to high-speed operation and is responsible to a considerable degree for the high-speed opening performance obtained with this new circuit breaker.

The contact arrangement designed for this high-speed breaker represents a considerable advance in the art of circuit-breaker design. Bearing in mind that it was considered desirable to design a breaker which would successfully withstand any tendency to blow open on currents of high magnitude in the forward or normal direction, it was decided to advantageously use the magnetic forces rather than to resort to brute force which would lead to a massive hard-to-accelerate structure. To this end the contacts were arranged so that the magnetic forces would add to the contact pressure rather than subtract from it.

Figure 8 shows that all points of contact are beneficially affected by the magnetic forces. The path of the current at the arcing contacts, main contact fingers, and at the lower end of the movable bridging contact is reversed sufficiently to "Magne-seal" then closed against currents of high magnitude and to gain equally from the accelerating effect of the magnetic forces when the restraint of the operating mechanism is removed.

Several other advantages accrued from this contact construction other than those listed above. A one-piece relatively light movable contact member was obtained which permitted the accomplishing of the high-speed operation objective. The pivoting of the lower end of this contact member on a fixed point on the lower stud permitted the eliminating of a heavy flexible connection which would otherwise have been mandatory. The difficulties experienced in designing adequate life into heavy braids capable of carrying currents in the order of 1,600 amperes with reasonable temperature limits and in overcoming their inherent resistance to angular movement are well known. The mounting of the arcing and main contacts on the upper stud resulted in light low-inertia parts which solved the problem of obtaining proper contact sequence between the primary and secondary circuits. Proper contact sequence is especially difficult to obtain with high-speed operation if the parts involved in the sequence are of relatively high inertia.

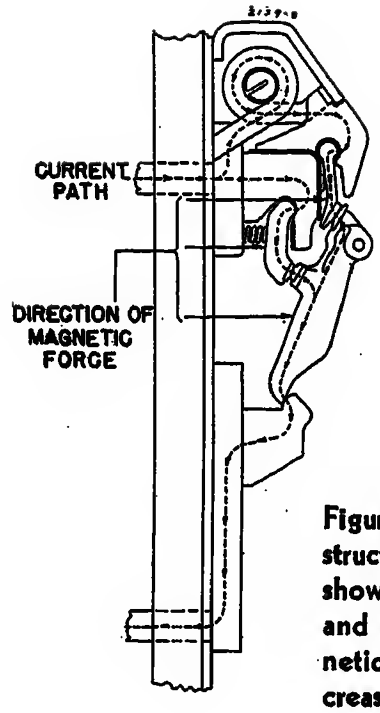

Figure 8. Contact structure closed showing current path and effect of magnetic forces to increase contact pressure

Three fingers were used for the stationary main contact. The middle finger was arranged to lead the other two slightly, so as to minimize burning on the other two fingers and to facilitate current transfer from the main to the arcing contact circuit. As a general result, a contact structure which is suitable for high-speed operation and which would satisfactorily meet existing switchgear standards as to temperature rise and reliability was obtained. Since electrochemical processes generally signify continuous full-current operation, this new contact structure for high-speed breakers provides a practical answer to continuity of service, by virtue of having both main and arcing contacts, generally considered necessary for continuous low-temperature-rise operation.

Current-Interrupting Device

The current-interrupting device designed for this breaker is extremely simple in construction and in operation. Figure 9 is a side view showing the component parts. The interrupting unit consists of a simple open-type arc chute and two blowout coils. One coil is in series with the arcing contacts on the upper stud of the breaker. Associated with this coil is an iron core and two pole pieces of conventional construction which act upon the arc terminus on the arc runner and the arc proper. The other coil is in series with arc runner located over the movable contact. This coil has only an iron core (no pole piece) which acts only on the arc terminus when it strikes the arc runner.

Successful operation is based entirely on rapidly increasing the length of the arc, therefore, the resistance, to the point where extinguishment takes place. Evidence of the effectiveness of this simple chute is shown in Figure 10. From current peak to zero is a smooth unbroken line

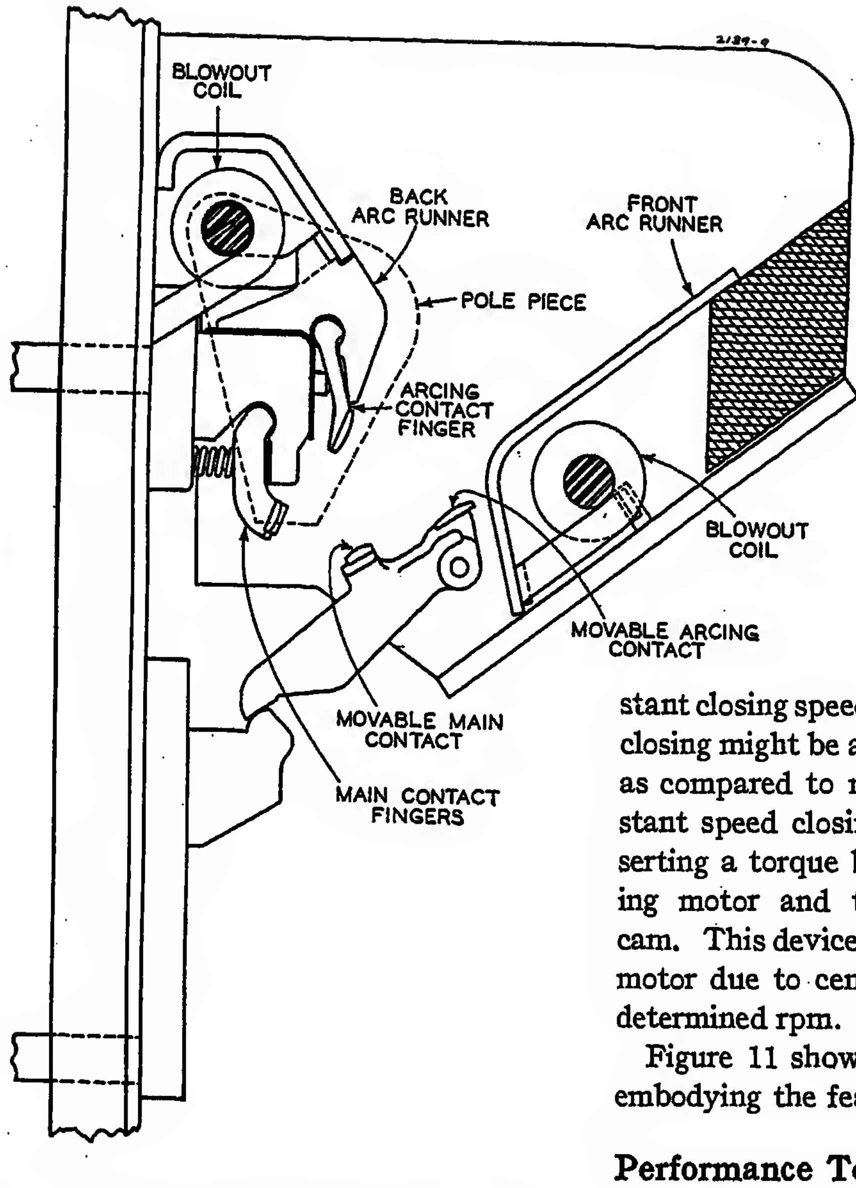

Figure 9. Side view of contacts (open) and arc chute, showing blowout coils

descending at a rapid rate, an excellent illustration of efficient current interruption. The advantage of this type of chute is that, having been designed for a specific voltage level, it has no current limitation. Any increase in current merely increases the magnetic forces which in turn speed interruption.

Closing Drive

Since rectifier anodes are operated in groups of six or multiples of six, it was decided that six individual breaker poles, each with its independent current directional trip, would be mounted on a common panel. A motor-driven closing mechanism was selected as the most suitable means for obtaining reliable closing performance. This mechanism consisted of a series motor suitable for either a-c or d-c operation, a torque brake, and a gear-driven closing cam. This complete unit was connected to a closing crossbar affixed to the closing lever of each individual pole. Operating the closing crossbar through 360 degrees of cam travel would cause any number of poles in the open position to be closed. This was particularly desirable since on arc-back with high-speed breaker operation, the arc-back is removed before all anodes feeding into the rectifier are caused to arc back. Since under this condition the closing load on the motor drive can vary widely, it was desirable to obtain a relatively constant closing speed. Otherwise single-pole closing might be accomplished too rapidly as compared to multipole closing. Constant speed closing was obtained by inserting a torque brake between the driving motor and the gear-driven closing cam. This device functioned to brake the motor due to centrifugal force at a predetermined rpm.

Figure 11 shows the completed design embodying the features just described.

Performance Tests on the High-Speed Anode Breaker

Factory Tests

During the progress of development of this new high-speed anode air circuit breaker, several representative short-circuit tests were made in the factory testing department. After the final design had been reached a complete six-pole model was built and tested in a rectifier circuit in the factory. Figure 12 indicates the test arrangements made and power circuits used.

Results of these tests were gratifying, but it was realized that the test conditions imposed might not be so severe as would be encountered in the field, especially for large electrochemical pot lines. The rectifier transformer used during these tests and the a-c system capacity were such that current contributions from other anodes in the same rectifier which fed into the anode in arc-back were as high as would be usually encountered in the field. However, it was impossible to duplicate d-c contributions from parallel rectifiers such as would be encountered in large electrochemical installations. Instead, an 1,800-kw 600-volt motor-generator set was connected to the same bus, but this unit lacked capacity for such large d-c contributions as were anticipated in the field. It also required its own high-speed breaker protection to prevent commutator damage, so that the duration of

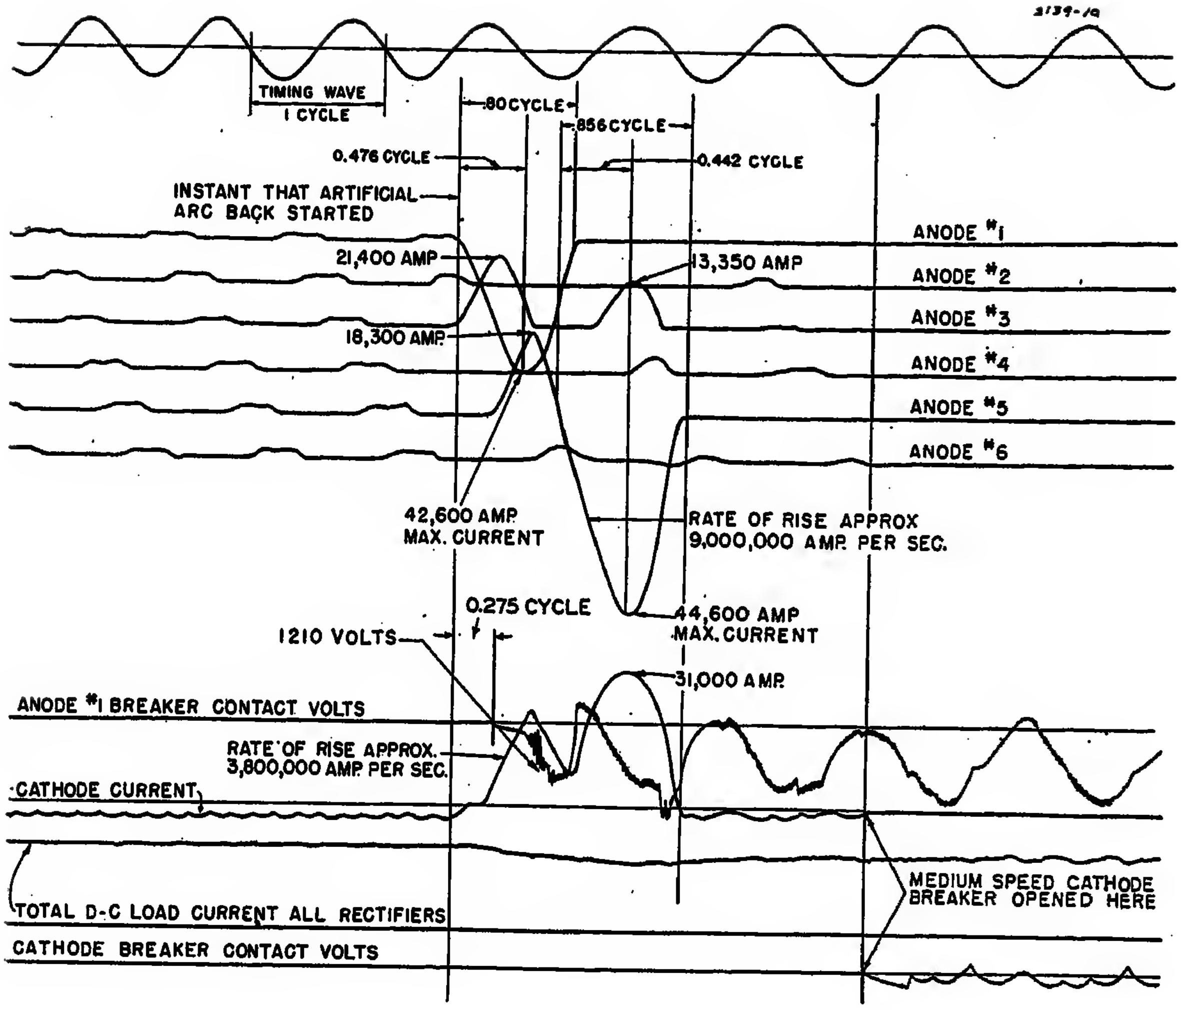

Figure 10. Typical oscillogram taken during field tests

its current contribution to the arc-back was limited.

Field Tests

Therefore, it was felt advisable to confirm final factory tests by making operating-speed and interrupting-capacity tests in a large rectifier installation. Arrangements were made for such tests. This rectifier installation consisted of eight 650-volt 2,600-kw rectifiers, supplied from four rectifier transformers, all connected to the same d-c bus. Short-circuit capacity at the 13.8-kv a-c supply bus was approximately 400,000 kva. D-c load during the test period averaged 20,800 kw on the eight rectifiers.

Figure 13 shows the one-line power-circuit diagram for the eight rectifiers and test arrangements for the rectifier and six-pole high-speed anode circuit breaker. Two six-element oscillographs were used to record current and voltage behavior in the various circuits simultaneously.

Since arc-backs cannot be produced at a predictable instant, it is necessary to simulate an arc-back by short-circuiting one rectifier element with a switch at the desired instant. Such a method imposes short-circuit currents which exceed the values reached under natural arc-back conditions, because they eliminate the effect of arc drop in the rectifier element in arc-back. Thus such test conditions are in error in the conservative direction. A large electrically operated power circuit breaker was used as the short-circuiting switch during the tests. No overcurrent tripping action was provided with this switch and so it remained closed until it was opened manually after each short-circuit test was conducted.

This particular installation had been made with the cathode switching-type arc-back protective equipment on all rectifiers. During the tests the regular high-speed cathode breaker remained in the open position at all times. A suitable 4,000-ampere medium-speed air circuit breaker with overcurrent tripping device was substituted instead.

Oscillographic Results

Figure 10 is a reproduction of an actual oscillogram obtained during the field tests. Several such oscillograms were taken, and this particular one is typical of the maximum fault conditions recorded.

Trace for anode 1 shows the current through the short-circuiting switch. It is apparent that the instant of switch closure occurred during the time of normal forward-current conduction for anode 1. Performance of pole 1 of the high-speed anode circuit breaker is clearly indicated on the oscillogram. Maximum current contributions come from anodes 1 and 5 and from the other paralleled rectifiers through the cathode line.

An interesting piece of incidental data obtained in this test is the record of the natural arc-back in anode 5. After its high forward-current contribution, it immediately went into arc-back as proved by the reversal of current. Performance

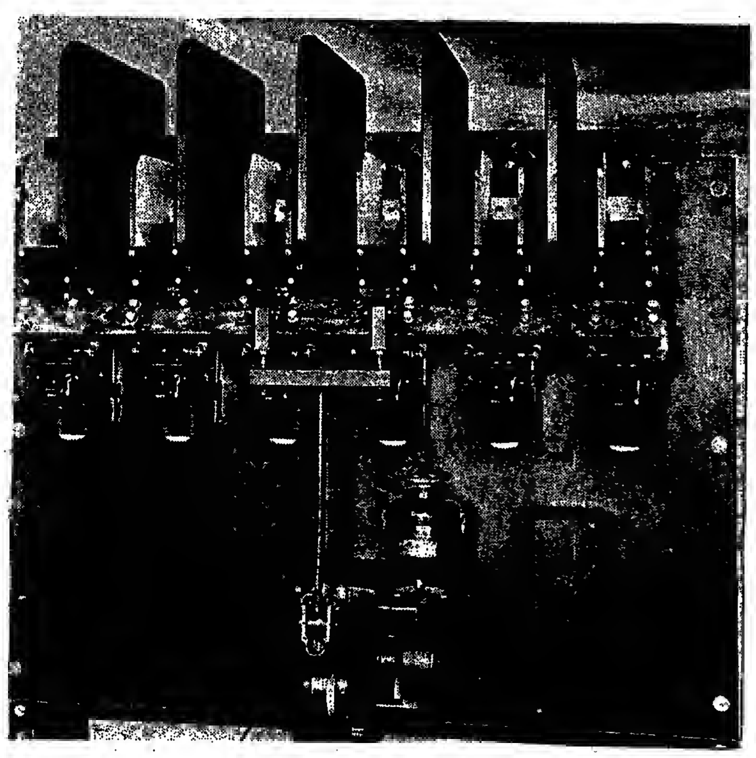

Figure 11 (left). The new high-speed breaker

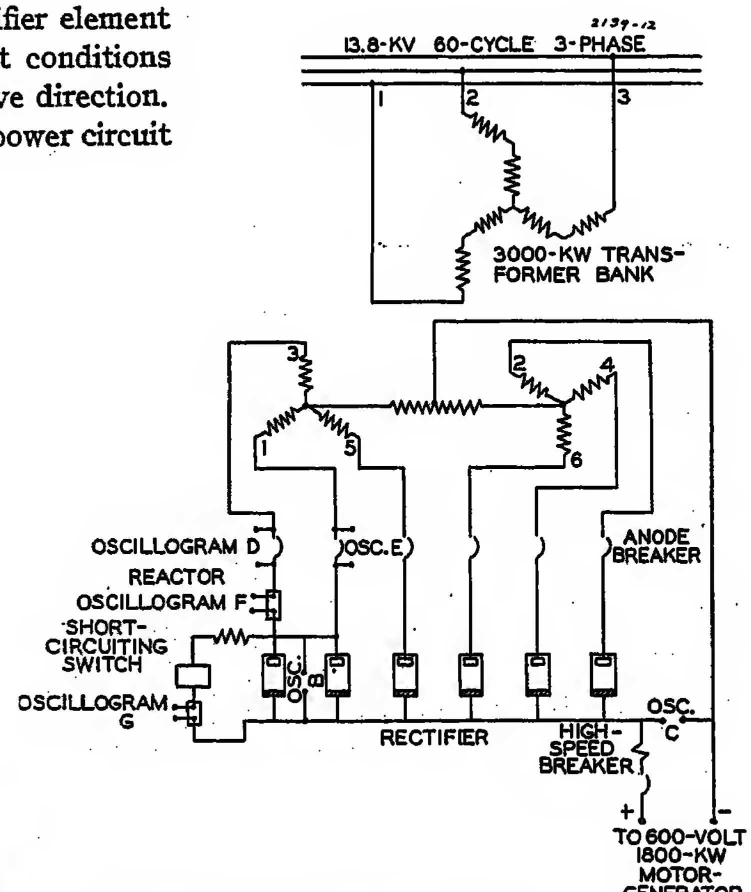

Figure 12. Factory-test circuit

of pole 5 is clearly indicated by the current trace for that anode.

Time required for contacts of pole 1 to part after current reversal was 0.275 cycle as measured by the trace of "anode 1 breaker contact volts." Current reduction as a result of arc quenching in the arc chute always started appreciably earlier than one-half cycle, according to the oscillograms taken during each test. The values of 0.476 cycle and 0.442 cycle illustrated in Figure 10 were typical.

Study of the cathode-current behavior shows that the individual poles each contributed interrupting effort, not only to that of the currents from the other anodes, but also to those from other rectifiers as well. In fact, pole 5 successfully interrupted all contributions. This is proved,

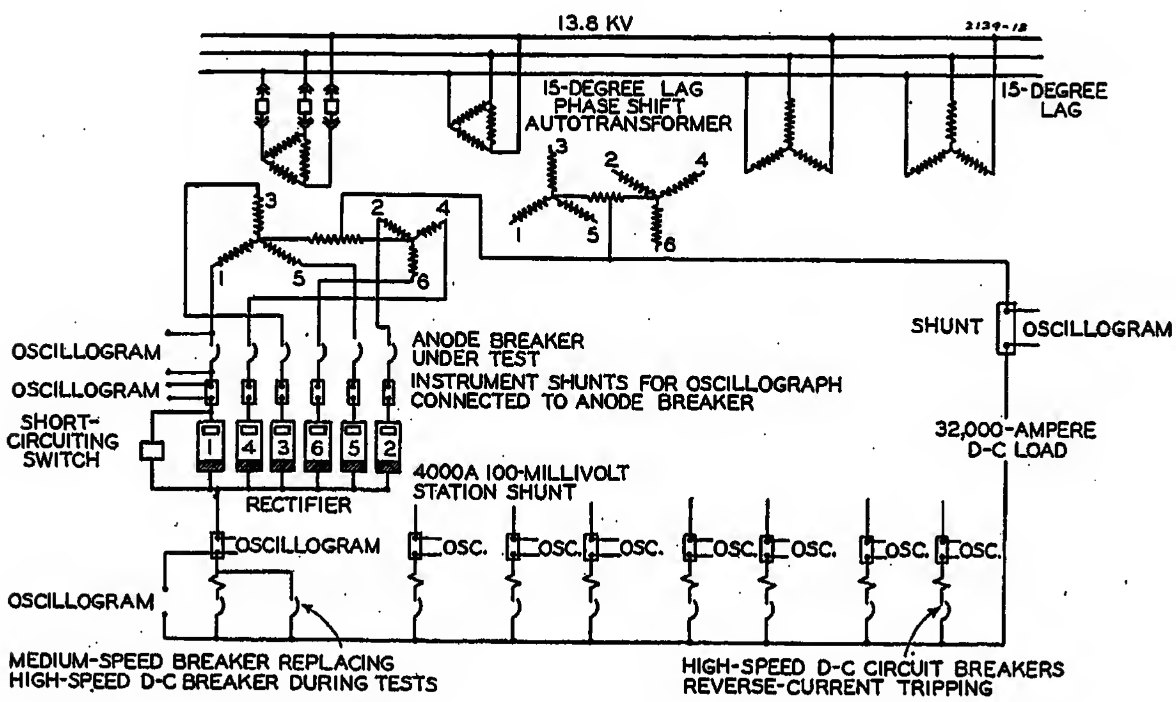

Figure 13. Field-test circuit

because the traces for anodes 2, 3, 4, and 6 show normal forward-current rectifier operation lasting approximately $1^1/_4$ cycles after the last reverse current has been interrupted by pole 5.

Traces of anode current for anodes 2, 3, 4, and 6 cathode current, and medium-speed cathode-breaker volts indicate that regular rectifier operation may have continued without distress on the remaining four anodes, had service not been interrupted by the operation of the cathode breaker. This circuit breaker interrupted less than normal full-load current when it opened $2^1/_2$ cycles after the event.

None of the several short-circuit tests conducted caused arc-back in any of the other rectifiers connected to the same d-c bus. Evidence of continuity of service is indicated by the trace of the "Total D-C Load Current All Rectifiers" in Figure 10. During these tests there were no a-c power circuit-breaker operations for the main rectifier transformer included in the test circuit. The companion rectifier connected to the same rectifier transformer always remained in service.

Surge-voltage recording instruments were connected across the interphase transformer and anode to neutral low-voltage main-transformer windings to detect any evidence of surge voltages which might result from the high-speed breaker action. No evidence of surging was recorded.

Oscillographic tests were conducted to determine the time required to interrupt normal load on the rectifier when tripping all six poles by means of removing polarizing coil voltage. Approximately $1^1/_8$ cycles were required after the switch in the polarizing circuit was opened.

Condition of Anode Circuit Breaker After Tests

A total of six tests were made in the field using the circuit shown in Figure 13. In addition to obtaining satisfactory high-speed operation, the results were particularly gratifying, in view of the condition of the breaker after the completion of the tests. The contacts were in excellent condition and justified the adoption of this arrangement for commercial use. No parts would have required replacement to continue in service. The condition of the breaker after tests and the high-speed performance obtained during tests clearly indicated that a new and useful tool had been provided to cope with mercury-arc rectifier arc-backs.

Conclusion

The advantages obtained by using such high-speed anode breakers include:

1. Shock to the transformer is reduced.
2. Shock to the rectifier is reduced.
3. Maintenance on a-c power circuit breaker is reduced, because it no longer is required to interrupt the high currents due to arc-back.
4. The vacuum in the rectifier is not so adversely affected when the arc-back is limited to one cycle or less, as compared with the longer time for a-c power-breaker operation. This means any rectifier which arcs back can be returned to service at once, whereas time out for pumping is often necessary with cathode-switching protection.
5. When two rectifiers are connected to the same transformer, only the one which arcs back is subjected to outage. The other remains in service. This has a most important bearing on improved continuity of service in many cases.
6. Likelihood of simultaneous arc-backs or spread of arc-backs to other parallel rectifiers is minimized. The reason is that the short circuit on the d-c bus is removed in one cycle or less. Again continuity of service is improved.
7. The anode breakers are useful disconnecting devices when two rectifiers are fed from a single transformer. They lend themselves to the isolating of one rectifier for maintenance or repair work without interrupting operation on the other rectifier.
8. High overcurrent duty is confined to one device for the anode-switching arrangement, whereas with cathode switching both cathode switch and a-c power circuit breaker open under high duty requirements. Maintenance is thus reduced.
9. Since each pole of the six-pole anode breaker opens independently of the other poles, and each pole is equipped with an operation counter, a record is provided of the anode arc-backs. This often is advantageous in locating and correcting arc-back trouble.

Field Harmonics in Induction Motors

M. M. LIWSCHITZ
MEMBER AIEE

I. Introduction

About 40 papers have been written on the asynchronous torques, synchronous cusps at running, synchronous cusps at standstill (dead points), and noise of the induction motor. The subject has been also treated in some textbooks.* My aim is to give a coherent representation of the harmonic problem in induction motors. It is based on the work of my predecessors, on my own work, and on my experience.

It is intended to give not only a physical explanation of the phenomena but also to determine them quantitatively, that is, to determine the magnitudes of the different forces which produce the noise as well as of the different torques which influence the torque-speed curve. An exact knowledge of the currents produced by the field harmonics in the rotor is necessary for solving this problem. Since the magnitude of the harmonic currents in the rotor depends on the rotor leakage, a special study of the leakage of the single harmonics will be necessary. Of great influence is here the differential leakage; its amount increases with the order of the harmonic and therefore becomes important for the slot harmonics.

Thus a complete representation of the harmonic problem in induction motors involves the following topics:

1. The harmonics of the stator, their amplitudes, and their speed with regard to the stator and rotor.
2. The harmonics of the rotor, their amplitudes, and their speed with regard to the stator and rotor.
3. The force waves produced by the harmonics and their frequencies.
4. The resistance and reactance of the rotor with regard to the different harmonics.
5. The rotor currents produced by the different harmonics.
6. The forces produced by the harmonics.
7. The asynchronous torques.
8. The synchronous torques during running and at standstill.
9. Means to avoid the noise and the parasitic torques.

It is intended to divide the representation in three parts. This paper contains the topics 1, 2, and 3, that is, it treats the noise problem qualitatively. The magnitude of the forces that produce the noise will be determined in the third part, when the resistance and reactance of the rotor with regard to the different harmonics have been discussed in the second part.

II. The Stator and Rotor Harmonics

Since not only the windings with an integral number of slots per pole per phase are considered, but the windings with a fractional number of slots as well, it becomes expedient to take as the "fundamental" harmonic the wave, the length of which is equal to the circumference of the stator bore. The synchronous wave will be then the harmonic of the order $n' = p$; this is the "main" or "synchronous" harmonic. If in the case when the number of slots per pole per phase is an integer, it is desirable to use the main harmonic as the fundamental, the ratio $n = n'/p$ is valid; n is then the order of the harmonic with regard to the synchronous wave.

As shown in appendix 1, the order as well as the direction of rotation of the stator harmonics is defined by the two equations

$$\left(\frac{n'}{p}+1\right)\frac{\beta}{2}=k \tag{1}$$

$$\left(\frac{n'}{p}\mp 1\right)\frac{\beta}{2m_1}=k_1 \tag{2}$$

where k is an integer excluding 0, k_1 an integer including 0. When the minus sign in equation 2 is used, n' travels with the synchronous harmonic; when the plus sign in equation 2 is used, n' travels opposite to the synchronous harmonic.

When the number of slots per pole per phase q_1 is an integer, β has to be set in equations 1 and 2 equal to 2, whence

$$n'=(k_1m_1+1)P \tag{3}$$

or

$$n=k_1m_1+1 \tag{4}$$

where k_1 is any positive or negative integer including 0. When q_1 is an integer, and the winding is a symmetrical three-phase 60-degree phase belt winding, k_1 is a positive or negative even integer including 0. When n' is positive, the harmonic travels with the synchronous harmonic; when n' is negative, the harmonic travels opposite to the synchronous harmonic.

In appendix 1, it is further shown that the n' harmonic of the stator produces the following rotor harmonics

$$m'=k_2Q_2+n' \text{ for the squirrel-cage rotor} \tag{5}$$

$$m'=k_2pm_2+n' \text{ for the wound rotor with } q_2 \text{ an integer} \tag{6}$$

where k_2 is a positive as well as a negative integer including 0. For positive values of the slip s_n' the harmonic m' travels with the rotor when m' is positive, opposite to the rotor when m' is negative.

The stator slot harmonics are given by the equation

$$n_{s1}'=\pm Q_1+p \tag{7}$$

and the rotor slot harmonics by the equation

$$m_{s1}'=\pm Q_2+p \tag{8}$$

It follows from equations 5, 6, and 8 that the rotor slot harmonics are produced by the main (synchronous) wave of the stator, and that $k_2 = \pm 1$ corresponds to the slot harmonics of the squirrel-cage rotor, while a large k_2 corresponds to the slot harmonics of the wound rotor.

Equation 6 assumes that the number of slots per pole per phase q_2 of the rotor is an integer. If q_2 is a fractional number, $k_2\frac{2}{\beta_2}pm_2$ has to be inserted in equation 6 instead of k_2pm_2 (corresponding to equation 34, appendix 1). This is valid also for the formulas derived from equation 6 in the following.

In appendix 2 formulas are given for the harmonics of the magnetomotive forces of the stator and rotor which take into account their speed relative to the stator as well as to the rotor. Since the noise problem only is considered here, the magnetomotive forces with regard to the stator are of importance.

The magnetomotive force of the n'th stator harmonic is

$$b_{n'}=B_{n'}\sin\left(\omega t-n'\frac{\pi}{p\tau}x_1\right) \tag{9}$$

and the magnetomotive force of the m'th rotor harmonic

$$b_{m'}=B_{m'}\sin\left[\left(1+\frac{m'-n'}{p}(1-s)\right)\times \omega t-m'\frac{\pi}{p\tau}x_1\right] \tag{10}$$

Paper 42-100, recommended by the AIEE committee on electrical machinery for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 6, 1942; made available for printing May 12, 1942.

M. M. Liwschitz is with The Polytechnic Institute of Brooklyn, Brooklyn, N. Y., and is also consulting engineer for Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

* The fundamental paper on the influence of harmonics in the squirrel cage rotor has been published by L. Dreyfus.[18] The most detailed representation is given in the textbook of R. Richter, Elektrische Maschinen.[10]

The rotor harmonic m' is produced by the stator harmonic n'; therefore, corresponding to the equations 5 and 6

$$b_{m'}=B_{m'}\ \sin\left[\left(1+\frac{k_2Q_2}{p}(1-s)\right)\times \omega t-m'\frac{\pi}{p\tau}x_1\right] \text{for the squirrel-cage rotor} \quad (10a)$$

$$b_{m'}=B_{m'}\ \sin\left[(1+k_2m_2(1-s))\omega t-m'\frac{\pi}{p\tau}x_1\right] \text{for the wound rotor} \quad (10b)$$

The values of $B_{n'}$ and $B_{m'}$ are given in appendix 2.

III. The Force Waves and Their Frequencies

The driving force of the machine is a tangential force produced by the main flux wave and the main magnetomotive force wave. The flux harmonics and the harmonics of the magnetomotive force produce parasitic tangential forces which contribute to the noise. However, the main source of noise is the group of radial forces produced by the flux harmonics. The radial force that corresponds to the induction b in the gap is

$f_r=1.385b^2\times10^{-8}$ pounds per square inch

b consists of all stator and rotor harmonics. Hence b^2 is the sum of the squares of all stator and rotor harmonics plus twice the product of each stator harmonic with each other stator harmonic, of each rotor harmonic with each other rotor harmonic and of each stator harmonic with each rotor harmonic. We write in general form

$f_r \equiv b_{\gamma'}b_{\mu'}$

We can use this formula for all five components of b^2 making γ' and μ' equal to the values of n' and m' in consideration. It is in general

$$b_{\gamma'}=B_{\gamma'}\ \sin\left(\omega_{\gamma'}t-\gamma'\frac{\pi}{p\tau}x_1\right)$$

$$b_{\mu'}=B_{\mu'}\ \sin\left(\omega_{\mu'}t-\mu'\frac{\pi}{p\tau}x_1\right)$$

so that

$$f_r\equiv b_{\gamma'}\ b_{\mu'}\equiv\frac{1}{2}B'B_{\mu'}\times \cos\left[(\omega_{\gamma'}-\omega_{\mu'})t-(\gamma'-\mu')\frac{\pi}{p\tau}x_1\right]-\frac{1}{2}B_{\gamma'}B_{\mu'}\cos\left[(\omega_{\gamma'}+\omega_{\mu}')t-(\gamma'+\mu')\frac{\pi}{p\tau}x_1\right] \quad (11)$$

Thus the radial force f_r consists of two force waves, one having $\gamma'-\mu'$ force pole pairs and the frequency $\omega_{\gamma'}-\omega_{\mu}$ the other having $\gamma'+\mu'$ force pole pairs and the frequency $\omega_{\gamma'}+\omega_{\mu'}$. We designate the number of force pole pairs by k. $k=0$ is a stationary pulsating force, $k=1$ is a force wave with two poles, $k=2$ is a force wave with four poles, and so on. The larger the value of k, the shorter is the wave length. The stator is, in general, stiffer to short wave distortion (k large) than to large wave distortion (k small). Yet, depending on the construction of the machine, the small wave distortion may be dangerous as well.

We consider now the different components of b^2.

(*a*). *Stator harmonics only.* In equation 11 we have to insert $\gamma'=n_a'$, $\mu'=n_b'$

It follows further from equation 9

$\omega_{\gamma'}=\omega_{\mu'}=\omega=2\pi f_1$

Thus

$$k=n_a'+n_b' \qquad f_+=2f_1$$
$$k=n_a'-n_b' \qquad f_-=0 \quad (12)$$

f_+ is the frequency of the force wave, when the sum of n_a' and n_b' is taken; f_- is the frequency of the force wave, when the difference of n_a' and n_b' is taken. n_a' and n_b' can be positive as well as negative.

When a single stator wave is considered, then $n_b'=n_a'$ and

$$k=2n_a' \qquad f_+=2f_1 \quad (12a)$$

Thus the force waves produced by the stator harmonics have double the line frequency. Also the main harmonic produces a force wave of double the line frequency.

The consideration of the case $k=1$, which must be avoided, we limit for the sake of clearness to integral values of q_1, since fractional numbers of q_1 are not often used in induction motors. $k=1$ means

$n_a'+n_b'=\pm1$ or $n_a'-n_b'=\pm1$

With equation 3 this gives

$$n_a'+n_b'=[(k_{1a}+k_{1b})m_1+2]p=\pm1$$
$$n_a'-n_b'=(k_{1a}-k_{1b})m_1p=\pm1$$

Since k is a positive or a negative integer including 0, the case $n_a'+n_b'=\pm1$ cannot occur. $n_a'-n_b'=\pm1$ is possible only when $p=1$, $m_1=1$ and k_{1a} or k_{1b} is an odd number, that is, when the magnetomotive force contains even harmonics.

(*b*). *Rotor harmonics only.* In this case $\gamma=m_a'$, $\mu=m_b'$. It follows further from equation 10

$$b_{m_a'}=B_{m_ba'}\ \sin\left[\left(1+\frac{m_a'-n_a'}{p}(1-s)\right)\times \omega t-m_a'\frac{\pi}{p\tau}x_1\right]$$

$$b_{m_b'}=B_{m_b'}\ \sin\left[\left(1+\frac{m_b'-n_b'}{p}(1-s)\right)\times \omega t-m_b'\frac{\pi}{p\tau}x_1\right]$$

Inserting here equation 6, we find for the wound rotor with q_2 integral

$$k=m_a'+m_b' \qquad f_+=[2+(k_{2a}+k_{2b})\times m_2(1-s)]f_1 \quad (13)$$
$$k=m_a'-m_b' \qquad f_-=[(k_{2a}-k_{2b})m_2(1-s)]f_1$$

and inserting equation 5, we find for the squirrel-cage rotor

$$k=m_a'+m_b' \qquad f_+=\left[2+(k_{2a}+k_{2b})\frac{Q_2}{p}(1-s)\right]f_1$$
$$k=m_a'-m_b' \qquad f_-=\left[(k_{2a}-k_{2b})\frac{Q_2}{p}(1-s)\right]f_1 \quad (14)$$

m_a', m_b', k_{2a}, and k_{2b} in equations 13 and 14 can be positive as well as negative.

For the case of the squirrel-cage motor as shown in appendix 2, the value of $B_{m'}$ becomes smaller, the larger the value of k_2. $k_2=\pm1$ gives the largest amplitude for the rotor harmonic. Considering this case, that is,

$k_{2a}=\pm1 \quad k_{2b}=\pm1$

we find for the squirrel-cage rotor

$$f_+=\left[1\pm\frac{Q_2}{p}(1-s)\right]2f_1$$
$$f_-=0 \quad (13a)$$

when k_{2a} and k_{2b} have the same sign and

$$f_+=2f_1$$
$$f_-=\frac{Q_2}{p}(1-s)2f_1 \quad (13b)$$

when k_{2a} and k_{2b} have different signs.

When a single harmonic is considered, then $m_a'=m_b'$; $k_{2a}=k_{2b}=k_2$

$$k=2\mu_a' \qquad f=\left[1+k_2\frac{Q_2}{p}(1-s)\right]2f_1 \quad (13c)$$

m_2 instead of Q_2/p is to be inserted in this equation for the wound rotor.

If we limit again the consideration of the case $k=1$ to q_1 integral there will be

$m_a'+m_b'=\pm1$

or

$m_a'-m_b'=\pm1$

With equations 3 and 5, this gives for the squirrel-cage rotor

$$m_a'+m_b'=\pm1=(k_{2a}+k_{2b})Q_2+[(k_{1a}+k_{1b})m_1+2]p$$

k_{2a} and k_{2b} are positive or negative integers including 0. In the usual case of a 60-degree-phase-belt winding, k_{1a} and k_{1b} are even integers including 0. Only the 120-degree-phase-belt winding, (two speed motors) may have even values as well as odd values of k_1. In order that $m_a'+m_b'=\pm 1$, the equation must be satisfied.

$$(k_{2a}+k_{2b})Q_2=-(k_{1a}+k_{1b})m_1p-2p\mp 1$$

With k_{1a} and k_{1b} even integers, this is possible only when Q_2 is an odd number. For $m_a'-m_b'=\pm 1$ it follows that

$$m_a'-m_b'=\pm 1=(k_{2a}-k_{2b})Q_2+(k_{1a}-k_{1b})m_1p$$

or

$$(k_{2a}-k_{2b})Q_2=(k_{1a}-k_{1b})m_1p\mp 1$$

With k_{1a} and k_{1b} even integers this equation can be satisfied when Q_2 is an odd number. Thus the rotor harmonics produce $k=1$ (two-pole force waves) when Q_2 is an odd number. When the stator winding produces even harmonics (120-degree-phase-belt winding) also an even Q_2 may produce $k=1$. The wound rotor has usually q_2=integer and Q_2 an even number. In the case q_2=fractional number, the equation 3 and equation 34, appendix 1, have to be used in order to find whether or not $k=1$ is possible.

The value $\dfrac{Qn}{60}=\dfrac{Qf}{p}$ is the slot frequency. It follows from equations 13*a* and 13*b* that the frequency of the noise which the rotor harmonics produce is approximately equal to double the slot frequency or to double the line frequency. Seldom another frequency corresponding to equation 13 may occur.

(*c*). *Products of stator and rotor harmonics.* Here

$$\gamma'=n_b' \qquad \mu'=m_a'$$

m_a' is produced by the stator harmonic n_a'. From equations 9 and 10 we get for the squirrel-cage rotor

$$\left.\begin{aligned} k&=n_b'+m_a' \quad f_+=\left[2+K_{2a}\frac{Q_2}{p}(1-s)\right]f_1 \\ k&=n_b'-m_a' \quad f_-=\left[K_{2a}\frac{Q_2}{p}(1-s)\right]f_1 \end{aligned}\right\} \qquad (15)$$

In this equation m_2 is to be substituted for $\dfrac{Q_2}{p}$ for the wound rotor with q_2 equal to an integer.

It follows from equation 15 that the frequency of the force waves produced by stator harmonics in co-operation with rotor harmonics does not depend on the order of the stator harmonic; it depends on the factor k_2 and also on the number of rotor phases, if the rotor is a wound rotor, or on the number of rotor slots, if the rotor is of squirrel-cage type.

When $k_{2a}=0$, m_a' is equal to n_a' and there will be

$$\left.\begin{aligned} k&=n_b'+m_a' \quad f_+=2f_1 \\ k&=n_b'-m_a' \quad f_-=0 \end{aligned}\right\} \qquad (15a)$$

For the rotor slot harmonics of the squirrel cage, $k_{2a}=\pm 1$. Thus, when the rotor slot harmonics are involved, the frequencies of the force waves of the squirrel-cage rotor are

$$\left.\begin{aligned} k&=n_b'+m_a' \quad f_+=\left[2\pm\frac{Q_2}{p}(1-s)\right]f_1 \\ k&=n_b'-m_a' \quad f_-=\pm\frac{Q_2}{p}(1-s)f_1 \end{aligned}\right\} \qquad (15b)$$

It follows from equations 7 and 8 for the co-operation of the stator slot harmonics with the rotor slot harmonics

$$k_{s1}=n_{s1}'+m_{s1}'=\pm Q_1+p\pm Q_2+p$$

and

$$k_{s1}=n_{s1}'-m_{s1}'=\pm Q_1\mp Q_2$$

The smallest absolute values of k_{s1} are

$$\begin{aligned} k_{s1}&=Q_1-Q_2\pm 2p \\ k_{s1}&=Q_1-Q_2 \end{aligned} \qquad (16)$$

Disturbing noise can be expected, when k_{s1} as given by equation 16 is a small number. $k_{s1}=1$ is dangerous, but under certain conditions even $k_{s1}=20$ may not be permissible. The noise produced by the machine depends not only on the harmonics and the radial forces produced by them, it depends also on the mechanical construction of the machine and on the number of poles which determines the depth of the stator core.

When the stator harmonics co-operate with rotor harmonics, the case $k=1$ results in

$$n_b'+m_a'=\pm 1$$

or

$$n_b'-m_a'=\pm 1$$

With equations 3 and 5, this gives for the squirrel-cage rotor (q_1 is an integer)

$$n_b'+m_a'=\pm 1=[(k_{1a}+k_{1b})m_1+2]p+k_{2a}Q_2$$
$$n_b'-m_a'=\pm 1=(k_{1b}-k_{1a})m_1p-k_{2a}Q_2$$

Applying here the same considerations as in the case of two rotor harmonics, treated under (*b*), we find the same results as there, namely that $k=1$ occurs when Q_2 is an odd number.

It follows from equations 15*a* and 15*b* that the frequency of the force waves of a squirrel-cage motor which are produced through the co-operation of the stator and rotor harmonics have approximately the slot frequency or double the line frequency. Occasionally higher frequencies corresponding to equation 15 may occur.

Since equation 8 is valid also for the wound rotor, the results derived for the squirrel-cage motor are valid also for the wound-rotor motor.

(*d*). *Zero-pole forces* ($k=0$). Under special circumstances the case $k=0$ may cause considerable trouble. $k=0$ means that there are no force poles, that the force is constant around the stator bore at any instant, but that it changes its value with the frequency $\omega_{\gamma'}-\omega_{\mu'}$ or $\omega_{\gamma'}+\omega_{\mu'}$ (equation 11). It can be seen from this equation and from the considerations under (*a*) and (*b*) that $k=0$ is possible only when stator harmonics co-operate with rotor harmonics; then we have $\omega_{\gamma'}-\omega_{\mu'}\neq 0$ and also $\omega_{\gamma'}+\omega_{\mu'}\neq 0$

Referring to (*c*) we have

$$\gamma'=n_b' \qquad \mu'=m_a'$$

and from equations 3 and 6 for the wound rotor

$$k=n_b'+m_a'=0=(k_{1b}+k_{1a})m_1+2+k_{2a}m_2$$
$$k=n_b'-m_a'=0=(k_{1b}-k_{1a})m_1-k_{2a}m_2$$

The number of phases of the rotor m_2 is usually equal to three. Thus $k=n_b'+m_a'$ will be equal to 0, when

$$(k_{1b}+k_{1a})\frac{m_1}{3}+\frac{2}{3}=-k_{2a}$$

that is, the sum $n_b'+m_a'$ cannot produce $k=0$, if the stator has $m_1=3$. $k=n_b'-m_a'$ will be equal to 0, when

$$(k_{1b}-k_{1a})\frac{m_1}{3}=k_{2a} \qquad (17a)$$

If the stator has a three-phase winding there will be in this case, many combinations which will give $k=0$. The frequency of the force is given by equation 15 when m_2 is substituted for Q_2/p. The equation 15 is independent of the value of k.

We consider for example, the combination (q_1 integral)

$$m_1=m_2=3 \quad k_{1a}=0 \quad k_{1b}=-2=k_{2a}$$

To $k_{1a}=0$ corresponds $n_a'=p$; to $k_{1b}=-2$ corresponds $n_b'=-5p$; to $k_{2a}=-2$ corresponds $m_a'=-6p+p=-5p$ and $n_b'-m_a'=0$. The frequency of the stationary force produced by $n_b'=-5p$ and $m_a'=-5p$ is (equation 15)

$$f_-=-2\times 3(1-s)f_1=360(1-s) \text{ cycles per second}$$

If we would consider the combination $k_{1a}=0$, $k_{1b}=-4=k_{2a}$, that is, $n_a'=p$, $n_b'=-11p$, $m_a'=-11p$, we would find that

the stationary force oscillates with 720 $(1-s)$ cycles per second.

For the squirrel-cage rotor we find from equations 3 and 5

$$k=n_b'+m_a'=0=[(k_{1b}+k_{1a})m_1+2]p+k_{2a}Q$$

$$k=n_b'-m_a'=0=(k_{1b}-k_{1a})m_1p-k_{2a}Q_2$$

Since k_{1a} and k_{1b} are integers, $k=0$ will occur here when

$$\left.\begin{array}{l} \dfrac{k_{2a}Q_2}{p} \text{ is an integer or} \\[2ex] \dfrac{k_{2a}Q_2}{m_1p} \text{ is an integer} \end{array}\right\} \quad (17b)$$

The frequency of the forces is given by equation 15 which is independent of the value of k.

The equation $17a$ for the wound rotor can be satisfied by small values of k_{1a}, k_{1b}, and k_{2a}. The corresponding field amplitudes as well as the $k=0$ force will therefore be considerable. To the equation $17b$ corresponds usually a relatively large value of k_{2a} or k_{1b} or k_{1a}, that is, a harmonic with small amplitude. This is the reason why $k=0$ may more often make trouble in a machine with a wound rotor than in a machine with a squirrel-cage rotor.

The natural frequency of a stator core for radial vibrations is approximately

$$f_{\text{rad. vib.}}=\frac{32.4\times10^3}{r}\sqrt{\frac{1}{1+h_t/h_c}} \text{ cycles per second} \quad (18)$$

where r is the radius in the middle of the core, h_t the depth of the tooth and h_c the depth of the core. It depends mainly on the radius of the core.

Influence of Saturation

For the stator harmonics (equation 37, appendix 2) is valid.

$$b_{n'}=B_{n'}\sin\left(\omega t-n'\frac{\pi}{p\tau}x_1\right)$$

Since all harmonics n' are produced by the same current, ω is common for all harmonics, and each harmonic travels exactly its wave length during one cycle of the current.

If the magnetic circuit is saturated, the main harmonic of the magnetomotive force produces, besides the main field harmonic, also saturation field harmonics which travel 3, 5, ... wave lengths when the main harmonic travels only one wave length. The saturation harmonics are bound to the main harmonic and travel with it without changing position with regard to each other. For these harmonics we have to write

$$b_\gamma=B_\gamma\sin\left(\gamma\omega t-\gamma\frac{\pi}{\tau}x_1\right)\quad \gamma=3,5,\ldots. \quad (19)$$

The saturation harmonics produce in cooperation with the rotor harmonics, force waves, the frequencies of which can be found from equations 11, 10, and 18 as follows

$$\left.\begin{array}{l} k=\gamma_b'+m_a' \\ \quad \gamma_b'=3\quad f_+=\left[4+\dfrac{m_a'-n_a'}{p}(1-s)\right]f_1 \\ \quad \gamma_b'=5\quad f_+=\left[6+\dfrac{m_a'-n_a'}{p}(1-s)\right]f_1 \\ k=\gamma_b'-m_a' \\ \quad \gamma_b'=3\quad f_-=\left[2-\dfrac{m_a'-n_a'}{p}(1-s)\right]f_1 \\ \quad \gamma_b'=5\quad f_-=\left[4-\dfrac{m_a'-n_a'}{p}(1-s)\right]f_1 \end{array}\right\} \quad (20)$$

The difference $m_a'-n_a'$ is given for the wound rotor as well as for the squirrel-cage rotor, by equations 5, 6, and equation 34, appendix 1.

Appendix I. The Order of the Stator and Rotor Harmonics

(a) The Stator Harmonics

We consider a stator winding with a fractional number of slots per pole per phase. Since subharmonics are possible, we take as fundamental the wave, the length of which is equal to the complete developed armature, that is, to 2π. The harmonic $n'=p$ is then the main harmonic (the "synchronous" harmonic).

The stator may have m_1 phases. The n'th harmonic of the magnetomotive force of one of the phases which we designate by 0 is

$$f_{1n'}{}^0=F_{1n'}\sin\omega t\cos n'\frac{x_1}{p\tau}\pi \quad (21)$$

When the number of slots per pole per phase is

$$q_1=a+\frac{b}{\beta} \quad (22)$$

where a is an integer, b/β a fractional number, and b and β have not a common divisor, then the winding repeats itself after each β poles. The winding with q_1=integer repeats itself after two poles. The time and space angle between two adjacent phases are for q_1 an integer $\frac{2\pi}{m_1}$ and $n'\frac{2\pi}{pm_1}$; correspondingly these angles are for q_1 a fractional number

$$\frac{\pi\beta}{m_1} \text{ and } n'\frac{\pi\beta}{pm_1}$$

The time and space angle between the phase designated by 0 and the cth phase are therefore for q_1=fractional number

$$\frac{\pi\beta}{m_1}c \text{ and } n'\frac{\pi\beta}{pm_1}c$$

Thus the magnetomotive force of the cth phase is

$$f_{1n'}{}^c=F_{1n'}\sin\left(\omega t-\frac{\pi}{m_1}\beta c\right)\times \cos\left(n'\frac{x_1}{p\tau}\pi-n'\frac{\pi}{pm_1}\beta c\right) \quad (23)$$

or

$$f_{1n'}{}^c=\frac{1}{2}F_{1n'}\left\{\sin\left[\left(\omega t-n'\frac{x_1}{p\tau}\pi\right)+\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta c\right]+\sin\left[\left(\omega t+n'\frac{x_1}{p\tau}\pi\right)-\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta c\right]\right\} \quad (23a)$$

In order to find the resultant magnetomotive force we have to take the sum of all m_1 phases, that is, from $c=0$ to $c=m_1-1$. Thus

$$\begin{aligned} f_{1n'}=\frac{1}{2}F_{n'}\Bigg\{&\left[\sin\left(\omega t-n'\frac{x_1}{p\tau}\pi\right)\times\sum_{c=0}^{c=m_1-1}\cos\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta c+\cos\left(\omega t-n'\frac{x_1}{p\tau}\pi\right)\times\sum_{c=0}^{c=m_1-1}\sin\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta c\right]+ \\ &\left[\sin\left(\omega t+n'\frac{x_1}{p\tau}\pi\right)\times\sum_{c=0}^{c=m_1-1}\cos\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta c-\cos\left(\omega t+n'\frac{x_1}{p\tau}\pi\right)\sum_{c=0}^{c=m_1-1}\sin\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta c\right]\Bigg\} \end{aligned} \quad (24)$$

The four sums we designate in turn by a, b, a_1, and b_1, and the angles in the round parenthesis by α and δ. We can write

$$f_{1n'}=\frac{1}{2}F_{n'}[(a\sin\alpha+b\cos\alpha)+(a_1\sin\delta-b_1\cos\delta)] \quad (25)$$

or

$$\begin{aligned} f_{1n'}&=\frac{1}{2}F_{n'}\left[\sqrt{a^2+b^2}\sin(\alpha+\gamma_1)+\sqrt{a_1^2+b_1^2}\sin(\delta+\gamma_2)\right] \\ &=\frac{1}{2}F_{n'}\sqrt{a^2+b^2}\sin\left(\omega t-n'\frac{x_1}{p\tau}\pi+\gamma_1\right)+\frac{1}{2}F_{n'}\sqrt{a_1^2+b_1^2}\sin\left(\omega t+n'\frac{x_1}{p\tau}\pi+\gamma_2\right) \end{aligned} \quad (25a)$$

These are two waves traveling in different directions, and both of the same order n'. Since the stator currents produce from each harmonic only one wave, traveling with the synchronous harmonic or opposite to it, it follows that for some harmonics the sums a and b, for other harmonics the sums a_1 and b_1, must be equal to zero.

We assume that a given harmonic, for example the n'th harmonic, travels with the synchronous harmonic. Then for this harmonic the sums a_1 and b_1 must be equal to zero, while $\sqrt{a^2+b^2}$ must have a definite

value. It can be seen that this will occur when

$$\left(\frac{n'}{p}+1\right)\frac{\beta}{2}=k \quad k \text{ integer excluding } 0$$

and

$$\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta=2\pi k_1 \quad k_1 \text{ integer including } 0$$

There will be

$$a=\sum_{c=0}^{c=m_1-1}\cos\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta c$$
$$=\sum_{c=0}^{c=m_1-1}\cos k_1 2\pi c=m_1$$
$$b=\sum_{c=0}^{c=m_1-1}\sin\left(\frac{n'}{p}-1\right)\frac{\pi}{m_1}\beta c$$
$$=\sum_{c=0}^{c=m_1-1}\sin k_1 2\pi c=0$$
$$a_1=\sum_{c=0}^{c=m_1-1}\cos\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta c$$
$$=\sum_{c=0}^{c=m_1-1}\cos k\frac{2\pi}{m_1}c=0$$
$$b_1=\sum_{c=0}^{c=m_1-1}\sin\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta c$$
$$=\sum_{c=0}^{c=m_1-1}\sin k\frac{2\pi}{m_1}c=0$$

On the other hand, if we assume that a given harmonic travels opposite to the rotation, we find that when

$$\left(\frac{n'}{p}+1\right)\frac{\beta}{2}=k \quad k \text{ integer excluding } 0$$

$$\left(\frac{n'}{p}+1\right)\frac{\pi}{m_1}\beta=k_1 2\pi \quad k_1 \text{ integer including } 0$$

the sums a and b will be zero while $\sqrt{a_1^2+b_1^2}$ has a definite value. Thus

$$\left.\begin{array}{ll}\left(\frac{n'}{p}+1\right)\frac{\beta}{2}=k & k \text{ integer excluding } 0\\ \left(\frac{n'}{p}\mp 1\right)\frac{\beta}{2m_1}=k_1 & k_1 \text{ integer including } 0\end{array}\right\} \quad (26)$$

are the criterions for the existence of the n'th harmonic in the magnetomotive force. When the minus sign is used, the harmonic travels with the synchronous harmonic; when the plus sign is used, the harmonic travels opposite to the synchronous harmonic.

The first criterion is independent of m_1, it indicates the existence of the n'th harmonic in the magnetomotive force of a single phase; the second criterion indicates the existence of the nth harmonic in the magnetomotive force of the total winding.[18]

It follows from the preceding that with $\beta=2$, the equations 26 are the criterions for the existence of the nth harmonic in a winding with q_1=integer. Thus, when q_1=integer,

$$\left.\begin{array}{ll}\frac{n'}{p}+1=k & k=\text{integer excluding } 0\\ \left(\frac{n'}{p}\mp 1\right)\frac{1}{m_1}=k_1 & k_1=\text{integer including } 0\end{array}\right\} \quad (27)$$

are the criterions for the existence of the n'th harmonic. Since n'/p is also an integer when q_1=integer, the first criterion says that the magnetomotive force of a single phase contains in general all odd as well as all even harmonics. The usually used 60-degree phase-belt winding does not contain even harmonics; for this winding k is limited to even integers.

The second criterion can be more conveniently used in the form

$$n'=(k_1 m_1+1)p \quad (28)$$

where k_1 is a positive as well as a negative integer including 0. For the normal 60-degree phase-belt winding, k_1 is again limited to positive and negative even integers including 0.

(b) The Rotor Harmonics

The n'th stator harmonic induces in the rotor phase designated by 0 the current

$$i_{2n'}=\sqrt{2}\,I_{2n'}\sin s_{n'}\omega t$$

s_n' is the slip of the rotor relative to the n'th stator harmonic. To the current $i_{2n'}$ corresponds a rotor magnetomotive force, which contains different harmonics. We consider the m'th of these harmonics. Its magnetomotive force is

$$f_{2m'}=F_{2m'}\sin s_{n'}\omega t\cos m'\frac{x_2}{p\tau}\pi \quad (29)$$

We assume at first that the number of slots per pole per phase of the rotor is an integral number. Then the space angle between two adjacent phases is, as for the stator, $m'\frac{2\pi}{pm_2}$. The time angle between the electromotive forces of two adjacent rotor phases is determined by the n'th harmonic of the stator which produces the m' harmonic of the rotor, and since the space angle between two adjacent rotor phases is equal to $\frac{2\pi}{pm_2}$ this time angle is $n'\frac{2\pi}{pm_2}$. The time and space angle between the phase 0 and the cth phase are $n'\frac{2\pi}{pm_2}c$ and $m'\frac{2\pi}{pm_2}c$, and thus the resultant magnetomotive force

$$f_{2m'}=\frac{1}{2}F_{2m'}\left\{\left[\sin\left(s_{n'}\omega t-m'\frac{x_2}{p\tau}\pi\right)\times\sum_{c=0}^{c=m_2-1}\cos(m'-n')\frac{2\pi}{pm_2}c+\cos\left(s_{n'}\omega t-m'\frac{x_2}{p\tau}\pi\right)\sum_{c=0}^{c=m_2-1}\sin(m'-n')\frac{2\pi}{pm_2}c\right]+\left[\sin\left(s_{n'}\omega t+m'\frac{x_2}{p\tau}\pi\right)\sum_{c=0}^{c=m_2-1}\cos(m'+n')\times\frac{2\pi}{pm_2}c-\cos\left(s_{n'}\omega t+m'\frac{x_2}{p\tau}\pi\right)\times\sum_{c=0}^{c=m_2-1}\sin(m'+n')\frac{2\pi}{pm_2}c\right]\right\} \quad (30)$$

Since m' and n' are integers, the sums are equal to 0 except when

$$(m'-n')\frac{2\pi}{pm_2}=k_2 2\pi \quad k_2 \text{ integer including } 0$$

and

$$(m'+n')\frac{2\pi}{pm_2}=k_2 2\pi \quad k_2 \text{ integer including } 0$$

or except when

$$m'=k_2 pm_2 \pm n' \quad (31)$$

For a given value of k_2 to any value of n' correspond two different values of m', that is, two traveling waves. Giving k_2 positive as well as negative values including 0, we can write

$$m'=k_2 pm_2+n' \quad k_2 \text{ positive or negative integer including } 0 \quad (32)$$

n' can be here, as before, positive or negative.

For the squirrel-cage rotor $m_2=\frac{Q_2}{p}$, and therefore

$$m'=k_2 Q_2+n' \quad (33)$$

While considering the wound rotor we have made the assumption q_2=integer. When q_2=fractional number it will be

$$m'=\frac{2}{\beta_2}k_2 pm_2+n' \quad (34)$$

This equation can be found by a similar consideration as for the stator.

Appendix 2. The Amplitudes of the Stator and Rotor Harmonics and the Speed of the Harmonics Relative to the Stator and to the Rotor

(a) The Stator Harmonics

For the n'th harmonic of the stator magnetomotive force

$${}_1, t)=F_{n'}\sin\left(\omega t-n'\frac{x_1}{p\tau}\pi\right) \quad (35)$$

is valid, where

$$F_{n'}=\frac{\sqrt{2}}{\pi}m_1 N_1\frac{K_{dn'}K_{pn'}}{n'}I_1 \quad (36)$$

For the n'th harmonic of the field

$$b_{n'}(x_1, t)=B_{n'}\sin\left(\omega t-n'\frac{x_1}{p\tau}\pi\right) \quad (37)$$

where

$$B_{n'}=\frac{3.19}{gk_c k_s}\frac{\sqrt{2}}{\pi}m_1 N_1\frac{K_{dn'}K_{pn'}}{n'}I_1 \quad (38)$$

k_c is the Carter factor. The factor k_s takes into account the saturation. It is

$$k_s=\frac{AT_g+AT_{t1}+AT_{t2}}{AT_g} \quad (39)$$

For the higher values of n', k_s is to be set equal to 1, since the paths of these harmonics are through the tooth tops without penetrating further into the teeth and the core.

The velocity of the n'th harmonic of the field with regard to the stator will be found

by differentiation with respect to t of the equation

$$\omega t-n'\frac{x_1}{p\tau}\pi=\text{constant}$$

as

$$v_{1n'}=\frac{dx_1}{dt}=\frac{p}{n'}\frac{\tau}{\pi}\omega=\frac{P}{n'}v_p \qquad (40)$$

where

$$v_p=\frac{\tau}{\pi}\omega=2\tau f_1 \qquad (41)$$

is the velocity of the main (synchronous) harmonic ($n'=p$).

In order to determine the electromotive force induced by the n'th stator harmonic in the rotor winding, it is necessary to know the velocity of this harmonic with regard to the rotor.

If s is the slip of the rotor relative to the main harmonic, the velocity of the rotor is

$$v_r=(1-s)v_p=(1-s)\frac{\tau}{\pi}\omega$$

and therefore

$$x_2=x_1-v_rt=x_1-(1-s)\frac{\tau}{\pi}\omega t$$

or

$$x_1=x_2+(1-s)\frac{\tau}{\pi}\omega t \qquad (42)$$

Inserting this in equation 37 there will be found

$$b_{n'}(x_2,t)=B_{n'}\sin\left(s_{n'}\omega t-n'\frac{x_2}{p\tau}\pi\right) \qquad (43)$$

where

$$s_{n'}=1-\frac{n'}{p}(1-s) \qquad (44)$$

is the slip of the rotor with regard to the n'th stator harmonic. It is also

$$s_{n'}=\frac{f_{2n'}}{f_1} \qquad (45)$$

$f_{2n'}$ is the frequency of the electromotive force induced by the n'th stator harmonic in the rotor winding. It follows from equation 43 for the velocity of the n'th stator harmonic with regard to the rotor

$$v_{2n'}=\frac{dx_2}{dt}=s_{n'}\frac{p}{n'}v_p=s_{n'}v_{1n'} \qquad (46)$$

It follows further from equation 40

$$(\text{Rpm})_{n'}=\frac{P}{n'}n_s=\frac{60f_1}{n'} \qquad (46a)$$

that is, the speed of a harmonic is inversely to its order. If there exists a fundamental ($n'=1$), its speed relative to the stator will be equal to $60f_1$, that is, 3,600 rpm for $f_1=60$ cycles per second. This is the highest speed that a stator harmonic can reach.

(b) The Rotor Harmonics

Corresponding to equation 37 we can write for the m'th harmonic of the rotor field

$$b_{m'}(x_2,t)=B_{m'}\sin\left(s_{n'}\omega t-m'\frac{\pi}{p\tau}x_2\right) \qquad (47)$$

This m'th rotor harmonic is produced by the n'th stator harmonic. The frequency of the rotor currents depends on the slip of the rotor relative to the n'th stator harmonic. For the amplitude $B_{m'}$ is valid (equation 4)

$$B_{m'}=\frac{3.19}{gk_ck_s}\frac{\sqrt{2}}{\pi}m_2N_2\frac{K_{dm'}K_{pm'}}{m'}I_{2n'} \qquad (48)$$

$I_{2n'}$ is the current induced in the rotor by the stator harmonic n'.

For the squirrel-cage rotor we have to insert in equation 48

$$m_2=\frac{Q_2}{p},\quad N_2={}^1/_2,\ \text{and}\ K_{dm'}=K_{pm'}=1$$

Further, we have to multiply equation 48 by p, if we understand $I_{2n'}$ to be the current per slot. Thus the field amplitude $B_{m'}$ of the squirrel-cage rotor is

$$B_{m'}=\frac{3.19}{gk_ck_s}\frac{\sqrt{2}}{2\pi}Q_2\frac{1}{m'}I_{2n'} \qquad (48a)$$

It follows from equation 33 (appendix 1) for the squirrel-cage rotor that its value of $B_{m'}$ is usually the larger the smaller is k_2. $k_2=\pm 1$ gives usually the largest value for $B_{m'}$.

From equations 47 and 44, it follows for the velocity of the m'th rotor harmonic with regard to the rotor

$$v_{2m'}=\frac{dx_2}{dt}=s_{n'}\frac{p}{m'}\frac{\tau}{\pi}\omega=\frac{p}{m'}\left[1-\frac{n'}{p}\times(1-s)\right]v_P \qquad (49)$$

In order to study the noise problem it is necessary to know the velocity of the harmonics of the rotor fields with regard to the stator. Inserting in equation 47 the value of x_2 from equation 42

$$b_{m'}(x_1,t)=B_{m'}\sin\left[\left(1+\frac{m'-n'}{p}(1-s)\right)\times\omega t-m'\frac{x'}{p\tau}\pi\right] \qquad (50)$$

The velocity of the m' rotor field harmonic with regard to the stator is thus

$$v_{1m'}=\frac{dx_1}{dt}=\frac{p}{m'}\left[1+\frac{m'-n'}{p}(1-s)\right]v_p \qquad (51)$$

In the last two equations we have to substitute equations 32, 33, and 34 (appendix I)

$$\frac{m'-n'}{p}=k_2m_2 \quad \text{for the wound rotor with } q_2=\text{integer}$$

$$\frac{m'-n'}{p}=\frac{2}{\beta_2}k_2m_2 \quad \text{for the wound rotor with } q_2=\text{fractional number} \qquad (52)$$

$$\frac{m'-n'}{p}=k_2\frac{Q_2}{p} \quad \text{for the squirrel cage}$$

where k_2 is a positive or negative integer including 0.

We have seen that with $f_1=60$ cycles per second, the speed of the stator harmonics cannot exceed 3,600 rpm. The rotor harmonics are produced by currents of low as well as of high frequency. The speed that corresponds to the latter harmonics may be very high. It follows from equations 49 and 51

$$(\text{Rpm})_{2m'}=\frac{p}{m'}\left[1-\frac{n'}{p}(1-s)\right]n_s \qquad (53)$$

and

$$(\text{Rpm})_{1m'}=\frac{p}{m'}\left[1+\frac{m'-n'}{p}(1-s)\right]n_s \qquad (54)$$

We consider for example a squirrel-cage motor of 30 horsepower, four poles, 60 cycles, three-phase, with $Q_1=72$, $Q_2=58$ and examine the combination $n'=+62$, $k_2=-1$, $m'=+4$. It follows from equations 53 and 54 with $s=1.5$ per cent

$$(\text{Rpm})_{2m'}=\frac{1}{2}\left(1-\frac{62}{2}\times 0.985\right)1{,}800=26{,}500$$

$$(\text{Rpm})_{1m'}=\frac{1}{2}\left(1-\frac{58}{2}\times 0.985\right)1{,}800=24{,}800$$

The frequency of the rotor currents that correspond to the combination in consideration is (equation 44 or 45)

$$f_{2n'}=\left(1-\frac{62}{2}\times 0.985\right)60=1{,}768 \text{ cycles per second}$$

Nomenclature

- b—Instantaneous value of the field intensity
- B—Amplitude of the field
- f—Instantaneous value of the magnetomotive force
- f—Frequency
- f_1—Line frequency
- F—Amplitude of the magnetomotive force
- k—Integer
- k—Number of force pole pairs
- k_d—Distribution factor
- k_p—Pitch factor
- k_c—Carter factor
- k_s—Saturation factor
- m_1—Number of stator phases
- m_2—Number of rotor phases
- m'—Order of the rotor harmonics
- m_{s1}'—Order of the slot harmonics of the rotor
- n—Speed (rpm)
- n'—Order of the stator harmonic
- n_{s1}'—Order of the slot harmonics of the stator
- N—Number of turns per phase
- p—Number of pole pairs
- q—Number of slots per pole per phase
- Q—Total number of slots
- s—Slip
- v—Velocity
- β—Number of poles per group, when q_1=fractional number
- τ—Pole pitch
- ω—$2\pi f_1$

Transient Recovery Voltages and Circuit-Breaker Performance

R. C. VAN SICKLE
MEMBER AIEE

EXPERIENCE with power circuit breakers has frequently shown that two breakers of identical design may give radically different performances, even though the operating voltages and short-circuit currents to which they are subjected are the same. Studies of the conditions surrounding these circuit breakers have traced the cause to the differences in the manner in which the recovery voltage has appeared across the contacts of the circuit breakers subsequent to the final interruption. This voltage which occurs between the final arc voltage and the 60-cycle recovery voltage is an equalizing phenomenon defined as the transient recovery voltage. To take it into account in breaker applications, studies have been made of the transient voltages which can occur on systems, and other studies have been made of the response of the circuit breakers to transient recovery voltages.

In the higher-voltage classes of circuit breakers, 34.5 kv and above, the voltage-recovery rates encountered in service are most severe when the circuit breaker is located adjacent to the power transformers. This is exactly the condition which is encountered in high-power laboratories, and so the recovery rates produced on the laboratory circuits for a given voltage and current closely approximate the maximum natural frequency and voltage-recovery rate which can be encountered in the service. In fact, service conditions will frequently involve the use of transmission lines supplying power to the circuit breaker. These lines may be supplying only a fraction of the total power which the breaker is called upon to interrupt, but the presence of the line on the bus greatly increases the capacitance of the circuit and reduces the rate at which the voltage appears across the breaker contacts. Consequently, when the voltages and currents can be duplicated on the laboratory high-voltage circuits, the transient recovery voltages obtained will probably be as severe or more severe than the transient recovery voltages encountered in service. A laboratory demonstration of the interrupting ability of a high-voltage breaker is, therefore, an excellent assurance of equally good service performance.

Studies of power-system circuits at generator voltage have revealed that the location of a reactor close to a circuit breaker produces a very high natural frequency in the transient recovery voltage. Some of these values have been found to be even higher than those encountered in normal high-power laboratory circuits. Very little was known about the performance of circuit breakers when subjected to these extremely high frequencies, and the need for additional data was apparent.

To eliminate this deficiency by studying transient recovery voltages having very high natural frequencies and to determine the effect of two-frequency transients, the tests described in this paper were made. These tests, made on four different types of circuit breakers, demonstrate the effects of various types of transient recovery voltages and show that the extremely high natural frequencies obtained with reactors close to breakers are not appreciably more severe on the circuit breakers than the natural frequencies normally obtained in the laboratory. They also reveal that tests made on the regular laboratory circuits may often be used to demonstrate the ability of the breaker to open under the most severe circuit conditions.

The Problem

Interrupting a circuit by a breaker consists of changing the current path through it from a good conductor to a good insulator. This is done preferably in as short a time as possible, with a minimum depreciation of breaker parts and as little external demonstration as possible. To accomplish this, the breaker separates the metallic current-carrying parts, thereby drawing an arc which temporarily completes the circuit. This current goes to zero periodically twice each cycle, and it is at one of these current zeros that the breaker completes the transition from a conductor to an insulator by deionizing the space between the contacts. An opportunity to do this occurs at each zero, but the arc will restrike if the voltage applied across the breaker exceeds the dielectric strength of the arc space. The dielectric strength of an ionized space has been defined by J. Slepian as the voltage required for sustaining or increasing the conductivity of the arc space, and it depends on the amount of ionization remaining and the rate at which the breaker is reducing it. The removal of the ionization requires time, and the breaker dielectric strength increases at a finite rate. This strength as defined above is finite at all times but increases toward the end of a half-cycle and just before current zero may attain high values. Unless at some time the applied voltage exceeds it, the dielectric strength will continue to increase after current zero, and the transition to an insulating state will be completed.

At the time of current zero in the

breaker, the amount of ionization will sometimes be negligible, and at other times a sufficient amount may remain so that a current of a few amperes will flow through the arc space when the transient recovery voltage is applied across it.

The transient recovery voltage rises at a rate determined by the ability of the circuit to charge the capacitance adjacent to the breaker. The voltage does not increase at a constant rate nor always in the same general manner. The characteristics of the transient are determined primarily by the circuit constants. A simple circuit will have a transient recovery voltage which is essentially a sinusoidal wave as illustrated in Figure 1A. If the circuit breaker separates two parts of a circuit as shown in Figure 1B, each part will oscillate independently, and recovery voltage on the circuit breaker will be a two-frequency transient, the relative frequencies and amplitudes depending upon the inductances and capacitances of the circuit. A similar transient is produced by the more complicated circuit shown in Figure 1C. The addition of feeders to the bus, as shown in Figure 1D, may produce transients that are not sinusoidal.

These variations in the character of the transients are, of course, accompanied by variations in the speed with which they take place, as the inductances, capacitances, and number of lines are variable. The natural frequencies of the circuits used in these tests varied from 250 to 210,000 cycles per second.

The higher natural frequencies are caused by a low value of capacitance adjacent to the breaker, and only small currents flow into these capacitances during the transient. Consequently, if the ionization remaining in the arc space permits a comparable current to flow through the breaker in parallel with the current through the capacitance, a considerable modification of the transient recovery voltage is to be expected and actually takes place, as will be shown by cathode-ray oscillograms.

The circuits of a high-power laboratory for testing the interrupting capacity of breakers have one or more generators, current-limiting reactors, closing switches, backup breakers, and the circuit breaker on test. For convenience, the reactors are permanently installed as a part of the laboratory equipment and are provided with suitable switching arrangements for varying the effective value of the reactance in the lines over a relatively wide range. Consequently, the capacitance of the bus and switches between the reactor and the circuit breaker may be greater than it would be in a power station having the current-limiting reactors located within a few feet of the circuit breaker. To determine how much effect this additional capacitance might have and to extend the range of tests up to as high values as could be obtained, reactors were placed in the test cells with the breakers and were connected to them by short leads.

Four types of breakers were studied. The first was an oil circuit breaker using plain-break-type contacts with no means of controlling or directing the gases generated in the oil. The second was also an oil breaker but was equipped with modern arc-rupturing devices ("De-ion grids"), Figure 2. It belonged to the class of breakers using self-generated gas blasts. The third was an air circuit breaker which produced a magnetic blast to drive the arc into a confining slot. The fourth type was the compressed-air circuit breaker which subjected the arc to a transverse blast of compressed air and forced it against arc splitters.

Because of the various transients which may be encountered, three different types of tests were used.

In one type of test, the single-frequency transients, illustrated in Figure 1A, were used with the voltage and current constant and the capacitance varied. These tests demonstrated the effect of varying the natural frequency of the transient over a very wide range.

Another type of test covered a wide range of currents at a given voltage. Two series of tests were made, differing only in the natural frequency of the transient recovery voltage. Due to the inductance varying with current and the limitations within which the capacitances of the laboratory could be controlled, it

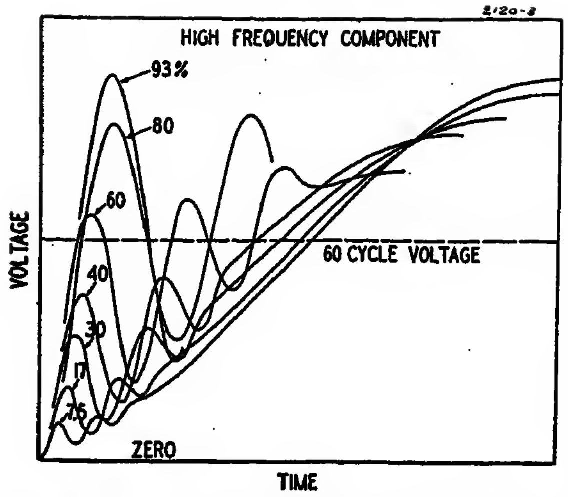

Figure 3. Calculated transient voltages for circuits used to determine the effect of varying the amplitude of the high-frequency component

was not possible to maintain the same natural frequency for all of the current settings or even to keep them all of the same general type. Consequently, for comparison, they were all based on the average rate of increase in voltage to the first peak, the transient voltage-recovery rate. This value was about 2,000 volts per microsecond for one group and 3,000 volts per microsecond for the other.

In the third type of test, voltage-recovery transients composed of two components having different frequencies were studied (Figure 1C). The tests were made at a given voltage and current, and, by varying the distribution of the impedance in the circuit, the amplitude of the high frequency component was varied from 7.5 to 93 per cent of the total amplitude of the transient (Figure 3). This was done to determine how high the first peak of voltage had to be before it exerted an influence on the performance of the circuit breaker. If the amplitude of the higher frequency component is relatively small, the voltages reached during the part of the transient controlled by it may be so low that they exert little or no influence on the breaker performance. However, if the amplitude of the higher-frequency component is relatively high, the transient approximates a single-frequency transient and naturally produces practically the same effect.

All tests were made on single-phase 60-cycle circuits. The 7,620-volt circuits had one side of the breaker grounded. The 13,200-volt circuits had the neutral of the generator grounded through a resistor. Records were made on a magnetic oscillograph and on a cathode-ray oscillograph having a rotating film drum. To expedite the testing, records of two similar tests frequently were made on one cathode-ray-oscillograph film using two different time scales.

Plain-Break Oil Circuit Breaker

The tests on the oil circuit breaker not equipped with arc-extinguishing devices demonstrated its performance over a wide range of circuit voltage-recovery rates. The breaker used had a tank diameter of 30 inches, a contact stroke of $11^1/_8$ inches and an average contact opening speed of 8.2 feet per second. The two breaks were each ten inches long. All tests were single-phase with one side grounded at the breaker. The tests were close to the voltage-interrupting ability but were well below the current-interrupting ability of the breaker.

A series of tests was made to determine the effect of varying the natural frequency of the circuit. This was done on a 7,620-volt 5,200-ampere circuit but at a potential of about 3,810 volts and a current of 2,600 amperes. A wide range of natural frequencies was obtained. The highest frequency, 208,000 cycles per second, resulted from placing a 1.2-ohm reactor in the test cell immediately adjacent to the circuit breaker. The lower values, down to 380 cycles per second, were obtained by various laboratory circuit connections and by adding capacitance to the normal laboratory circuit. The arcing time was a function of the natural frequency as shown by Figure 4.

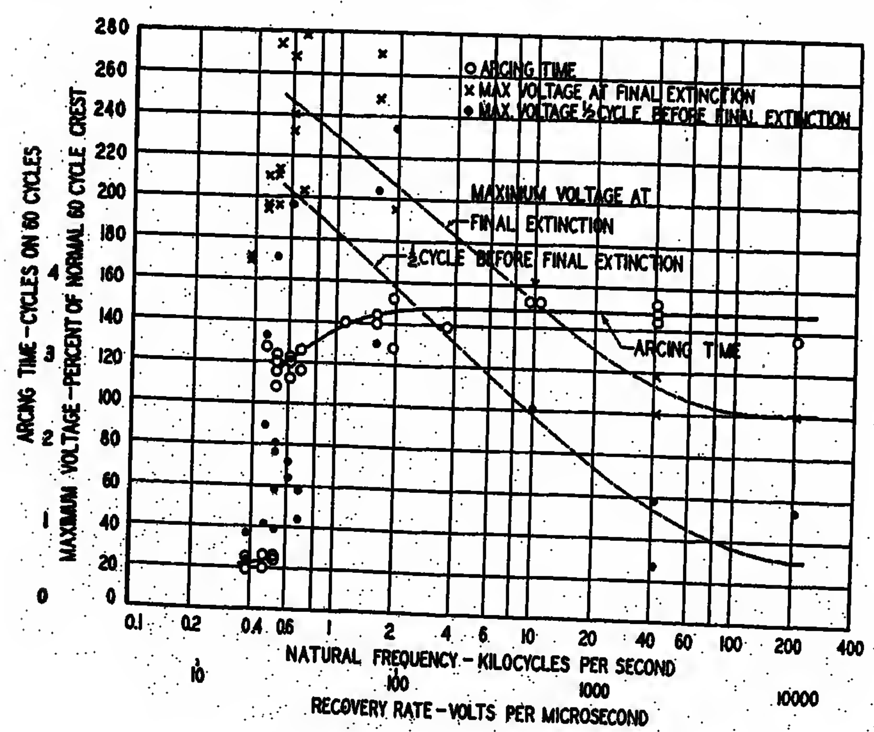

Figure 4. Plain-break circuit breaker, 3,800 volts, 2,600 amperes

Effect of natural frequency of transient recovery voltage

The cathode-ray oscillograms, Figure 5, show that at the higher frequencies the oscillations of the transients were completely damped, and the damping became relatively less at lower frequencies so that the maximum voltage which was reached during the extinction transients varied as shown in Figure 4. The voltage reached by the transient a half-cycle before interruption was also measured and plotted in Figure 4. At the higher frequencies, these voltages were well below the voltages reached on the final transient. However, as the frequency was reduced, and the energy of the transient was increased, the voltage on the transients increased and approached double the normal crest of the sixty-cycle wave. As this approximates the normal maximum voltage of a recovery transient, further reduction in frequency permitted the arc to extinguish on this transient which then became the final transient. The group of crosses representing maximum voltages on final transient recovery voltages for 500 to 600 cycles per second can be considered an indication of the end of this curve.

An interesting discontinuity exists in the arcing time curve at about this frequency. The breaker seemed to make a good effort to extinguish the arc within the first cycle and, if it failed to do so, would be unable to accomplish it until about the end of the third cycle of arcing. Below 400 cycles per second the breaker interrupted with about one-half cycle of arcing.

At six of the steps the maximum voltage which could be consistently interrupted was determined and was found to be about 3,810 volts 2,600 amperes. At higher voltages occasional failures occurred, and this limit appeared to be independent of the natural frequency of the circuit.

Two other series of tests were made to determine the effect of the amplitude of the higher-frequency component of two-frequency transients. They were planned and made prior to the series described above and before it was known that this breaker had a constant arcing time over such a wide range of natural frequencies. The lower frequencies chosen were as low as could be easily obtained but varied from 2,700 to 8,000 cycles per second on the low-current series and from 7,000 to 17,000 cycles per second on the higher-current series. These series gave data

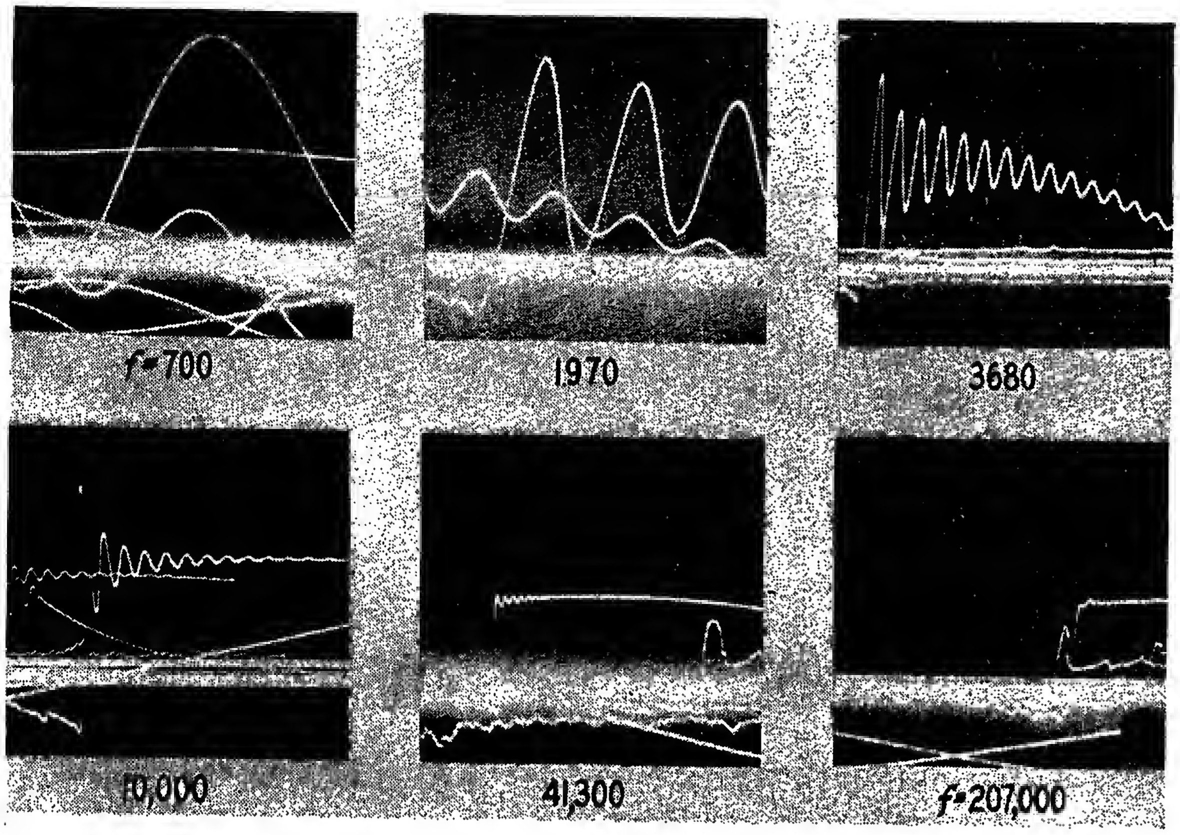

Figure 5. Plain-break circuit breaker, 3,800 volts, 2,600 amperes

Cathode-ray oscillograms showing effect of conductivity in the arc space on the transient recovery voltage

which indicated that at both currents the arcing time was substantially independent of the amplitude of the higher-frequency component, and this result was difficult to explain until the effect of varying the single-frequency transients over much wider ranges was disclosed by the later test. Consequently, the data on these tests are of interest in supplementing the previous data and in showing the effect of the conductivity of the arc space on the damping of the double-frequency transients.

In one series of tests, made with a current of 1,400 amperes at 3,180 volts, the amplitude of high-frequency component was varied from 7.5 to 93 per cent of the total amplitude in about ten per cent steps. The transients calculated during the planning of the test are shown in Figure 3, and the transients actually obtained are shown in Figure 6. The actual transients were modified considerably by the current being passed through the arc space of the circuit breaker.

The transients having calculated high-frequency components of 80 and 90 per cent were so heavily damped by the current through the arc space that they appeared aperiodic. Data from these tests are plotted in Figure 7 as a function of the amplitude of the calculated high-frequency component. The arcing time remained substantially constant. The maximum peak voltage decreased almost linearly, indicating that the higher-frequency component had negligible amplitude at the time of the maximum crest. The first peak increased almost linearly with the amplitude but at a rate only about half as great as would have been reached without conductivity in the arc space.

A similar series of tests were made at higher current, 6,000 amperes at 3,050 volts with high-frequency components having from 7 to 75 per cent of the total amplitude. For these values also the arcing time was independent of the amplitude of the high-frequency component, Figure 8. The conductivity was sufficient in all cases to damp completely the high-frequency component, and in some cases, the low-frequency component also. The low-frequency components increased in frequency as the amplitude decreased, but the range was only from 7,000 to 17,000 cycles per second. The constant arcing time and the damping of the transients indicates that the breaker easily dissipated all of the energy of the high-frequency component and that arcing times were the same for either the high or the low frequency.

The maximum voltage-interrupting ability was found at each setting by making tests at increasing voltages until failure occurred. The limit was found to be approximately the same for all of these circuits. The breaker failed on about half of the tests at 3,430 volts 6,750 amperes.

The tests on the plain-break oil circuit breaker operating near its maximum voltage-interrupting ability indicates that conductivity of the arc space following the normal current zero plays a big part in modifying the transients. The very slow high-energy transients are not appreciably affected as the energy loss is relatively low. As the frequency increases, and the energy decreases, the losses through the breaker result in increasing damping of the transients. At high natural frequencies, the admittance of the parallel capacitance path is so much smaller than the conductivity of the arc space that the capacitance current becomes negligible. Consequently, although reducing the capacitance further can greatly increase the natural frequency of the circuit and the calculated voltage-recovery rate, the actual transients obtained on test or in service will not be changed. When the conductivity damps out the higher-frequency components, the lower-frequency greater-energy components become more important. No increase in arcing time occurs with increase in natural frequency above the value where conductivity modifies the transients.

Only at natural frequencies below 2,000 cycles per second, corresponding to less than 45 volts per microsecond, did the arcing time decrease with decrease in frequency. Above 2,000 cycles per second, the arcing time was independent of the natural frequency or of the combination of components in double-frequency transients.

"De-ion Grid" Oil Circuit Breakers

The breaker used for this part of the test had a tank diameter of 30 inches, a stroke of 11¹/₈ inches, a contact separation of 10 inches and an average opening speed of about 8.2 feet per second. It was equipped with a heavy-duty type of "De-ion grid" of the type shown in Figure 2. The breaker was tested at normal operating voltages but well below its interrupting ability.

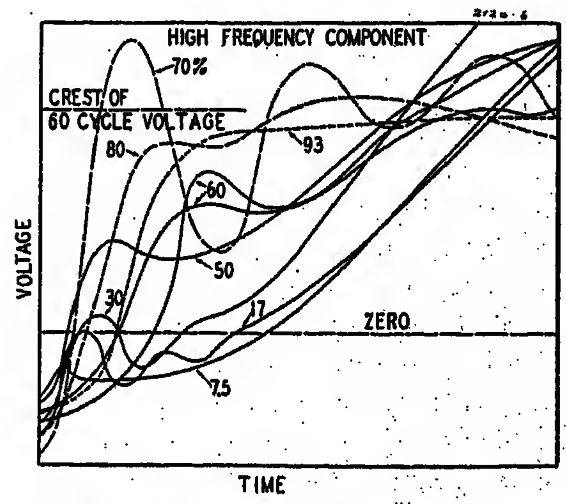

Figure 6. Plain-break circuit breaker, 3,800 volts, 2,600 amperes

Tracings of cathode-ray oscillograms for comparison with calculated transient voltages of Figure 3

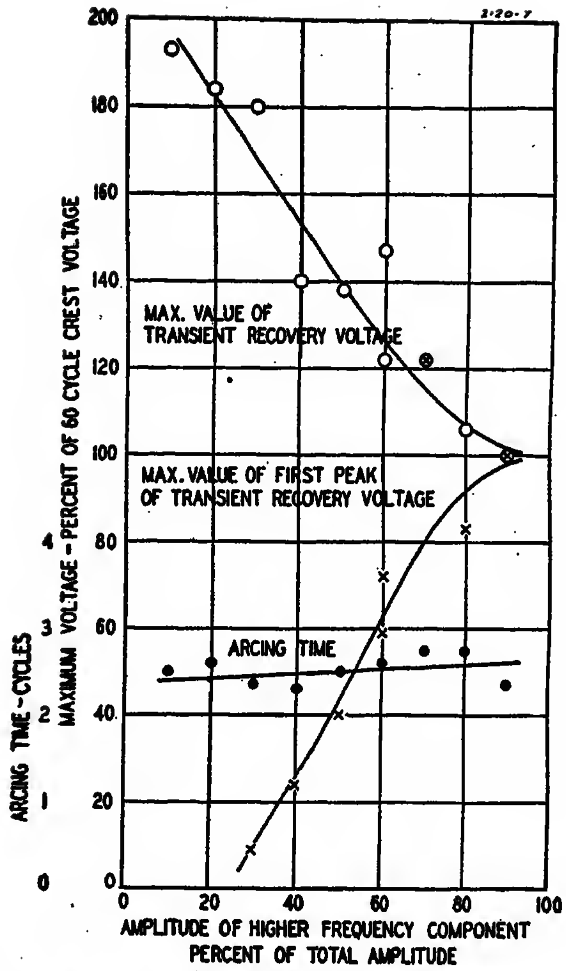

Figure 7. Plain-break circuit breaker, 3,800 volts, 2,600 amperes

Effect of the amplitude of the higher-frequency component

The tests made on this breaker were similar to those made on the plain-break circuit breaker. In many cases the circuits were the same, but the voltages and currents were higher.

One series of tests was made to determine the effect of varying the frequency of a single-frequency transient. This test was made at 7,620 volts 5,350 amperes. Frequencies from 375 cycles per second to 209,000 cycles per second were used.

The arcing time obtained on these tests varied with the natural frequency and voltage-recovery rate as shown in Figure 9. At the lower values the arcing times were less with a gradual rise up to a recovery rate of about 200 volts per microsecond. Above this voltage-recovery rate, no increase in the arcing time was obtained, although values up to 8,500 volts per microsecond were obtained with 209,000 cycles per second.

At the maximum frequency two of the four transient recovery voltages recorded were damped, and two were not damped by the conductivity of the arc space. Throughout these tests, the arc voltage had a tendency to rise and form an extinction peak. This resulted in some increase in the amplitude of the transient. The extinction peak indicates rapid deionization of the arc space and a high effective resistance at current zero. Consequently, damping of the transient was observed only at the highest natural frequency where the total energy of the oscillation was very small.

The preceding tests were supplemented by another series which showed that at 13,200 volts 8,000 amperes, the arcing time was constant for natural frequencies from 3,900 cycles per second up to 200,000 cycles per second. The highest natural frequency was practically completely damped by the energy discharged into the arc spaces, and the transient showed only the 32,000-cycle per second component having an amplitude about 15 per cent of the total. At the next step which had frequencies of 26,000 cycles and 42,000 cycles per second, the highest-frequency component was not appreciably damped, and the extinction peaks were definitely increased.

This breaker was also tested to determine its reaction to double-frequency transients. When the higher-frequency component is either very large or very small, the performance can be expected to be the same as the performance obtained with single-frequency transients corresponding to the predominant frequency. Accordingly, a series of tests was made at 7,620 volts 5,200 amperes with transients having components of two frequencies, one normally causing a shorter arcing time than the other. As the amplitude of the higher-frequency component increased, the arcing time increased as shown in Figure 10. The change in arcing time is gradual, and even small high-frequency components exert a noticeable influence.

These same relations were demonstrated at 15,000 amperes 7,620 volts, as shown on the same curve. The lower frequency varied from 594 cycles per second at the lower amplitude of the high-frequency component to 1,280 cycles per second at the higher amplitudes. These frequencies may be a little higher than those producing minimum arcing and may explain why the arcing time does not increase for high-frequency components greater than about 65 per cent of the total amplitude.

An attempt to get a similar curve at 7,620 volts 2,800 amperes failed, because at the lowest frequency available, 250 cycles per second, the arcing time was as long as at the higher frequencies. The first peak of the transient recovery voltage increased approximately linearly with the increase in amplitude of the higher-frequency component and indicated a negligible damping of the high-frequency component by the conductivity of the arc space. The maximum voltage reached during the transient was highest when one of the two components predominated and was lower when the two components approached each other in magnitude. The arcing time was practically independent of both the first peak and the maximum voltage of the transient.

The tests on this breaker demonstrated that the effect of single-frequency transients varied with the current. At 2,800 amperes no appreciable increase in arcing time resulted from increasing the natural frequency of the circuit above 250 cycles per second. At 5,200 amperes the corresponding point was 3,000 to 4,000 cycles, and at 15,000 amperes it was about 10,000 cycles.

Double-frequency transients demonstrated that the breaker performance varied gradually with the amplitudes of the two components. The limits were the two end conditions which occurred when either the higher-frequency or lower-frequency component was negligible.

Magnetic Blowout Air Circuit Breaker

During the development of a magnetic blowout air circuit breaker, tests were made in the high-power laboratory on single-phase circuits giving about 15,000 amperes at four kilovolts to determine the effect of recovery voltages on the arcing time and voltage-interrupting ability. These values were near the maximum interrupting capacity of the breaker. By

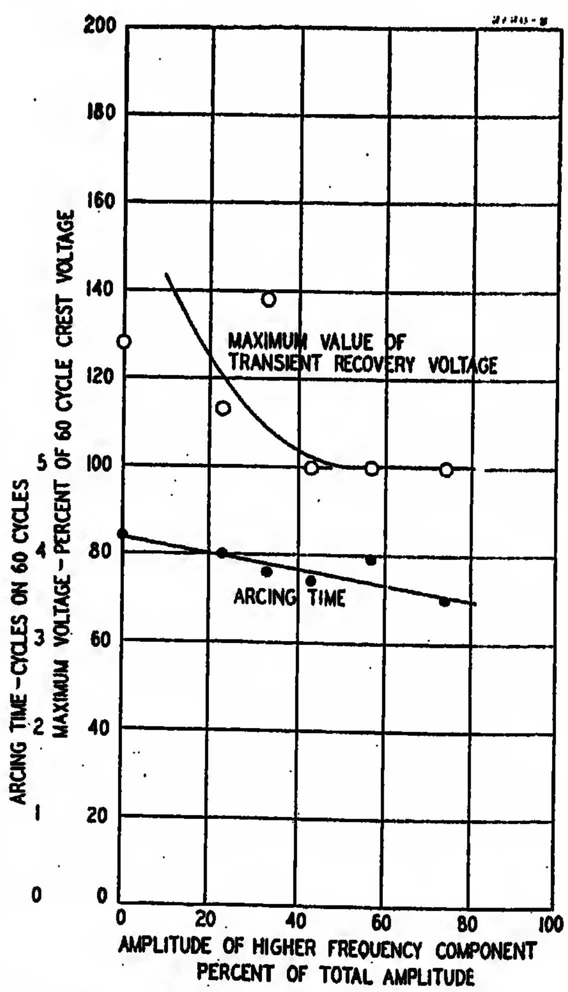

Figure 8. Plain-break circuit breaker, 3,050 volts, 6,000 amperes

Effect of the amplitude of the higher-frequency component

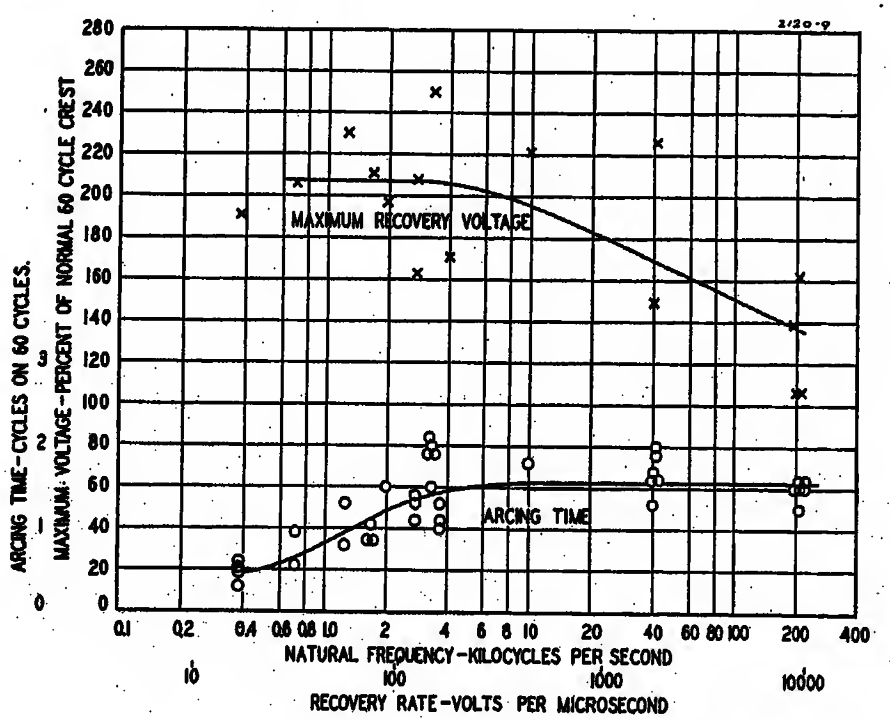
varying the capacitance of the circuit, natural frequencies from 3,880 cycles per second to 12,000 cycles per second were obtained. For still lower transient recovery voltages a resistor was connected across the breaker to simulate a parallel resistive load. Some of the transient recovery voltages obtained are reproduced in Figure 12.

The arcing time was less than one cycle and independent of the transient recovery voltage. This indicated that the arc was interrupted at the first current zero after it had reached a suitable location in the arc chute. The arc voltage prior to interruption was relatively high and smooth. The lack of an extinction peak indicated that there would be some conductivity in the arc space subsequent to the current zero, and this is further indicated by the subsequent damping of the recovery transients. The damping is very noticeable on the circuits having high frequencies at which the current through the arc space is comparable to the current into the capacitance. At the lower frequencies the damping is less pronounced, as the current into the capacitance is large with respect to the current through the arc space.

How large this current into the parallel capacitance can become is illustrated in a striking manner in Figure 13. This is a section of an oscillogram made on one of the tests at 4.4 kv, a little above the interrupting ability of the breaker, and on a circuit having a large parallel capacitance obtained by connecting to it three large power transformers. The natural frequency of the transient recovery voltage was 4,000 cycles per second. Due to the high test voltage, the arc continued to restrike, and traces of the natural frequency of the transient recovery voltage appear in the arc voltage. The transient at the time of restriking excited the resonant circuit and produced a sinusoidal current in it which modified the current through the circuit breaker sufficiently to produce a sinusoidal ripple on the arc voltage.

Figure 9. "De-ion grid" oil circuit breaker, 7,620 volts, 5,350 amperes

Effect of natural frequency of transient recovery voltage



With the transient recovery voltages of an oscillatory character, the breaker could interrupt about 4 kv regardless of frequency of the oscillation. By placing a resistor across the breaker to simulate a parallel resistive load, the breaker was able to interrupt 4.95 kv. Possibly the increase in the voltage was due to elimination of the tendency of the transient recovery voltage to reach crest voltages in excess of the normal crest of the 60-cycle recovery voltage.

This type of breaker, having a relatively high arc voltage, appears to be sensitive to the crest value which may be reached by the transient recovery voltage, but the arcing time remained constant from 3,880 to 12,000 cycles per second.

Compressed-Air Circuit Breakers

The compressed-air circuit breaker was the fourth type to be included in this investigation. One series of tests, made on a 15-kv 1,500,000-kva breaker with currents up to 36,000 amperes, showed that for circuit voltage-recovery rates of 1,500 to 2,250 volts per microsecond, the arcing time was substantially constant and lasted only to the first current zero after the contacts had been separating for one-tenth cycle. This resulted from the ability of the breaker to interrupt currents in this range at the first current zero, after contact separation adequate to hold this voltage was reached. Another series of tests over the same range, but with higher recovery rates varying from 2,600 to 3,800 volts per microsecond, showed that the minimum contact separation at which arc extinction could be accomplished varied with current. It corresponded to an arcing time of 0.35 cycle at 6,000 amperes (the same as for the lower recovery rate), and to an arcing time of about one cycle at 36,000 amperes, as shown by Figure 14.

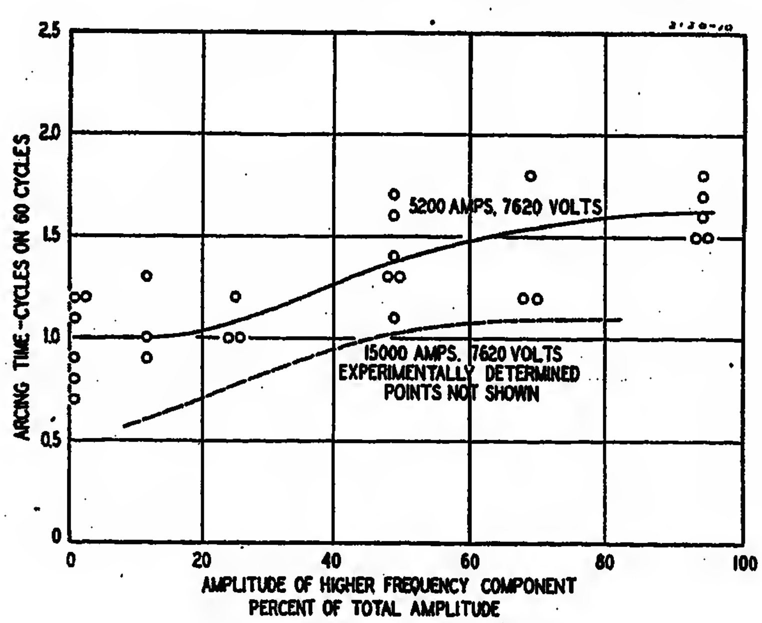
This increase in arcing time with current was not due to a corresponding increase in voltage-recovery rate. The increased arcing time was apparently associated with the increased difficulty of interrupting the heavier currents which have greater quantities of ionized gases and which approach current zero at higher rates.

This is an important relation, since it indicates the nature of the mechanism by which arc extinction is brought about. It indicates that the arc column is being deionized, and that this process requires more time as the diameter of the arc (and its current) increases. If the arc extinction were brought about by a breaking of the arc column and the separation of the two ionized sections of the arc, higher recovery-voltage rate, rather than higher current would require additional arcing time for the introduction of additional arc splitters.

These tests also show the sensitivity of the compressed-air circuit breaker to relatively low high-frequency components in the transient recovery voltage. At the maximum current setting and the lower recovery rate, 2,200 volts per microsecond, the transient was composed of a single component having a frequency of 28,500 cycles per second. For the higher recovery rate, about 2,600 volts per microsecond, the transient had two compo-

Figure 10. "De-ion grid" oil circuit breaker

Effect of the high-frequency component is roughly proportional to amplitude



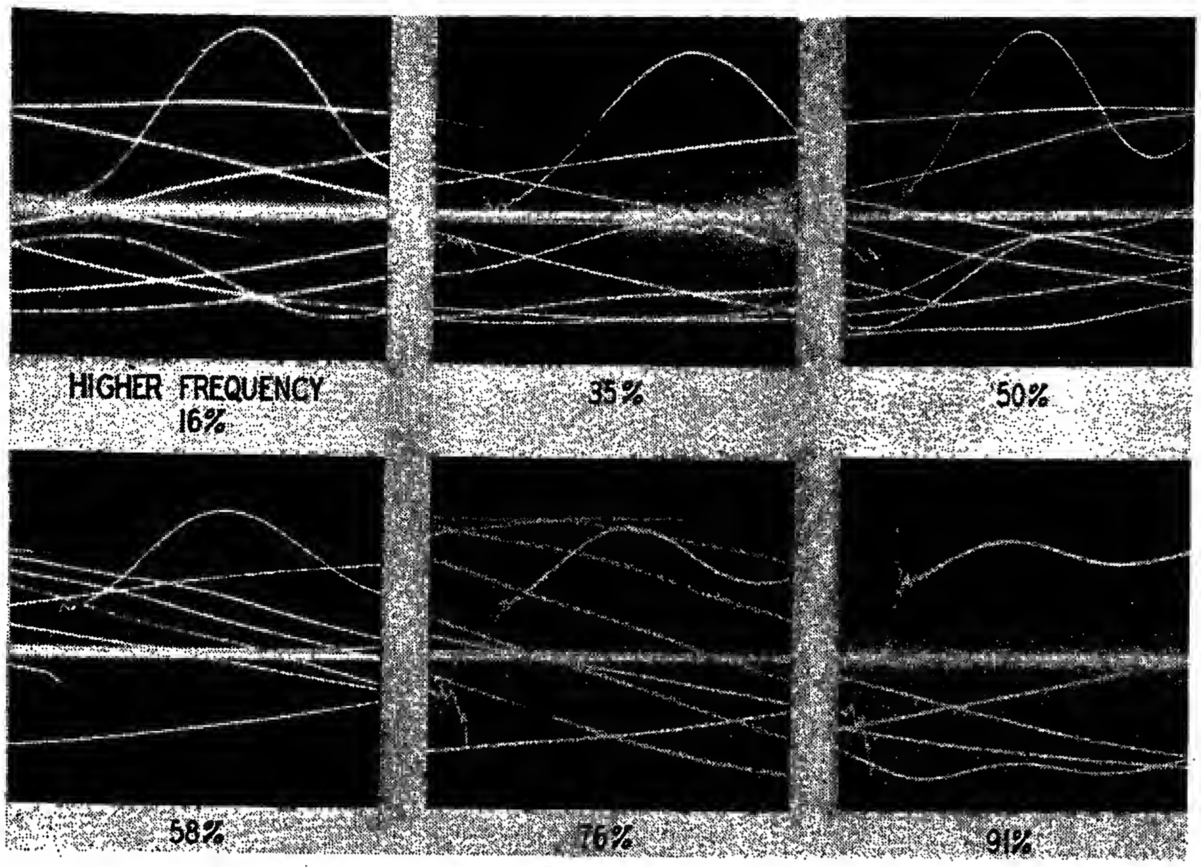


Figure 11. "De-ion grid" oil circuit breaker, 7,620 volts, 15,000 amperes

Cathode-ray oscillograms showing variation in high-frequency component

nents with frequencies of 33,600 and about 190,000 cycles per second. The amplitude of the 190,000-cycle component was only about 25 per cent of the total amplitude of the transient, but as shown by Figure 14, it caused at least a half-cycle increase in arcing time, and the last breakdown occurred at approximately the crest of this first peak of voltage, about 45 per cent of the crest of the 60-cycle recovery voltage.

The circuit transient recovery voltage on this setting, which would be based on zero arc voltage, would have a first crest of voltage about 57 per cent of the 60-cycle crest. This crest is below the 80 per cent which has been used as an arbitrary minimum voltage to be used in calculating circuit transient recovery voltage rates and emphasizes that lower amplitudes must be considered for some types of breakers. The circuit voltage-recovery rate to this first peak is approximately 4,600 volts per microsecond and, in this case, would be a better criterion of the circuit severity than the 2,600 volts per microsecond based on the second peak at 120 per cent of the 60-cycle crest voltage.

Tests made on another breaker of similar design, rated 15 kv 2,500,000 kva, supplemented the tests on the 1,500,000-kva breaker.

Tests varying the natural frequency of the transient recovery voltage from 3,900 to 200,000 cycles per second, and the circuit voltage-recovery rate from 300 to 13,600 volts per microsecond were made at 8,000 amperes 13,200 volts. The arcing time was practically constant over the entire range, varying in minimum and maximum value by only one or two tenths of a cycle.

The series of recovery voltage transients obtained on these tests and shown in Figure 15 is particularly significant and interesting. They show that at the lower frequencies, the transient is almost unaffected by the conductivity of the arc space. With smaller parallel capacitances, the charging current is less, and therefore the current through the breaker is relatively greater. The breaker current at moderate frequencies resulted in partial damping of the transient and finally at high frequencies became the controlling factor when the capacitance current became negligible with respect to it.

Other tests were carried up to 100,000 amperes, and the oscillograms indicated that the larger the current interrupted, the lower the effective resistance of the arc space at the final current zero. The approximate relations are shown on Figure 16. These resistances permitted sufficient current to flow subsequent to the normal current zero to partially damp the recovery transients at the higher currents.

Discussion

These studies of four types of circuit breakers indicate certain points of similarity in their performance, even though the manner in which arc extinction is produced within the interrupter differs considerably in detail between types. All of these types of breakers modify the transient recovery voltages. The means by which this is accomplished is the same, but the range in which the modification begins to appear, and the range in which it overcomes completely the oscillating tendency of the circuit vary with the types of breakers and not necessarily in relation to their rated voltages and rated interrupting currents.

All of the circuit breakers were tested over a sufficiently wide range to include both modified and unmodified transient recovery voltages. The modification was produced by the breaker when it passed a small current through the arc space subsequent to the final normal current zero. This was evidenced by the transient recovery voltage departing from the values

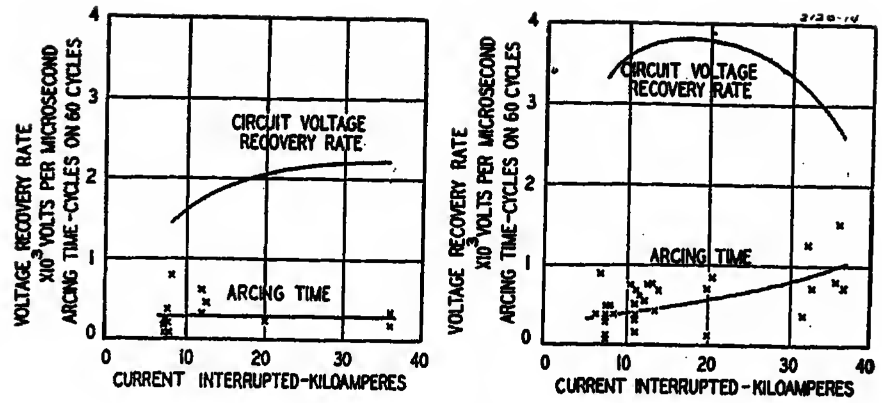

Figure 14. Compressed-air circuit breaker

Arcing time as a function of current interrupted for two series of tests made with different transient recovery voltages

which could be calculated for the circuit if all conductivity of the arc space was neglected. Also, the transient varied from test to test on the same circuit depending upon the conditions existing within the circuit breaker. The arc conductivity and rate of deionization are indicated roughly by the arc voltage prior to current zero.

The conductivity of the arc space at the time of current zero varies with the current being interrupted. This conductivity is a function of the ionization during the preceding half-cycle and the rate at which the space is being deionized. The ionization is produced by the current which will approach zero at a rate approximately a direct function of the rms current being interrupted. The residual ionization will depend on how rapidly these ions are removed.

In circuit breakers which use the energy of the arc to produce the deionizing effect, the rate of deionization might vary directly with the rms current, with the result that the right amount of deionizing activity would be present for each current. The larger the rms current being interrupted, the greater the rate at which the current approaches zero and the stronger the deionizing effect. The production and effectiveness of the deionizing action is probably never directly proportional to the current. Published data have frequently shown that breakers with self-generated deionizing action have shorter arcing times at high currents than at low currents. These shorter arcing times indicate that the deionizing activity produced by the arc is relatively stronger at the high currents.

Other breakers may have a deionizing activity produced by some source which is entirely independent of the current to be interrupted. For example, a compressed-air breaker delivers a deionizing blast of air, determined by the design of the circuit breaker and independent of the current being interrupted.

When very low values of current are interrupted, the deionizing activity may keep up with the current, and the conductivity at the current zero may be practically zero. Oscillograms made on various types of breakers show that even a short time before the normal zero in these low-current circuits, the arc may become unstable and extinguish suddenly, the current to the arc space transferring at this time to the path through the parallel capacitance of the circuit and resulting in a rise in the voltage across the breaker at the beginning of the transient recovery voltage. The oscillograms also show that this phenomenon, which mathematically can reach enormous voltages, is still under the control of the breaker, because, as the voltage rises, it cannot exceed the dielectric strength of the space between the contacts without the arc restriking. This dielectric strength, determined by ionization and contact separation, limits the voltages if an attempt is made to interrupt the current so early that the voltage rise is rapid and high. Oscillograms of a large number of tests on several oil and air breakers have indicated that the maximum voltage obtained in this manner probably is not over three times the normal crest of the line to ground voltage.

In other cases, the conductivity of the arc space may become zero as a current zero is reached, and the transient recovery voltage takes place in a manner which can be explained entirely on the basis of the inductance, capacitance, and losses of the power circuit. This type of phenomenon which is generally assumed in calculations may occur only at low currents, or it may extend even up to the rated interrupting current. In general, test data show that as the current is increased, the tendency for some of the ionization to remain at the time of current zero increases. From oscillograms made on the compressed-air circuit breaker, a curve was plotted to show qualitatively the relation between the equivalent resistance of the arc space at the time of current zero and the current which was being interrupted. Other types of breakers, including those having self-generated arc-extinguishing actions, have similar curves.

The residual ionization, lasting for an appreciable time interval after the normal current zero, acts as a variable resistor connected across the terminals of the circuit breaker. This residual ionization or conducting path between the breaker contacts permits a current to flow through the breaker during the time of the transient recovery voltage. This current is a function of the equivalent resistance of the arc space and the voltage impressed across it. It probably has only a very low current density in this space, and the deionizing activity can remove more ions than it produces. Calculations based on the voltage records and knowledge of the circuit characteristics have indicated that currents up to approximately 30 amperes have been carried through the arc space of breakers without the actual formation of an arc. The maximum value of current which can flow during this period without producing an arc probably depends upon the previous current and upon the design of the interrupter.

The actual value of current which flows through the arc space during the transient is, of course, very small with respect to the short-circuit current. In fact, it is too small to be indicated on a normal magnetic oscillogram of the interruption of a short circuit. It flows for only a part of the time consumed by the transient recovery voltage and is detected by its influence on it.

The significance of this small current lies in its magnitude with respect to the charging current which flows into the capacitance in parallel with the breaker. This capacitance can vary within wide limits. Its minimum value corresponds to the capacitance to ground of one terminal of a circuit breaker, a few feet of conductor, and one end of a reactor. Consequently, this current too can be very small. With about 200 micro-

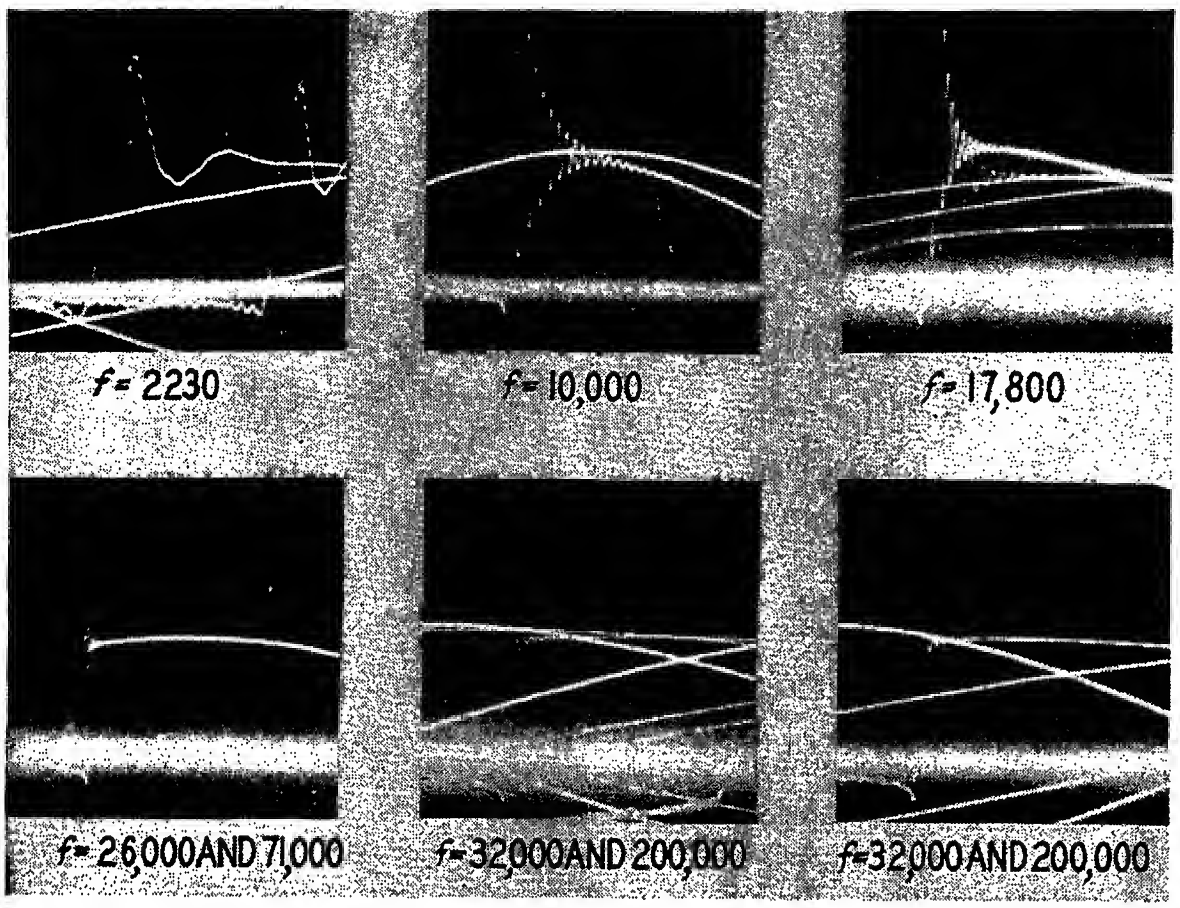

Figure 15. Compressed-air circuit breaker, 13,200 volts, 8,000 amperes

Cathode-ray oscillograms showing the effect of the natural frequency of the transient recovery voltage

microfarads, 200,000 cycles per second, and 7,600 volts rms to ground, it would be about two amperes. When the current through the breaker becomes comparable with the capacitance current, either by the increase of the one or the decrease of the other, it begins to exert a damping influence on the transient recovery voltage and, when large enough, critically damps the transient. For still larger currents through the arc path, the small current flowing into the capacitance becomes negligible, and the transient recovery voltage rises as though it were the voltage appearing across the resistance in a simple circuit containing resistance and inductance in series. As these values of resistance current and capacitive current are relative, the same results can be obtained by reducing the capacitance and thereby the capacitive current until such a point is reached that the current through the arc space is greater than the current through the parallel capacitance. These relations were demonstrated by these tests.

The testing of circuit breakers carried on in high-power laboratories at generator voltage can approximate closely the conditions under which the circuit breaker is to be used in service. The effects, if any, of differences in frequencies of the transients can sometimes be evaluated by a study of the test data to give a definite indication of the manner in which the breaker will perform in service.

The tests on the plain-break circuit showed that at very low values of natural frequency the recovery voltages were undamped. At higher natural frequencies damping of the transient recovery voltage appeared, and after a point of critical damping had been reached, further increase in the natural frequency of the transient recovery voltage resulted in no appreciable change in the actual voltage appearing across the circuit-breaker contacts. This was produced by the effect of the currents through the circuit breaker subsequent to the current zero. This current passing through the breaker was so large with respect to the current flowing into the parallel capacitance of the circuit that it controlled the transient recovery voltage, making it approach an exponential curve. After the point of critical damping was reached, further reduction in the capacitance across the terminals of the circuit breaker did not result in further increase in the severity of the duty on the circuit breaker. This was carried over a wide range above the critical damping without producing any appreciable change in these transients (Figure 5).

A similar set of cathode-ray oscillograms was obtained on the compressed-air circuit breaker, operating at a different current and voltage (Figure 15).

These data demonstrate that if a circuit breaker can successfully interrupt a given voltage and current and critically damp the transient recovery voltage, it can interrupt any other circuit having the same voltage and current and less parallel capacitance without any increase in the severity of the duty on the breaker.

Conclusions

These tests supplement each other to give a picture of the phenomena of arc interruption by high-power circuit breakers. They show that the interruptions brought about by air or oil breakers are similar in characteristics. In circuits having a low natural frequency, the recovery of the dielectric strength of the arc space proceeds with negligible influence exerted upon it by the slowly rising transient recovery voltage. The maximum value of the dielectric strength depends upon the distance between the contacts and the condition of the fluid or fluids filling the space. Above certain values of current and natural frequency, depending on the design of the breaker, the transient recovery voltage is impressed on the arc space while considerable ionization still remains. Consequently, a small current flows through this space, thereby hindering further deionization and modifying the transient recovery voltage. For very high natural frequencies this current may exceed the parallel current through the capacitance across the breaker and may control the transient recovery voltage. If the discharge current becomes too high, it develops into an arc which conducts current till the next normal current zero. The values of voltage, current, and natural frequency at which these phenomena occur vary with the designs of the breakers and not in proportion to their rated interrupting capacities.

The difficulty of circuit interruption

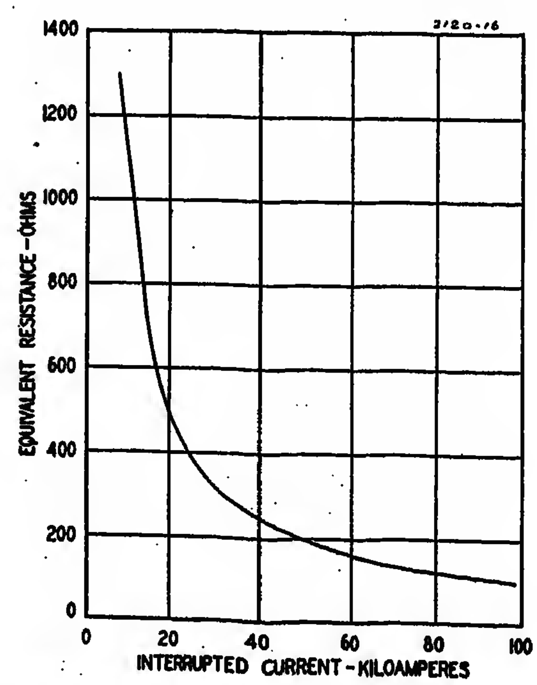

Figure 16. Compressed-air circuit breaker

Approximate resistance of the arc space at the time of the final current zero as a function of the current interrupted

does not increase indefinitely with increase in the natural frequency of the circuit. The speed with which the circuit tends to apply the transient recovery voltage to the circuit breaker varies directly with the natural frequency. However, if the current passed through the arc space is greater than the current through the capacitance across the breaker, further decrease in the capacitance does not materially increase the actual rate at which the voltage appears across the contacts and, consequently, does not make the circuit more difficult to interrupt.

The maximum arcing times on these tests were reached with transient recovery voltages having natural frequencies which were not heavily damped by the conductivity.

The tests indicate that the effect of the high-frequency component of a two-frequency transient voltage varies almost in proportion to the amplitude of the component. The effect is negligible when both frequencies tend to produce the same arcing time.

The transient recovery voltages obtained on high-voltage circuits energized through transformers can be equalled in high-power laboratories within the range of voltages and currents available. The laboratory circuits closely approximate the severe service conditions as the leads between the transformers and breakers are short. The lead capacitance is small with respect to the transformer capacitance, and, consequently, small variations in it are not significant.

At generator voltages, the reactors in the laboratory circuits have natural frequencies which are sufficiently high to produce the maximum arcing times in circuit breakers.

The plain-break oil circuit breaker at 3,800 volts 2,600 amperes did not increase in arcing time for natural frequencies above about 2,000 cycles per second. Similar points were found for the "De-ion grid" oil breaker, 250 cycles per second for 2,800 amperes, 7,620 volts, 3,000 to 4,000 cycles per second for 5,200 amperes, and 10,000 cycles per second for 15,000 amperes. The compressed-air breaker operating at 8,000 amperes 13,200 volts had the same arcing time for natural frequencies from 3,900 to 200,000 cycles per second, but at higher currents arcing times increased when the natural frequency was over 30,000 cycles per second. The lowest frequency at which the maximum arcing could be reached was not determined, but on a laboratory circuit a natural frequency of about 190,000 cycles was heavily damped, indicating that the maximum arcing time had been obtained.

Relative Expense for Service Restoration With Different Types of Overcurrent Protection for Distribution Circuits

G. F. LINCKS
ASSOCIATE AIEE

C. R. CRAIG
NONMEMBER AIEE

THE combination of line sectionalizing in the main feeder, individual protection at branch-line junctions, and reclosing relays and breakers at the substation has been shown to provide a cumulative reduction in consumer minutes outage (minutes of outage per consumer per year) that no one of the methods can provide alone.[1] Branch protection proved to be of greater value than line sectionalizing.

However, in order to be of any real assistance in efficient system planning, such knowledge of the ways and means to improve service continuity must be combined with an understanding of the expense involved in restoring service for all combinations and types of protective equipment that are available. Such "restoration expense" involves the man-hours required to locate the fault, to make any necessary repairs on the line, and to restore service, and involves also the automotive miles which must be traveled in doing it. Naturally, initial costs must be included for an over-all consideration of the economics of overcurrent protection.

Calculations and Presentation of Data

Separate studies were made on two different setups of the distribution lines, namely, one for branch protection, as in Figure 1, and another for line sectionalizing with protective devices connected in series as in Figure 2. The assumptions in the appendix are basically identical with those used in the previous study for the calculation of consumer minutes outage.[1] The minor changes involve interpretations as to what portion of this outage time is for location, repair, and restoration of service, and where automotive mileage is required. Thus, it is possible to correlate directly the service outage value of different combinations and types of protective equipment from the previous study[1] with the values now being presented for the "restoration time" and the automotive miles traveled.

The following special terms are used throughout the paper:

"*Restoration time*" is the minutes per year spent by the trouble crew for all faults from the instant of notification of an interruption in service until all necessary repairs are made and service is restored.

"*Automotive mileage*" is the miles traveled by the trouble crew in performing the duties listed under "restoration time."

Paper 42-129, recommended by the AIEE committees on power transmission and distribution and protective devices for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 21, 1942; made available for printing May 22, 1942.

G. F. Lincks, electrical designing engineer, and C. R. Craig are both with the distribution fuse cutout section of General Electric Company in Pittsfield, Mass.

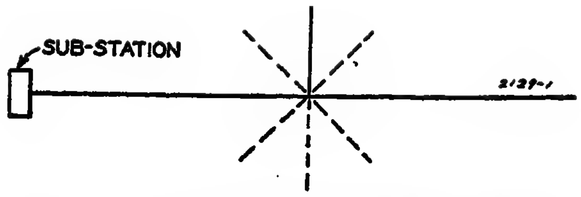

Figure 1. Individual branch-line protection added to 30-mile feeder

Branches located at center of feeder for average of even spacing along feeder

No. Branches	Total Length of Line: 1-Mile Branches	5-Mile Branches	10-Mile Branches
0	30	30	30
1	31	35	40
2	32	40	50
3	33	45	60
4	34	50	70
5	35	55	80
6	36	60	90

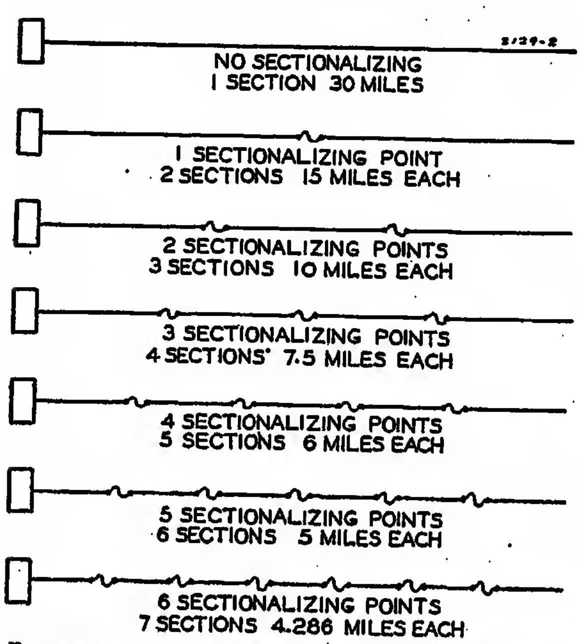

Figure 2. Line sectionalizing with protective devices connected in series on 30-mile line

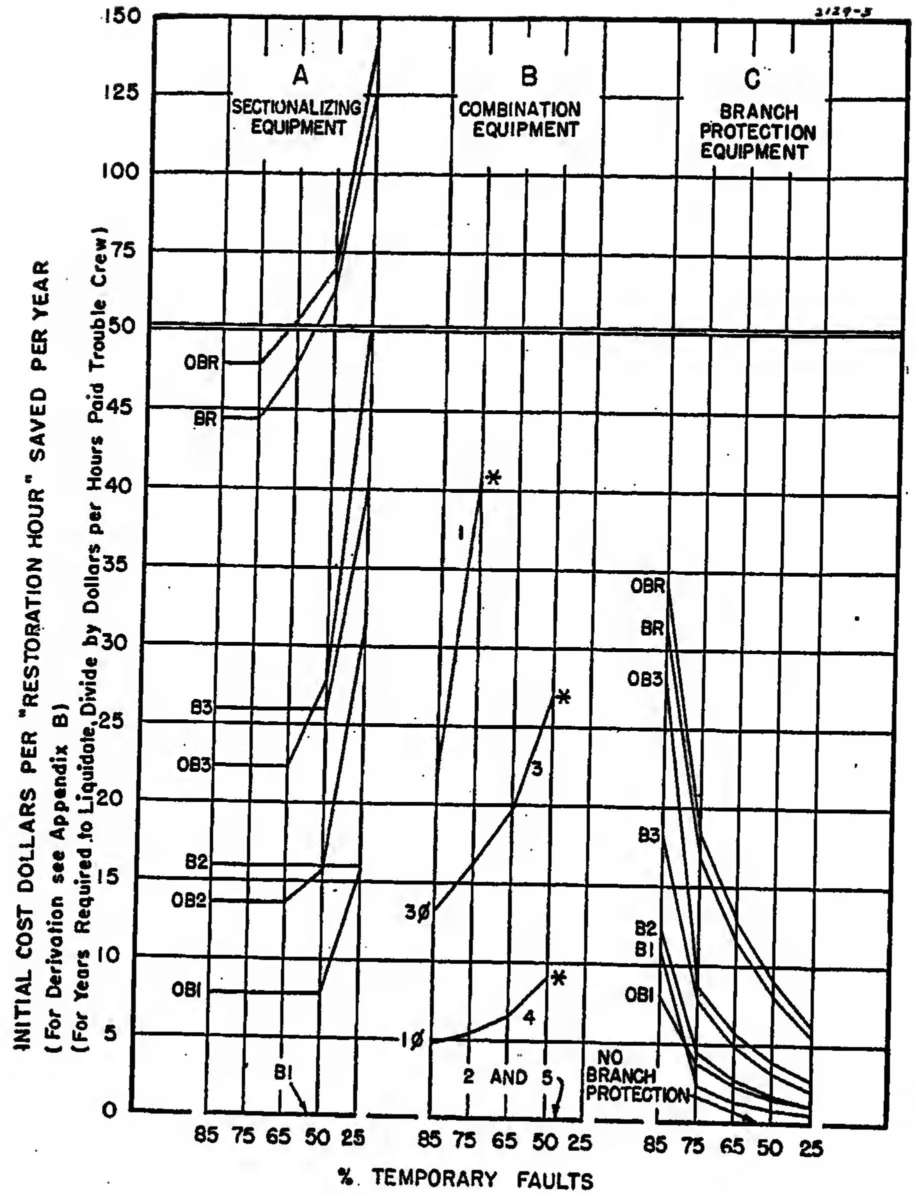

Figure 3. Curves showing cost per hour of "restoration time" saved per year to liquidate relative initial costs of protective equipment

Automotive mileage not included

Symbols defined in Figure 6

Column *A*. Curves for sectionalizing equipment show relative cost of making savings in "restoration time" over that required with single-element fuse cutouts

Column *B*. Curves for different combinations of equipment affording approximately equal service continuity show cost of saving in "restoration time" where made by higher cost equipment. *Such savings not made where curves not extended

Compare curve 1 with 2

Curve 1 for three resetting reclosers at sectionalizing points with three unprotected branches. Curves 2–8 for two-element reclosing cutouts, three at branches, five at sectionalizing points

Compare curves 3 and 4 with 5 (line sectionalizing only)

Curves 3 and 4 for three three-element reclosing cutouts three and one-phase circuits respectively

Curve 5 for five two-element reclosing cutouts one- or three-phase circuits

Column *C*. Curves for branch protection show the relative cost of savings in "restoration time" secured with different types and combinations of equipment

Observe that the cost of all reclosing equipment increases at a higher rate than the decrease in "restoration time" they provide

"*Restoration expense*" is the total expense for "restoration time" and automotive mileage.

The "yardstick" is either the "restoration time" in minutes per year or the automotive mileage per year caused by "permanent faults alone" with no automatic or manual line sectionalizing and no branch protection.

Using the assumptions in appendix A, calculations were made to determine the "restoration time" and the automotive mileage traveled for each system setup, and the values are given as a percentage of the "yardstick" on the curves, Figures 5 to 12 inclusive, that is:

$$\text{Per cent} = 100 \times \frac{\text{Actual calculated values for specific system setup*}}{\text{"the yardstick"*}}$$

By making comparisons in terms of this percentage, we eliminate to some extent the effect of departures of actual practice from the assumptions employed in the study. Wherever such departures might affect the calculations, an attempt was made to be conservative in showing benefits for line sectionalizing or branch protection with the less costly line protective devices.

Known first costs are brought into the picture to determine the length of time required to liquidate any increased initial costs for equipment which provides savings in "restoration expense," as in Figure 3. (See also appendix B.).

The Curves

The data are given in curve form showing the percentage of the "yardstick" for varying arrangements of line protection. Figures 5 to 10 inclusive are for *branch protection*, and Figures 11 and 12 are for *line sectionalizing* with a number of protective devices connected in series. While these data may not fit a specific circuit exactly, they should be sufficiently close to be usable in planning the overcurrent protection on practically all distribution systems.

Actual Values for "Yardstick" Affect Comparisons

In addition to comparing the percentages given on the curves, it is important to consider also the value of the "yardstick" and the calculated values for specific cases in terms of the actual "restoration time" in minutes per year or the automotive mileage per year. Since we have assumed a constant number of total faults, the "yardstick," which is based on "permanent faults alone," is obviously lowest with 85 per cent temporary faults. It increases to a maximum at the 25 per cent temporary faults as shown in Table I. These values would increase or decrease respectively if extended beyond the 25 to 85 per cent range that was studied.

Much greater "restoration time," automotive mileage, and consumer minutes outage are required to locate, repair, and restore service with a permanent fault than just to restore service with a tem-

* The calculated values and the "yardstick" may be in terms of either "restoration time" in minutes per year or automotive mileage traveled per year.

porary fault. Thus, as the percentage of temporary faults becomes greater, the "restoration time," automotive mileage, and consumer minutes outage caused by equipment opening on temporary faults increases less than the decrease in these values as caused by permanent faults. Because of this relationship, the calculated actual "restoration time" and automotive mileage for 25 per cent temporary faults are greater than that for 85 per cent temporary faults. This relationship is reversed when the calculated values are given as a percentage of the "yardstick" as on the curves, Figures 5 to 12 inclusive. This shift in relationship is important when evaluating the benefits secured by the use of the more effective device which usually costs more (see Figure 3).

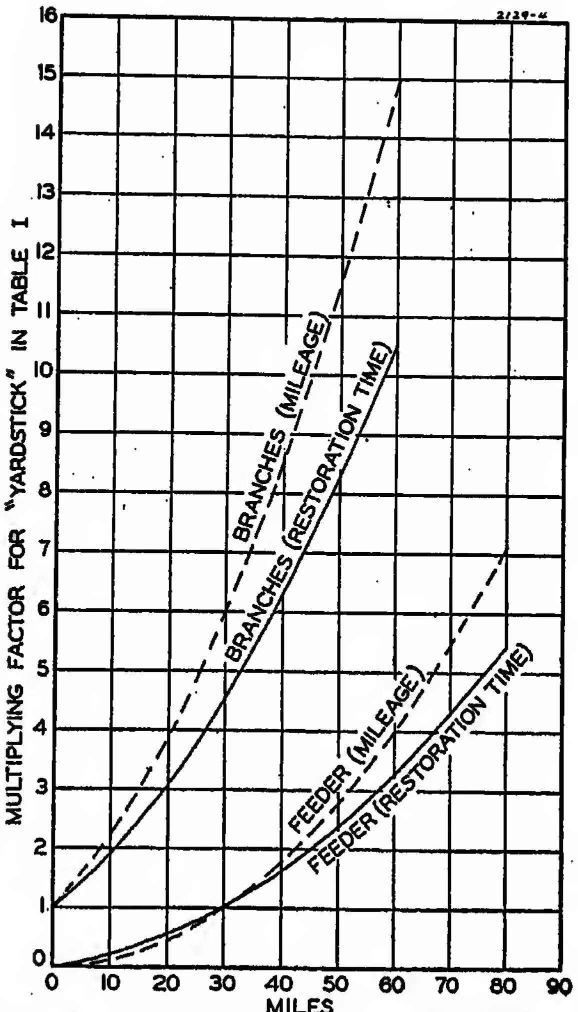

Figure 4. Conversion curves for determining "yardstick" with different lengths of feeder and total length of branches

How to use data:

1. Determine the multiplying factor
(1). For the proper length of the feeder
(2). For the total length of all the branches
2. Multiply the "yardstick" in Table I by the multiplying factor for the feeder
3. Multiply the corrected "yardstick" determined in item 2 by the multiplying factor for the branches

Observe that the "yardstick" is increased more by adding mileage to branches than by increasing the length of the feeder

Some Protective Devices Can Be Connected in Series in Greater Numbers Than Others

More two-element than three-element reclosing fuse cutouts can be connected in series and co-ordinated to provide about equal improvement in service continuity. Figures 11 and 12 indicate that the use of a greater number of two-element than three-element cutouts may increase the normal differences in "restoration expense" for these two devices at the higher percentages of temporary faults. However, when the difference in the initial costs of these two types of cutout is divided by the savings in "restoration expense," it shows that the cost per hour of "restoration time" saved per year by the use of the three-element design would be quite high, especially for three-phase circuits. For example, the use of two-element cutouts at five sectionalizing points and three-element cutouts at three sectionalizing points provides approximately the same service continuity. A comparison of these, as in Figure 3 (column *B*, curves 3, 4, and 5) indicates that from 6 to 13 years might be required to liquidate the extra cost of three three-element cutouts per phase on a three-phase 30-mile circuit, with a wage rate of one dollar per hour per man for a two-man crew.

A similar comparison is made in Figure 3 (column *B*, curves 1 and 2) to show the effect of the limitations in co-ordinating automatic resetting reclosers with fuses at branch junctions or at transformers. The use of three two-element cutouts to protect three branches added to a line sectionalized with the five two-element cutouts provides at least equal service continuity to that provided by three reclosers at sectionalizing points on the same line with the three branches unprotected. With 85 and 75 per cent temporary faults Figure 3 indicates that from 11 to 20 years respectively will be required to liquidate the additional cost of the reclosers with a wage rate of one dollar per hour per man for a two-man crew. With 65 and lower percentages of temporary faults the use of the two-element reclosing cutouts in the branches makes possible lower "restoration time" as well as a lower initial cost and a slight improvement in service continuity.

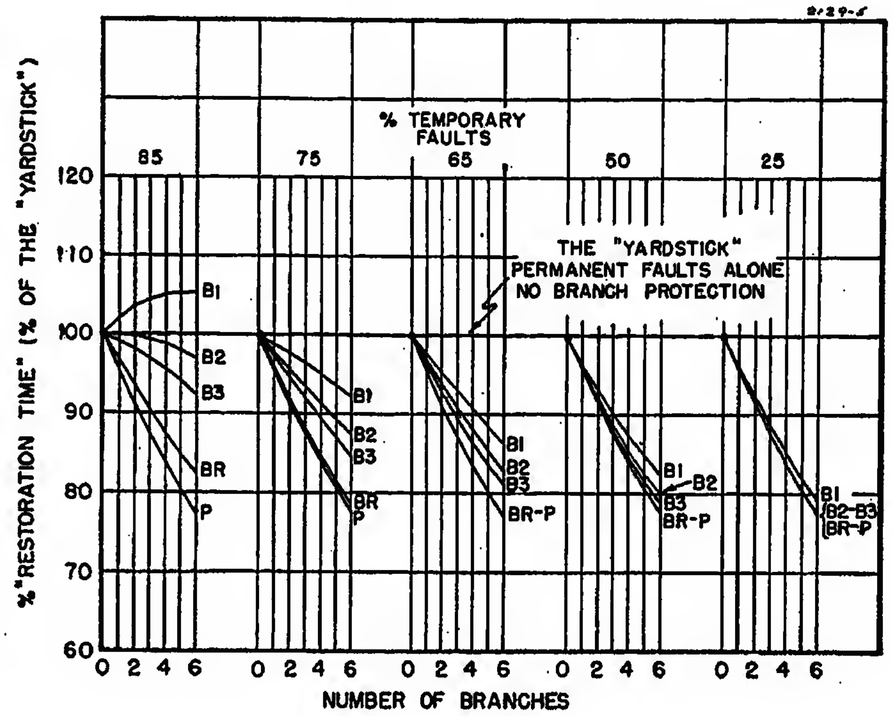

Figure 5. "Restoration time" for protected one mile branches employing nonreclosing or reclosing substation breakers and all available types of branch protective equipment

Symbols defined in Figure 6

Observe that a saving is made for all but single-element fuse cutouts when used with nonreclosing substation breakers at 85 per cent temporary faults

Effect of Nonreclosing and Reclosing Substation Equipment

With no line sectionalizing or branch protection, "permanent faults alone" are the only cause for sending out the trouble crew. The restoration of service after a temporary fault by manual or automatic reclosing of the substation breaker involves only the station attendant and thus the type of equipment employed has no effect on the "restoration time" or automotive mileage.

Combining Branch Protection and Line Sectionalizing

The cumulative effect on "restoration time" and automotive mileage of combining the protection of a number of short branches with line sectionalizing can be approximated from the data on the curves, Figures 5 to 12 inclusive. See appendix C for description of how to do this.

Where the circuit consists of two or more long branches, each branch should be studied separately from the standpoint of line sectionalizing and branch protection. Then the cumulative effect should be determined by adding or subtracting

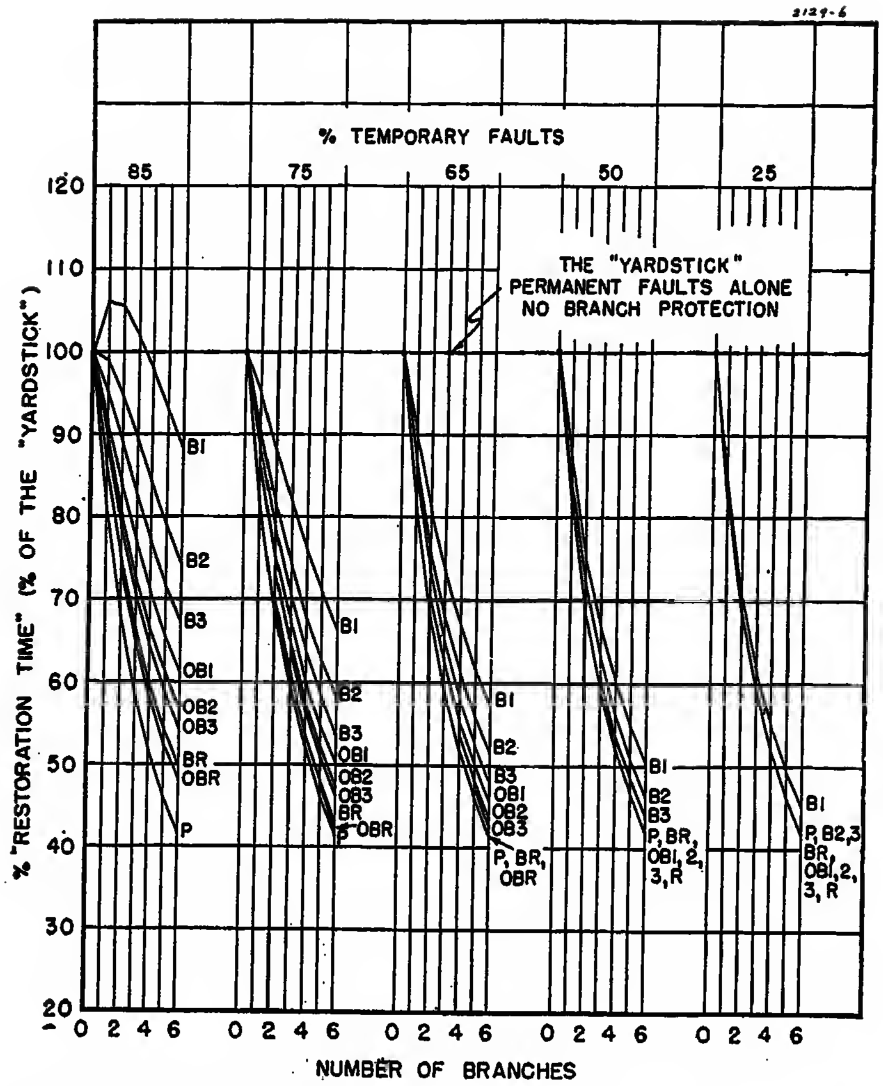

Figure 6 (left). "Restoration time" for protected five-mile branches employing all available types of substation and branch protective equipment

B=Nonreclosing or reclosing breaker at substation

OB=Overlapping reclosing breaker at substation, set for instantaneous tripping on first opening with all types of line protective equipment delayed to open only ahead of second opening of breaker

1=Single-element fuse

2=Two-element reclosing fuse

3=Three-element reclosing fuse

R=Automatic resetting recloser

P=Permanent faults alone—all temporary faults cleared with only a momentary outage

(These are combined to show type of substation and line equipment employed)

Observe:

1. The major reduction in "restoration time" for "permanent faults alone" with the branches protected

2. The comparatively small increase in "restoration time" for outages caused by equipment opening on temporary faults

3. Single-element fuses provide the major portion of the reduction obtainable except at 85 per cent temporary faults

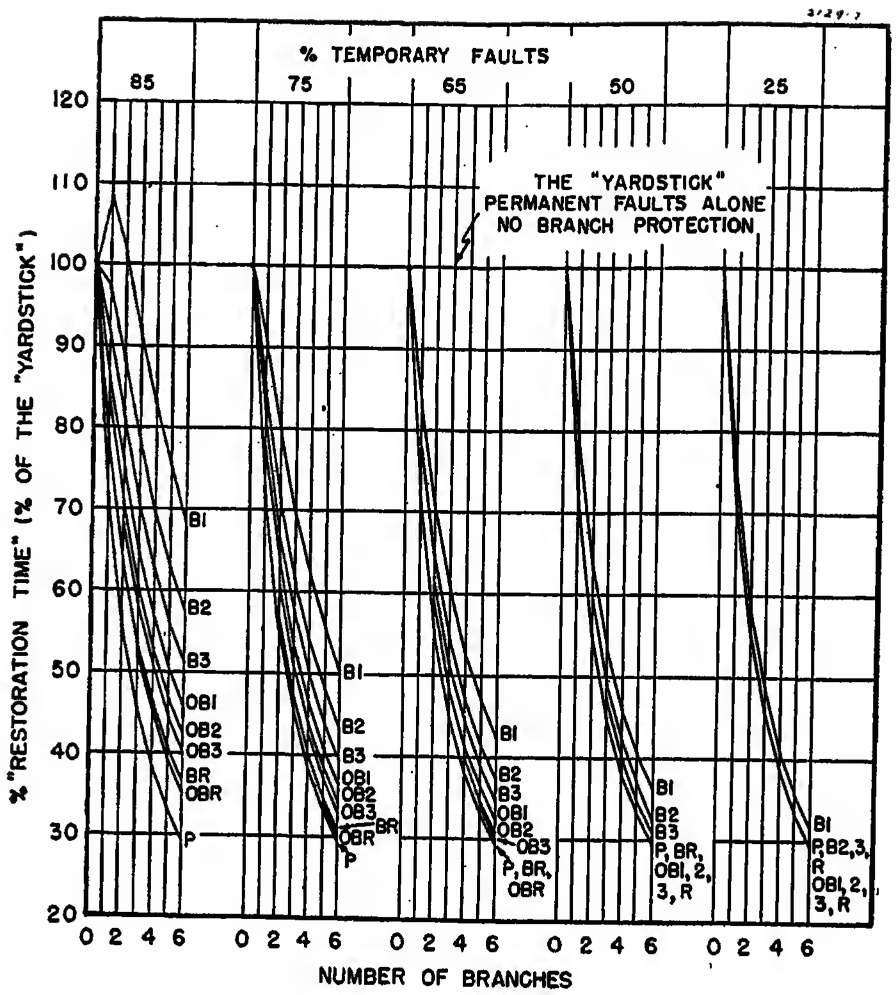

Figure 7. "Restoration time" for protected ten-mile branches employing all available types of substation and branch protective equipments

Symbols defined in Figure 6

Observe that the reduction in "restoration time" is greater with ten- than with five-mile branches with all other relationships being proportionally the same

the percentages as described in appendix C.

For Reclosers Which Do Not Reset Automatically

The conclusions drawn and the data in the curves for reclosing fuse cutouts apply to any type of apparatus with an equal number of reclosers and without the feature of automatically resetting after clearing a temporary fault.

Conclusions

Some general conclusions can be drawn from the study, although it is anticipated that the data will prove even more helpful in system planning when applied to the problems of specific circuits.

Substation Equipment

1. The substitution of reclosing for nonreclosing breakers at the substation, while improving service continuity, has no effect on the "restoration time" or automotive mileage (unless the substation attendant's time to manually reclose the breaker is classed as "restoration time").

2. Overlapping the substation reclosing protection with all line protective devices provides a major reduction in "restoration time" and automotive mileage. It is quite effective when combined with branch protective devices. (With such overlapping the breaker trips and recloses once without the branch or line protective device opening for all faults out to the ends of the line, and then the relay provides time delay so that the branch or line-sectionalizing protective device disconnects the faulted portion of the circuit ahead of the second tripping of the relay.)

3. Such overlapping protection of the entire line is the most economical of all system setups providing automatic reclosing, when both "restoration expense" and initial costs are considered.

4. Where such overlapping protection as in paragraph 2 reaches only part way out on the line, the decrease in "restoration time" and automotive mileage over a nonreclosing or reclosing breaker is only approximately one quarter of the decrease provided by overlapping the whole line.

Branch Protection Reduces Maintenance

1. Overcurrent protection of individual branches generally reduces "restoration time" and automotive mileage, even with short branches. The exceptions are with only a few or very short branches at high percentages of temporary faults where the actual number of minutes and miles are small (see Figures 5 to 10 inclusive).

2. The length of the branch has a major effect on the "restoration time" and automotive mileage.

3. Overcurrent protection of individual branches provides less reduction in terms of actual "restoration time" and automotive mileage at higher percentages of temporary faults than at the lower percentages.

4. The savings in "restoration expense" with branch protection are less likely to liquidate the initial cost of all types of overcurrent protective equipment at higher percentages of temporary faults than at

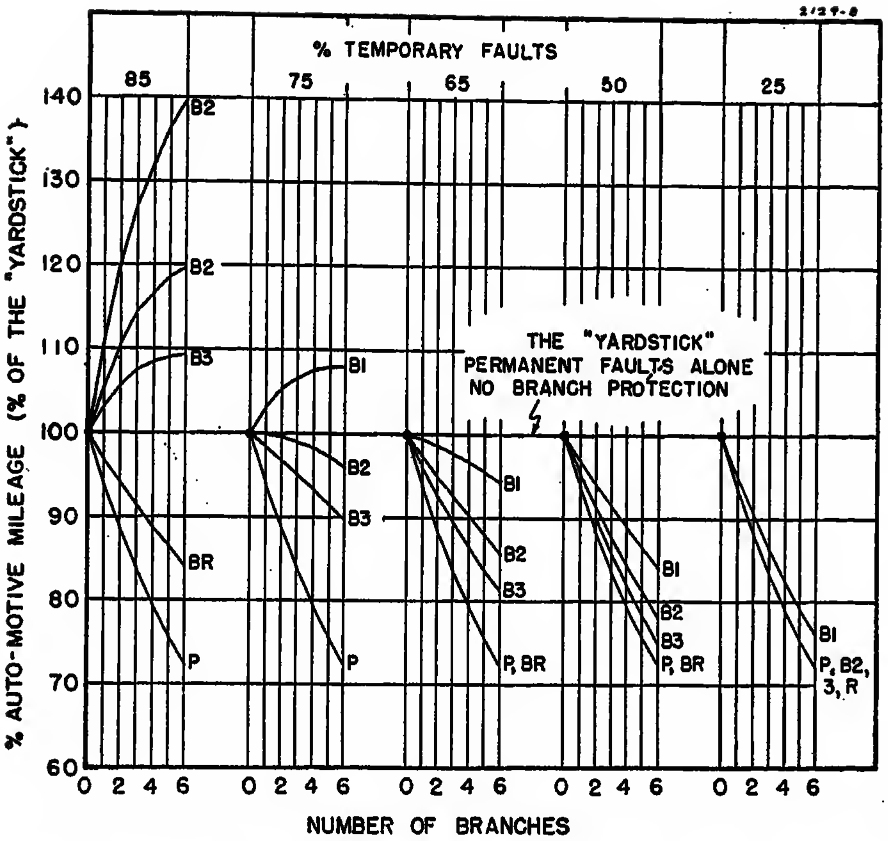

Figure 8. Automotive mileage for protection of one-mile branches employing nonreclosing or reclosing substation breaker and all available types of branch protective equipment

Symbols defined in Figure 6

Observe that the saving in automotive mileage for "permanent faults alone" is greater than the saving in "restoration time" (Figure 5). Also that the effect of outages caused by temporary faults is greater. However, the actual values for the "yardstick" in terms of automotive mileage is much less than for "restoration time"

the lower percentages, where the protective orbs of the substation relay and breaker includes the whole line.

5. Single-element fusing of branches, five miles and longer, is the most effective in saving sufficient "restoration time" and automotive mileage to liquidate the initial investment. Only a few years are required because of the comparative low first cost to the savings effected. For example, with 30 miles of single-phase branches on a 30-mile feeder and a wage rate of one dollar per hour per man for a two-man trouble crew, the liquidation would be effected in about 1 to 2.5 years. The exception is with 85 per cent temporary faults where the actual minutes and miles saved are too small to offset the initial cost of even single-element cutouts within a reasonable time.

6. Two and three-element reclosing fuse cutouts and automatic resetting reclosers provide reductions in "restoration time" and automotive mileage which are worthy of consideration. However, this saving is not proportionate with the increase in initial costs over that for single-element fuse cutouts.

7. Reclosing breakers at the substation which overlap single-element fuses at a num-

Figure 9 (below). Automotive mileage for protected five-mile branches employing all available types of substation and branch protective equipment

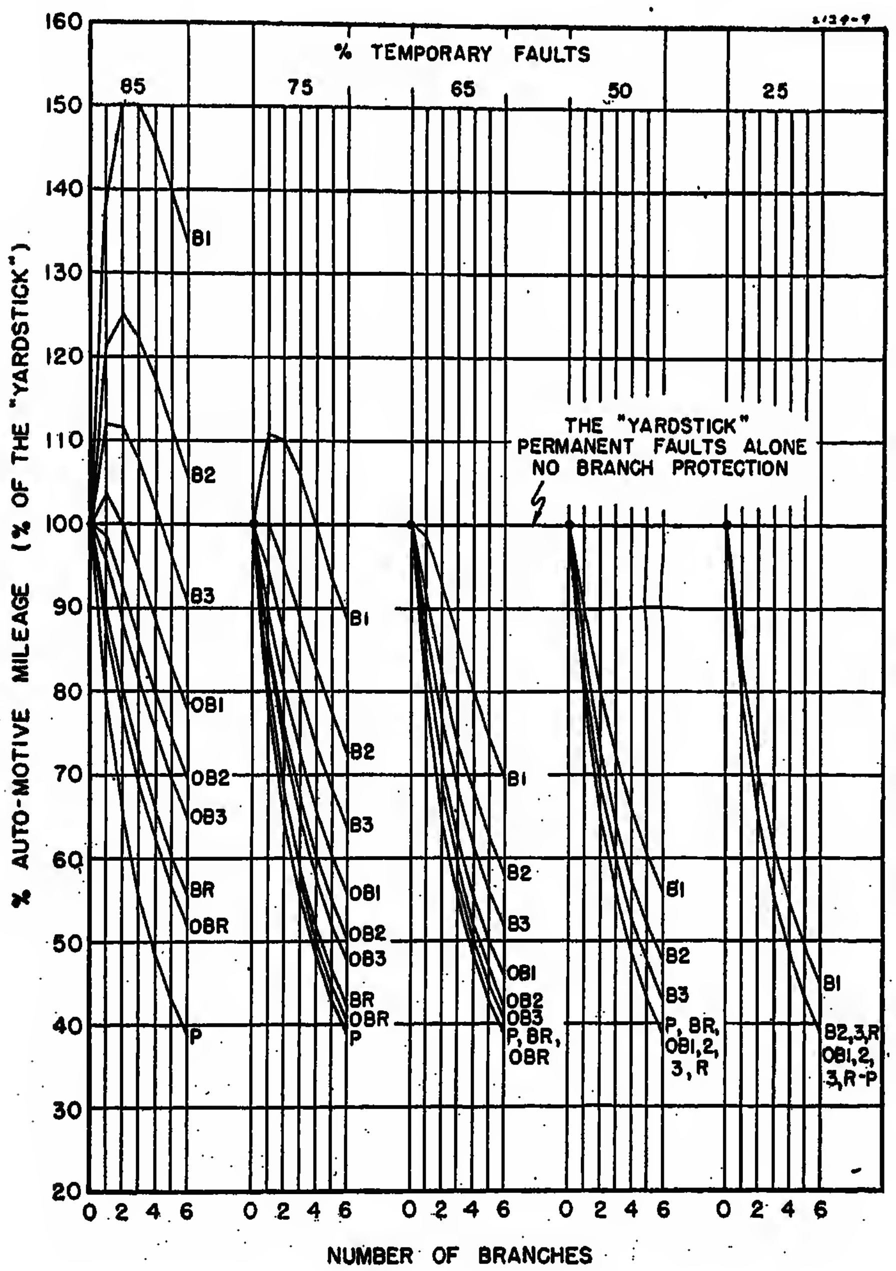
Symbols defined in Figure 6

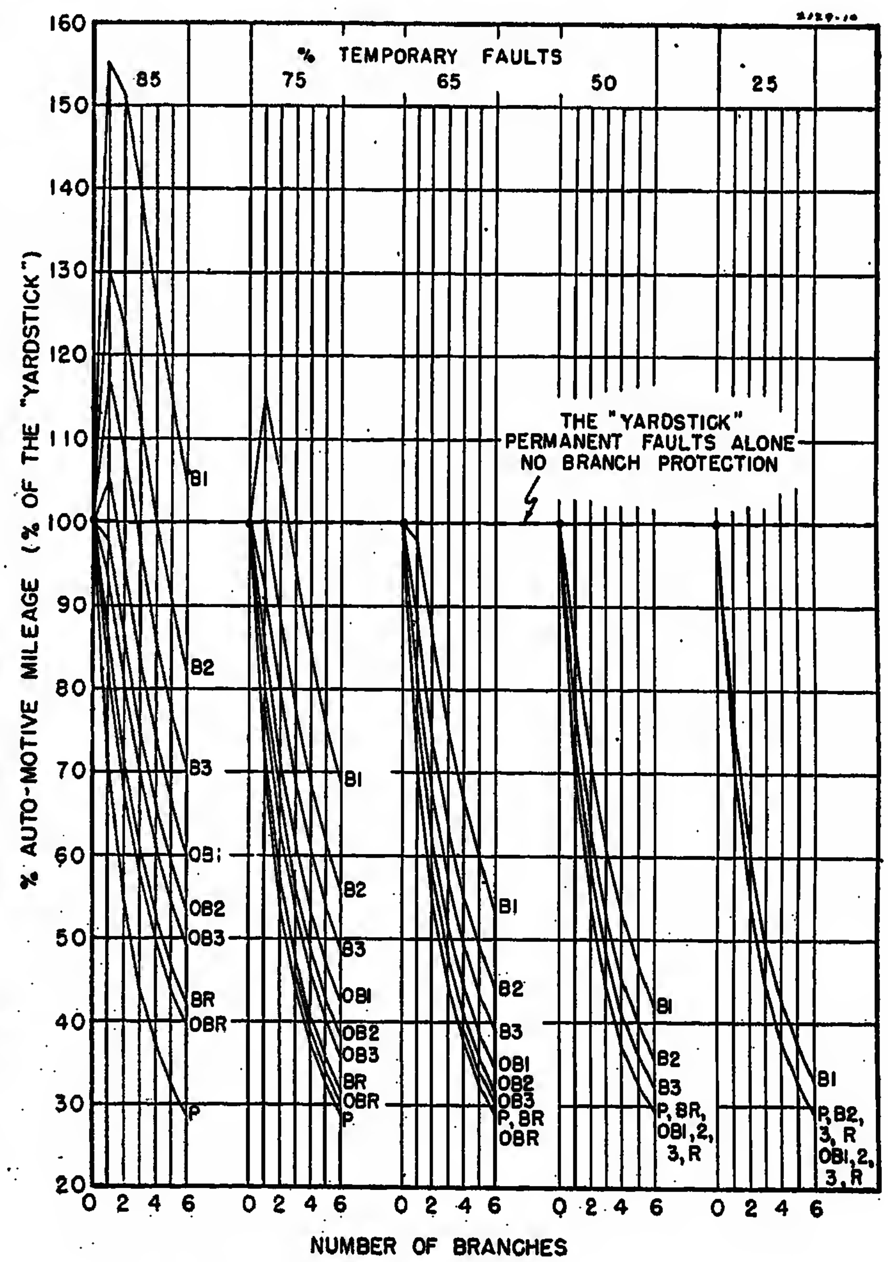
Observe the same greater reduction in automotive mileage for "permanent faults alone" and the effect of outages caused by temporary faults as observed in Figure 8

Figure 10. Automotive mileage for protected ten-mile branches employing all available types of substation and branch protective equipment

Symbols defined in Figure 6

Observe that the reduction in automotive mileage is greater than with one- and five-mile branches (Figures 8 and 9), and that the effect of outages due to temporary faults is proportionately greater, especially at the higher percentages of temporary faults





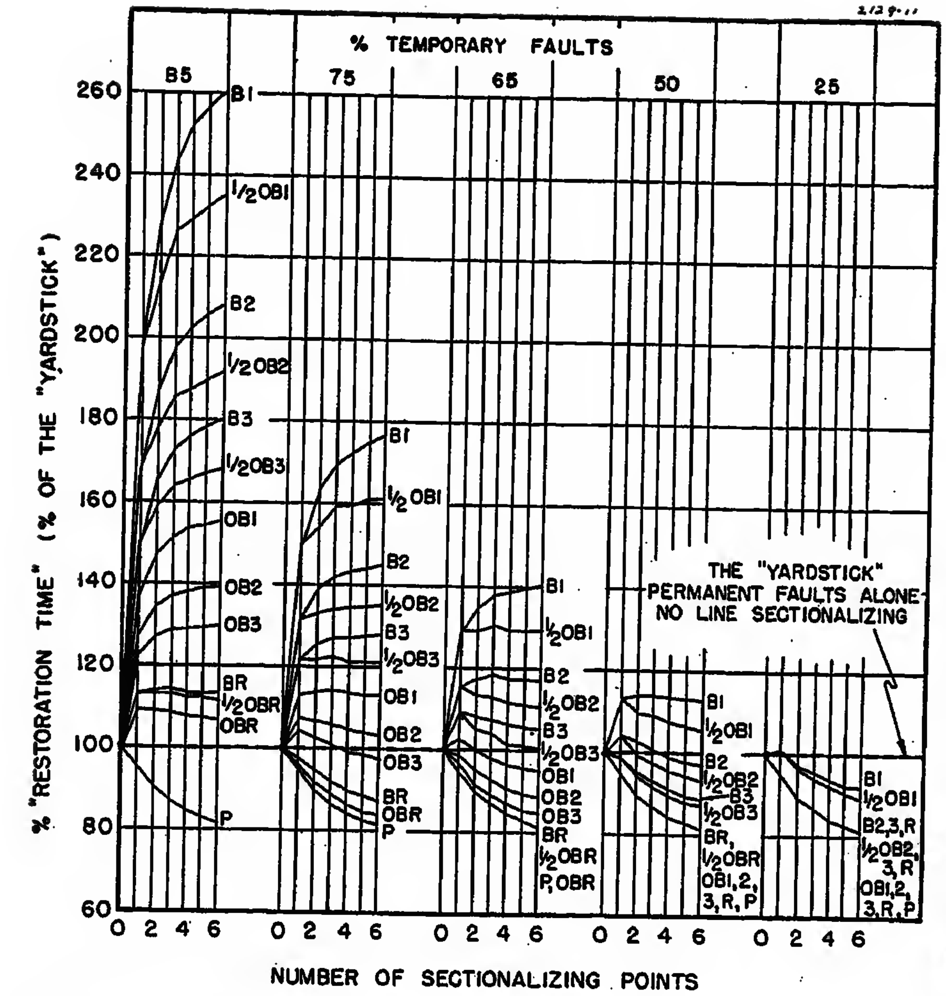


Figure 11. "Restoration time" with line sectionalizing employing all available types of substation and line overcurrent protective equipment

$^1/_2OB$ = overlapping reclosing breaker at substation, protection for only half of line

Other symbols defined in Figure 6

Observe:

1. The "restoration time" as caused by "permanent faults alone" is reduced only slightly by line sectionalizing
2. The effect of outages caused by devices opening on temporary faults is greater than with branch sectionalizing
3. Therefore, line sectionalizing generally increases "restoration time"

(This increase amounts to only about ten hours per year with single-element fuses at 85 per cent temporary faults on a 30-mile feeder)

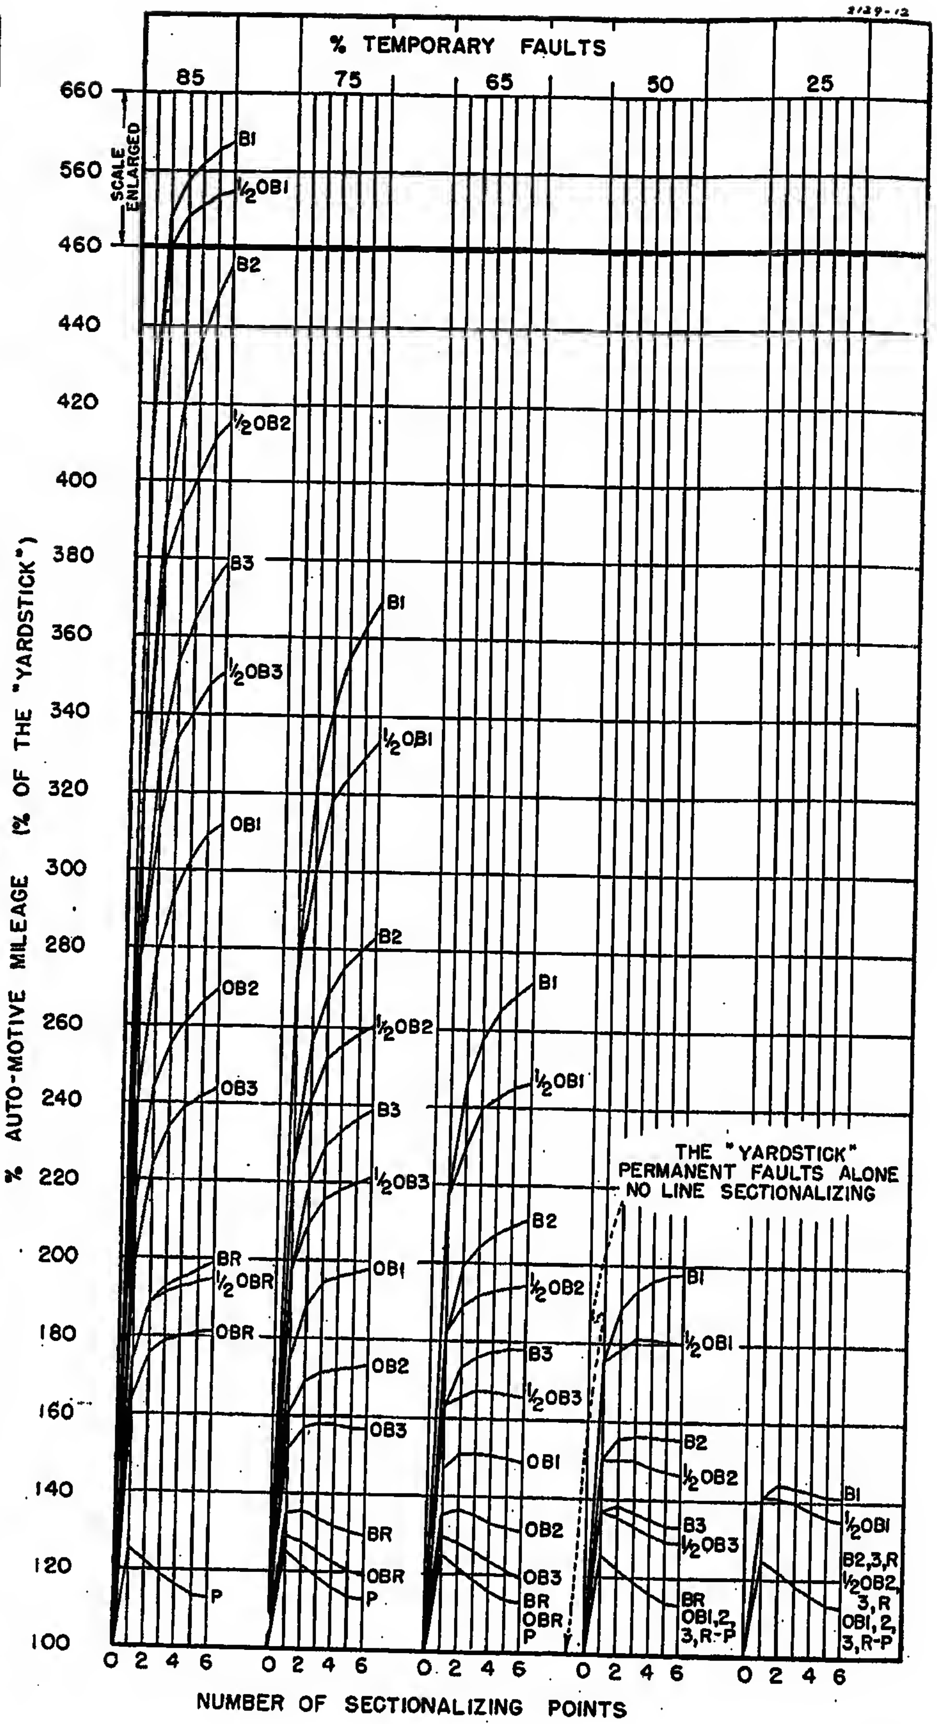

Figure 12. Automotive mileage with line sectionalizing employing all available types of substation and line overcurrent protective equipment

$^1/_2OB$ = overlapping reclosing breaker at substation, protection for only half of line

Other symbols defined in Figure 6

Observe:

1. The automotive mileage even for "permanent faults alone" is increased by line sectionalizing
2. As with branch protection, the effect of outages caused by temporary faults is greater than with "restoration time" (Figure 8)

ber of branch junctions provide more savings in "restoration time" and automotive mileage than three-element cutouts with reclosing breakers. This combination is almost as effective as single-element fusing of branches without overlapping protection in having the savings in "restoration time" offset the initial costs, at 75 and lower percentages of temporary faults, and is more effective at 85 per cent.

8. Consideration of the economic value of reducing the percentage of temporary faults appears to be justified. Such a reduction for the line as a whole might be obtained by the use of reclosing devices on a branch or branches having a much higher percentage of temporary faults than the line as a whole.

Automatic Line Sectionalizing

1. Automatic sectionalizing of the main feeder (and long branches treated as feeders) with protective devices connected in series generally increases "restoration time" and automotive mileage and thus must be justified by the savings in revenue and the improvement in customer good will resulting from the better service continuity. However, the automatic resetting reclosers reduce "restoration time" and automotive mileage, as do two and three-element reclosing fuse cutouts at 50 per cent temporary faults and lower, and reclosing breakers which overlap single-element and reclosing cutouts at 65 per cent and lower (see Figures 11 and 12).

2. The increase in actual "restoration time" and automotive mileage even with single-element fuse cutouts generally is comparatively small.

3. Automatic sectionalizing with single-element cutouts requires the most additional "restoration time" and automotive mileage but at a minimum over-all cost, see Figure 3, column 1. Therefore, sectionalizing with single-element cutouts may be justified economically in many instances.

4. Overlapping reclosing substation breakers combined with single-element fusing at sectionalizing points requires less additional "restoration time" and automotive mileage than sectionalizing with three-element reclosing cutouts and with a lower total first cost. This is especially true on three-phase circuits. (Only the additional equipment for the special relaying was considered necessary at the substation.)

5. Sectionalizing with automatic reclosing equipment provides a greater reduction in "restoration time" and automotive mileage compared to single-element cutouts than when the comparison is made with branch protection. However, as in the case with branch protection, the reduction in "restora-

tion time" and automotive mileage is not proportional with the increase in initial cost except possibly on lines appreciably longer than 30 miles.

Branch Protection and Line Sectionalizing Should Be Combined

The cumulative benefit obtained by combining branch protection and line sectionalizing should not be overlooked. Sectionalizing with equipment, the characteristics of which are such as to preclude branch protection, prevents the securing of major reductions in "restoration time" and automotive mileage.

Manual Line Sectionalizing

Manual line sectionalizing generally is employed where automatic protection has not been adopted. With manual sectionalizing "restoration time," automotive

the percentage of temporary faults, especially in the range above 75 per cent.

2. If the percentage of temporary faults is decreased, less costly equipment generally will provide equal or better service continuity with lower "restoration time" and automotive mileage.

3. A reduction in the percentage and thus the number of temporary faults on a specific system lowers the total number of faults and provides greater reductions in "restoration time" and automotive mileage than is shown in this study, where the total number of faults remain constant.

Use of Data for Continuing Expansion of Knowledge

Although over-all values of combining branch protection, line sectionalizing, and reclosing relaying at the substation as presented are based on a set of rigid assump-

Table I. Actual Calculated Values⊖ for "Yardsticks" for Feeder Without any Branches† or Manual Line Sectionalizing

Values Decrease as the Percentage of Temporary Faults Increases

Units in Which Calculated Actual Values Are Expressed	Per Cent Temporary Faults 25	50	65	75	85
	Actual Values for Permanent Faults Alone*				
Consumer minutes outage per year	2,137.5	1,425	996.25	712.5	427.5
"Restoration time" in minutes per year	2,137.5	1,425	996.25	712.5	427.5
Automotive mileage per year	337.5	225	157.5	112.5	67.5

⊖ The values in this tabulation are based on a 30-mile feeder. To convert the values for longer or shorter feeders, use the multiplying factors as determined in Figure 4.

* These actual values will not apply exactly to any system, but the relationship shown should apply about proportionally. To determine actual "restoration time" and automotive mileage for any system setup, multiply the "yardstick" by the percentage for that setup as given on curves 5 to 12 inclusive.†

† The values in this tabulation do not apply directly to feeders with branches. Corrections can be made by use of the multiplying factors for the total length of all branches as determined from Figure 4.

mileage, and consumer minutes outage are caused by "permanent faults alone" and thus are the same percentages of the "yardstick" at all percentages of temporary faults. Therefore, automatic sectionalizing and branch protection, which may cause outages on all or some temporary faults, are less likely to be justified over manual sectionalizing at the higher percentage of temporary faults (above 75 per cent) than is indicated when compared with the "yardstick." This is especially true on a feeder with relatively long branches where manual sectionalizing eliminates traveling out and back on a number of the branches in search of the fault.

Lowering of the Percentage of Temporary Faults Should Be Considered

1. Since outages caused by temporary faults make all types of equipment less efficient in attaining the minimum values for "permanent faults alone," consideration should be given to the economics of reducing

tions, these data should facilitate more efficient planning of overcurrent protection on specific systems. It is hoped that these data will be extended, or if necessary, modified as the result of operating records secured in actual practice.

Appendix A. Assumptions Employed in Mathematical Study

The same general assumptions employed in the study to determine the relative value of different types of overcurrent protection for distribution circuits in terms of service continuity[1] were used in continuing the mathematical study to check the effect on "restoration expense." All of the assumptions pertinent to the present study are tabulated below:

1. *The Distribution Lines Studied (Length of Lines)*

(*a*). In one part of the study one to six unprotected and protected branches, each one, five, or ten miles in length, were added at the mid-point of an unsectionalized 30-mile main feeder, increasing the total length of line, as in Figure 1. (The greater total length will increase the actual "restoration time" and automotive miles, but when these are expressed as a percentage of the "yardstick" (for "permanent faults alone" without branch protection), the effect of the length is cancelled. Thus the percentage shown on curves of Figures 5 to 10 inclusive for any system setup can be applied to any length of line or branches, if the "yardstick" is modified as directed in Figure 4. Connecting the branches at the mid-point provided an average for an even spacing of the branches along the feeder.)

(*b*). In the other part of the study, a 30-mile main feeder was broken up into from one to seven sections by zero to six overcurrent protective sectionalizing devices connected in series as in Figure 2.

2. *Equipment Employed.* Both studies included checking comparative results with overcurrent protection provided by:

(*a*). Substation breakers actuated by nonreclosing or automatic reclosing relays, and automatic reclosing relays which overlap all branch and line protective equipment so that the breaker trips and recloses once without the branch or line devices opening, and then provides time delay before the second tripping of the relay on more persistent faults; each combined with

(*b*). Sectionalizing or branch-line protection with single-element or two and three-element reclosing fuse cutouts or reclosers which reset automatically after clearing a temporary fault.

3. *Number and Type of Faults.* One fault per mile per year uniformly distributed with temporary faults equaling 25, 50, 65, 75, and 85 per cent of the total. (One fault per mile is probably somewhat high. Any lower value might have been used without changing the percentages used for comparison but would decrease the values for the "yardstick" in Table I and would change the values in Figure 3—decreasing these values for cost of "restoration" with line sectionalizing in column *A* and increasing the values for the cost to secure the savings with branch protection in column *C*).

4. *Attended Substation.* No "restoration time" was included for the substation attendant to close the station breaker or to notify the trouble crew. ("Restoration time" for temporary faults was zero, regardless of whether service was restored by manual or automatic reclosing of the station breaker. Thus, there is no difference in man-hours of "restoration time" or automotive mileage for nonreclosing or reclosing relays and breakers.)

5. *Trouble Crew.* Consisted of one man who was always available at the substation to start instantly with no time allowed for notification or preparation. (More often the crew consists of two men to meet safety requirements, but any multiple of one will have no effect on the percentages used in the presentation of the data. The actual "restoration time" in Table I can be multiplied by the exact number in the crew if over one, to make the values comparable with the utility's actual practice, see also the directions on Figure 3. Also, the crew is more likely to be out on the system, sometimes closer to and sometimes farther from the fault location, so that this assumption provided an average.)

6. *Time to Locate Fault, Make Necessary Repairs, and Restore Service.* The trouble crew:

A. With no branch protection or line sectionalizing (All temporary faults cleared when breaker locks open. Service restored by station attendant. Trouble crew required for "permanent faults only.")

(*a*). Traveled 15 miles per hour to the mid-point of the feeder as the average, and out to the mid-point

of each branch and back as the average for each branch.

B. With automatic line sectionalizing and individual branch protection

(*a*). Traveled 30 miles per hour to the sectionalizing point at which the protective device had opened. No time was allowed for examining sectionalizing or branch protective devices en route, as it was assumed that these would have indicating features visible from the car.

(*b*). Spent five minutes to climb the pole and to restore service if a temporary fault had caused the outage at the sectionalizing or branch protection point.

(*c*). Traveled 15 miles per hour to the mid-point of the branch or section on which the fault persisted. The mid-point provided the average for the uniform spacing of faults.

(*d*). Spent 30 minutes repairing a permanent fault. In a majority of cases the trouble crew will repair faults without calling for the assistance of the line crew, generally in less than 30 minutes. Where the services of the larger line crew are required, the time would generally exceed the 30 minutes average. This makes the values presented more conservative than actual practice.

(*e*). After repairing the fault:

1. No time was allowed to notify the substation attendant when he was required to close the breaker (although some time probably would be required for notification which would have increased the values of the "yardstick" Table I and the "restoration time" or automotive mileage for outages caused by temporary faults. This would have shown greater benefits for line sectionalizing and branch protection for reclosing cutouts and especially for automatic resetting reclosures).

2. The crew traveled 30 miles per hour to return to the sectionalizing or branch protective device to restore service.

3. No "restoration time" or automotive mileage was included after service was restored, since the crew might then be headed for another job to which the additional mileage and time would be charged.

7. *Service Restoration by First, Second, Third, and Fourth Reclosures* was assumed to be 50 per cent of the total number of faults for devices which reclose once, 65 per cent for those which reclose twice, 70 per cent for those which reclose three times, and 73 per cent for combinations which reclose four times (see Table IV in appendix of previous study[1]). This gives maximum advantage to three-element reclosing fuses and other multireclosing devices, as compared with two-element reclosing fuse cutouts, since these values for perfect operation are low for the first reclosing and high for the second as compared with operating experience. Some data show as high as 75 to 90 per cent restoration of service following the first reclosure.

8. *No Inspection With Reclosing Fuse Cutouts Was Assumed.* Because such inspection would have permitted refusing before an outage occurred, the data indicate only the minimum benefit for these devices.

(This benefit would be increased to a degree approaching that of the device that resets automatically, as such fuse renewal before the occurrence of an outage approaches 100 per cent. The percentage of such discovery and renewal is fairly high, because linemen and trouble crews are on the lookout for the indicating devices as they pursue their regular duties along the lines.)

Fuse renewal is accomplished in a few minutes while they are at the installation, without any traveling time or mileage as was included in the calculated values presented. Thus all reclosing fuse data are ultraconservative.

9. *The Protective Orbit of the Substation Breaker* (which is determined by minimum pickup current of the relay) included the whole feeder and all of the branches. In many instances distribution lines have outgrown this orbit. Consequently, the lower current individual protection of the branches and line sectionalizing on the otherwise unprotected portion may prevent burning down lines or annealing of the conductors. Such faults would require a long time to repair and might necessitate the assistance of the line crew. Conversely, this lower current protection may cause outages which might otherwise have burned clear. Depending on the type of equipment, after such outages service will be restored automatically or will require the trouble crew to go out to the sectionalizing or branch protection point in order to restore service. There would have to be a large number of such trips to equal the "restoration time" required for one case of putting back up lines burned down because of lack of protection.

Table II

Assumed Initial Costs Used for Figure 3	Cost Each†
Single-element fuse cutouts	$ 7.00
Two-element fuse cutouts	17.00
Three-element fuse cutouts	32.00
Automatic resetting reclosers	85.00
Additional relay equipment*	58.00

† These initial costs are approximately correct. Additional material other than the crossarm will be negligible as mounting hardware is furnished with the devices. Installation costs are not included as they will vary on different systems.

* It was assumed that induction-type reclosing relays and breakers are available.

No actual data are available on this relationship. However, it would appear that the "restoration time" in the area beyond the protective orbit of the station breaker would be reduced perceptibly by line sectionalizing and branch protection. This would decrease the higher "restoration time" and automotive mileage shown in this study for line sectionalizing, where the protective orbit encompassed the whole line, and would increase the savings shown for branch protection.

Appendix B. How to Determine the Cost Per Hour of "Restoration Time" Saved Per Year to Liquidate Relative Initial Costs of Protective Equipment

This is the method employed in figuring the values in Figure 3. It is applicable to the studying of automotive mileage costs as well (substitute mileage values for "restoration time" and proceed as described). Since with line sectionalizing the "restoration time" is increased over that for no sectionalizing, the comparison is made with the single-element cutout which requires the greatest "restoration time." Branch protection generally provides a reduction in "restoration time" from that with no protection and thus the comparison is made with the "yardstick" to determine the cost of securing this reduction.

Procedure

1. Determine the percentage for specific system setup from curves 5 to 12 inclusive, making additions for the cumulative effect of combining branch protection and line sectionalizing as described in the text.

2. Determine the actual "restoration time" for each specific system setup by multiplying the "yardstick" from Table I (modified if necessary for variations in length of the total line as described in Figure 4) by the percentage determined in paragraph 1.

3. Determine the difference in actual "restoration time" for the equipment being compared.

4. Determine the difference in initial costs of the equipment required for each system setup (see Table II).

5. Divide the difference in costs by the difference in "restoration time" to determine the cost per hour of "restoration time" per year.

6. Divide the values determined in paragraph 5 by the total wages per hour paid the trouble crew to determine the number of years required to liquidate the difference in initial cost (as determined in paragraph 4). Formulating this:

$$\text{Cost per unit† saved/year} = \frac{\begin{pmatrix}\text{unit† for less}\\ \text{effective device}\\ \text{(from item 2)}\end{pmatrix} - \begin{pmatrix}\text{unit† for more}\\ \text{effective device}\\ \text{(from item 2)}\end{pmatrix}}{\text{Cost of more effective device*} - \text{Cost of less effective device*}}$$

$$\text{Number of years to liquidate} = \frac{\text{cost/unit saved†/year}}{\text{dollars per hour paid trouble crew}}$$

Appendix C. How to Combine "Restoration Time" or Automotive Mileage Values for Branch Protection, Figures 5 to 10 inclusive, With Those for Line Sectionalizing, Figures 11 and 12

1. Where both cause "restoration time" or automotive mileage greater than 100 per cent (the "yardstick"), add to the percentage on one curve the percentage above 100 per cent on the outer curve, that is:

Resultant per cent = (per cent on one curve) + (per cent − 100 on other)

2. Where one system causes "restoration time" or automotive mileage greater than 100% and the other system less than 100 per cent, subtract from the first percentage the value of 100 − the second percentage, that is,

Resultant per cent = (per cent which is greater than 100 per cent) − (100 − per cent which is less than 100 per cent)

* The cost value should be either the initial cost or the installed cost.

† The unit used may be in terms of restoration hours per year or automotive mileage per year.

Tests and Analysis of Circuit-Breaker Performance When Switching Large Capacitor Banks

THE increased kilowatt burden on generation and transmission equipments—occasioned by the existing national emergency—calls for a reduction in the use of these equipments for generating and transmitting reactive kilovolt-amperes. When operating conditions permit the use of either capacitors or synchronous condensers, the relatively shorter production time of capacitors is making them more and more justifiable as a reactive source in the range of kilovolt-ampere ratings where economics might normally dictate a synchronous condenser.[1] At the present time the use of capacitors in banks up to 10,000 kva is being given increased consideration, and several installations having steps in this range have already been made.

With this growing use of capacitors, it is becoming increasingly necessary to apply adequate power circuit breakers to the task of switching these large banks, either totally or in steps, on and off the system. It has long been recognized that the job of switching capacitive circuits, such as long unloaded transmission lines, can become difficult, and it therefore logically follows that both the duty on the breaker and its effect on the system during switching of large capacitor banks should be investigated.

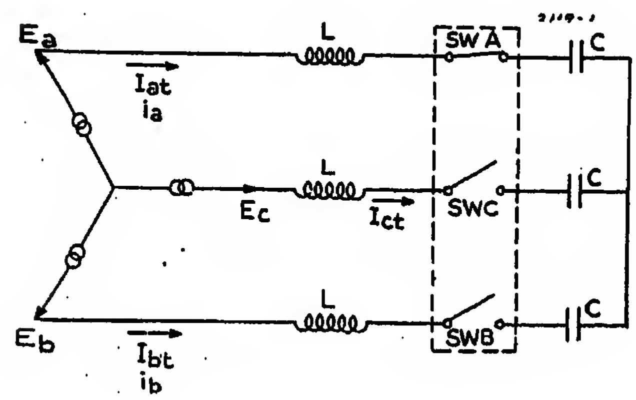

Figure 1: Transient-analyzer circuit for determining effects of sequential pole closing

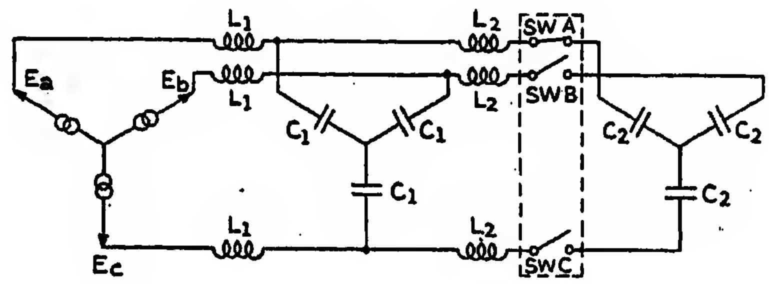
(a). Total capacitor bank energized

(b). Capacitor bank energized against already energized bank. L_2 is inductance of breaker and bus work between banks



When a capacitor bank is energized, a large component of natural frequency current initially flows in addition to the normal-frequency circuit current. If the bank is energized against an already energized bank, even larger natural-frequency equalizing currents may flow through the breaker. The effect of these currents must be evaluated.

When a capacitor bank is de-energized, larger than normal system voltages may exist across the breaker contacts because of the trapped charge on the capacitor. This may impose a greater than usual task on the breaker dielectric to interrupt with a minimum of restriking, and if restriking occurs, there may be voltage stresses above normal on the capacitor units as well as on the other connected equipment.

This paper offers an analysis of the problem together with test results on full-scale and miniature capacitor banks. Certain conclusions are drawn relative to the duty on and selection of breakers for this service.

Summary of Conclusions

A total of 338 tests on oil blast and Magne-blast types of power circuit breakers in the voltage class up to 15 kv and up to 250,000 kva short-circuit capacity, have been made. The results of this investigation, coupled with the analytical treatment contained in this paper, have allowed the following conclusions to be reached:

1. Based upon transient-analyzer analysis, it is shown that under the most pessimistic conditions of controlled restrike, abnormal circuit overvoltages can occur in de-energizing capacitors. This agrees with the results of other investigations[2] covering fault clearing on circuits containing capacitance.

2. Full-scale tests demonstrate that *standard* oil-blast breakers in the above classification recover their dielectric strength sufficiently fast to switch capacitor banks up to at least 10,000 kva without creating abnormal overvoltages.

As the capacitor kilovolt-amperes is further increased, a point is reached where restriking becomes more probable. Whether abnormal overvoltages appear or not is then determined by the randomness of the restriking phenomena and the inherent damping characteristics of the associated circuits.

3. Full-scale tests show that the high series resistance in the arc chute of the Magne-blast type of breaker, when restriking occurs, prevents the abnormal overvoltages usually associated with restriking phenomena. This is evidenced by the successful interruption of 31,400 kva—3,400 amperes at 5,350 volts.

4. Full-scale tests demonstrated that the peak values of transient equalizing currents upon energizing capacitor banks are within the values given by the equations presented in this paper and in reference 2.

5. The short-circuit interrupting rating of a breaker need not be increased by the

6. All tests made under various energizing and discharging conditions—many of which are presented in this paper—showed that the peak values of transient current obtained were not harmful to the breakers tested. The maximum value reached was 52,000 amperes.

The Energizing Problem

Energizing a Single Bank

It has been shown[3] that the maximum inrush current, neglecting system capacitance and damping, when energizing a single capacitor bank at the peak of the voltage wave is given by

$$I_{max}=I_0(1+\sqrt{X_c/X_L})$$

where

I_0 = peak value of steady-state capacitor current

X_c = reactance of capacitor bank

X_L = system reactance viewed from capacitor location

Since a switching problem is being considered, it may be appropriate to express inrush currents to capacitors in terms of the short-circuit current available at the capacitor location. Doing this, the above expression may be written as

$$I_{max}=I_c(1+\sqrt{I_{sc}/I_c})$$

where the subscripts stand for the capacitor rated current and the short-circuit currents—as initialed. All currents are expressed in peak values. This amounts to approximately 2,500 amperes for a 10,000-kva bank of capacitors closing on to a 13.8-kv system capable of delivering 250,000-kva short circuit.

These expressions hold for each phase of a wye-grounded bank on a grounded system. In wye floating neutral or delta-connected banks, however, the initial individual phase currents are a function of the order of pole closing. And since breakers probably do not close their contacts simultaneously, this case was investigated to determine if larger currents than those indicated by the above expression, could be obtained.

The analysis of this case*—as given in appendix B—indicates that the maximum current from this effect is 1.15 times that which can be obtained by simultaneous closing of contacts. The circuit of Figure 1(a) was set up in miniature on the transient analyzer[4] with the following constants:

L = 0.234 henry
C = 1 microfarad

For these values $\sqrt{X_c/X_L}=5.5$ hence I_{max} by above equation should be no greater than 1+5.5=6.5 times normal. Oscillographic results are presented in Figure 2. For the equivalent single-phase or simultaneous closing case, oscillogram 91-7 shows a peak inrush current in phase *b* of 4.5 times normal. Oscillogram 91-4 shows I_b for switch *b* closed at E_{ab} a maximum and switch *c* closed 36 degrees later to give I_b a maximum. This maximum of approximately 6.0 times normal, and the 4.5 above indicates that even the small damping in the miniature setup greatly reduces the maximum obtainable.

Energizing a Bank Against an Already Energized Bank

In this case the energized bank discharges into the oncoming bank through the relatively small impedance between them. The resulting large equalizing current of short duration oscillates at the high natural frequency determined by the value of series capacitance of the two banks, and the inductance of the connections between them.

Equations for determining these currents have already been given[3] for simul-

* A time of at least 1/4 cycle of natural frequency constitutes a severe nonsimultaneous pole-closing condition from this standpoint.

taneous pole closing, so will not be repeated. The case of sequential pole closing, however, was set up in a miniature circuit of Figure 2, using the following constants:

$L_1 = 0.234$ henry $C_1 = 3$ microfarads

$L_2 = 0.048$ henry $C_2 = 1$ microfarad

(L_1 and L_2 in per unit of the total capacitive kilovolt-amperes are 0.133 and 0.027, respectively)

The equalizing current on energizing C_2 was measured by means of the cathode-ray oscillograph. A comparison of the effect of simultaneous closure of the three poles of the switch with that of sequential closure (with the interval between pole closures controlled to give maximum current) is given in Figure 2 by oscillograms 91-10 and 91-13. It will be noted that the first natural-frequency current peak is nearly the same (eight times normal) in the two cases, indicating that sequential closing for the adjacent bank case has less effect on current maximum than in the single bank case.

Oscillogram 91-16 shows the effect of closing the second switch b ten degrees ahead of the time when the voltage across it would be a maximum. The same maximum current (in phase c) was obtained

by varying the angle of closing the last switch.

Full-Scale Tests

Tables I and II list a few of the typical test data recorded during the energizing tests. The test arrangement was designed to have small inductances in order to obtain maximum currents. In spite of this, the maximum current measured was below 20,000 amperes. In none of these tests were current-limiting impeders used. Figures 3, 4, and 5 are typical oscillographic records of the energizing phenomena with cross reference to Tables I and II giving the numerical values.

Discussion

The data in Tables I and II show the equalizing current values of adjacent single-phase and three-phase bank energizing. The largest adjacent bank energizing currents are well below the nominal values of current which these breakers are normally called upon to handle. The successful performance of the breakers under these conditions, together with the results presented in the section on "Capacitor Discharge During Short Circuit," shows that the "closing-in" duties of standard breakers constitute a very minor problem. The equalizing currents are high-frequency (1,000 to 5,000 cycles) highly damped discharges, producing negligible distress either as contact burning or as a delaying mechanical impulse to the closing breaker contact. Figure 6 shows an enlarged portion of the breaker contacts after 34 closing tests.

The De-energizing Problem

The initial voltage *across* a circuit breaker following the interruption of a capacitor circuit is zero, since the capacitor on one side holds the same crest voltage that existed on the bus side of the breaker at and immediately following current zero. This permits any circuit breaker to interrupt quite easily at the first arc current zero. The breaker is thus lulled into a feeling of easy triumph over the circuit with the minimum of contact separation when suddenly—with the cyclic reversal of system voltage—double instead of zero voltage appears across the open breaker just one-half cycle following the interruption. If the breaker withstands this double voltage without restriking, then and not until then can the circuit be considered as cleared. If, on the other hand, the circuit is restruck as the voltage approaches this cyclic reversal, then a series of events is possible which must receive special consideration.

In counterdistinction to capacitive interruptions, the current in inductive circuits is interrupted at each current zero, whereupon the double-voltage-recovery transient is immediate, and circuit interruption is either achieved, or the arc is restruck for another half cycle to repeat the attempt under similar conditions at the next current zero. Thus the insulation is permitted to build up between the separating contacts until such a point is reached that the circuit is cleared without accumulative voltage distress. (There

are however special cases of inductive circuits where abnormal restriking overvoltages can occur.[2] The effects of the restriking phenomenon on the capacitor switching problem are discussed under the section "Capacitor Discharge During Short Circuit.")

A comparison of these phenomena indicates that the interrupting capacity of standard breakers on capacitive circuits may be limited as described in this paper. The limitations are not so much in the ability of the breakers to eventually clear the circuit as they are in the desirability of limiting overvoltages on the system to safe values.

At this point, it is desirable to point out that the considerations contained in this paper deal with capacitor banks of high capacitive kilovolt-amperes, and in no way should the discussion presented here be construed to apply to circuits which contain relatively small capacitors —as for example, capacitors for the protection of electric equipment from lightning or switching surges and the lower-voltage equipments in industrial plants. In fact, the phenomena presented here are more akin to the phenomena of the interruption of line-charging current on high-voltage transmission systems. The two problems are identical in every major respect and differ only in degree. The capacitive kilovolt-amperes to be interrupted on high-voltage lines is usually large. As with the capacitor bank, interruption takes place easily at the first current zero in the arc, thus leaving the entire line charged to the crest value of generated voltage. As the generated voltage reverses on the bus side, double voltage appears across the switch. The breakers required to interrupt this line-charging current are inherently large, and although the contact velocity on parting is considerably larger than in the smaller breakers, it is not larger in proportion to the voltage. It follows that the voltage to appear across the open pole one-half cycle after contact parting is therefore much greater on the high-voltage systems. This fact, together with the large kilovolt-amperes to be interrupted explains why these interesting phenomena were first found on the high-voltage transmission systems. The trend toward large capacitor banks tends to project the above phenomena into the lower-voltage systems, not by reason of voltage, but because the heavier currents to be interrupted act to weaken the arc gap one-half cycle after parting, thus permitting the gap voltage on the reversal of bus voltage more easily to produce a restrike. The studies presented in this paper reveal the degree to which these phenomena are important to the lower-voltage switching equipments.

Analysis

Tests have been made on the transient analyzer[4] to determine the maximum magnitude of transient overvoltage that would be obtained when switching off various connections of capacitors, with the assumption that the circuit-opening mechanism would restrike once. The capacitor switch was opened at a funda-

All voltage calibrations in times normal of normal L-N crest voltage

mental frequency current zero and reclosed by means of a synchronous switch at the subsequent recovery voltage maximum to represent a restrike. Although this switching procedure does not involve the randomness present in the circuit-breaker performance, it gives the highest possible magnitudes of both switch and capacitor voltage.

Table III presents the results of these tests, giving the peak switch and capacitor volts for the condition of no restrike and one restrike. Figures 7 through 9 show some of the connections tested and a "free-hand" graphical analysis of the voltages. These supplement the oscillograms in Figure 10.

Figure 7 shows the fundamentals by which these transient overvoltages are obtained. At a current zero (peak of the voltage wave) the switch is opened, whereupon a full charge remains on the capacitor. The fundamental frequency system voltage moves onward until it is a negative maximum resulting in a switch voltage of twice normal. A restrike is permitted at this point, and the capacitor voltage changes to system voltage on the circuit natural frequency and overshoots (neglecting resistance damping) an amount equal to its attempted change, or to −3 times normal, as shown. At the first subsequent current (largely natural frequency) zero, the switch is reopened, and the charge of −3 times normal remains on the capacitor.

Figure 8 shows a similar analysis for switching off part of a bank (65 per cent of the total in all these tests) with one restrike. At the time just previous to restrike, C_1 is at −1.0 per unit volts and C_2 is at +1.0 per unit volts. In the transient-analyzer tests there was no intentional current limiter between C_1 and C_2; hence immediately upon restrike the charge on C_1 and C_2 equalized to a value

84-6 Voltage V_{BC} on unswitched capacitors

Case IX—Same as case VII. First switch to open, capacitor neutrals connected. (Comparison with case VII shows effect of unswitched capacitors in holding down neutral displacement of switched capacitors)

82-13 Voltage of switched capacitor to ground (phase *a*)

82-14 Voltage across first switch to open

82-15 Voltage of unswitched capacitor on phase *a* to ground

Figure 10 (continued.) Transient-analyzer oscillograms showing voltages obtainable when de-energizing capacitors, for various connections and assuming one restrike at peak of voltage wave

All voltage calibration in times normal of normal *L-N* crest voltage

given by $E(C_2-C_1)/(C_1+C_2)$ and then oscillated to a value given by $-E(C_1+3C_2)/(C_1+C_2)$. An analytical determination of this expression is given in appendix B.

The constants used for these transient-analyzer tests—in *L-N* values—were:

System inductance $L=0.85$ henry except cases 3 and 4, $L+1.67$ henries

Capacitance switched $C_2=0.5$ microfarad

Capacitance unswitched $C_1=0.2$ microfarad

The most severe overvoltage across the switch on de-energizing occurs when switching off part of an ungrounded wye (or delta bank) and when the second phase clears. This is shown by Figure 9 (case VIII). The capacitor overvoltage is equal to that obtained when switching all of the bank.

Full-Scale Tests

Analysis shows—Table III—abnormal voltages are possible with one restrike under the most pessimistic conditions. Full-scale tests were made to determine practical conditions obtaining.

* This peak current flows through breaker in addition to short-circuit current, but has disappeared with the arrival of peak short-circuit current.

The typical test results summarized in Table IV indicate the scope of these tests. Oil and Magne-blast breakers of the voltage class up to 15 kv and up to 250,000-kva interrupting capacity were tested. It is interesting to note that the Magne-blast breaker successfully interrupted 31,400 kva at 4,000 volts without disturbing overvoltage in spite of some restriking. This result is caused by the high series resistance present[6] when restriking occurs within the arc chute, see Figure 11a. This desirable characteristic of the Magne-blast type of breaker places it in a very favorable position when switching capacitive circuits. Figure 11 exhibits typical cathode-ray oscillograms of the voltages attending these interruptions.

The 15-kv, 250,000-interrupting-kva oil breaker was tested up to approximately 11,000 kva with results as tabulated. Figure 12 shows a typical recording of this series of tests when de-energizing the larger bank ratings.

Discussion of Results

The transient-analyzer approach allowed the circuit constants to be readily varied for determining generalized qualitative results, thus materially reducing the full-scale test requirements. Also, with complete control of the random phenomenon called "restriking," certain conclusions could be drawn with respect to the maximum possible overvoltages obtainable under the most pessimistic conditions, which again helped to plan and analyze the full-scale program. The miniature setup allowed the following conclusions to be drawn:

1. Effect of circuit constants (L and C). If the entire bank is switched, the magnitude of the switch or capacitor voltage is not appreciably affected by the system constants provided that the circuit natural frequency is not less than approximately 180 cycles. (Refer to cases I and II of Figure 10.)

2. Presence of an unswitched bank. If part of the bank remains unswitched, the capacitor and switch volts are the same as the condition of total bank switched, if no restrike occurs. If restrike occurs, the smaller the bank unswitched, the larger the switch voltage, the limit being a very small unswitched capacitance for which a somewhat greater voltage may be obtained than for the case of absolutely no unswitched capacitance. Table I summarizes quantitative results.

3. Effect of grounding. Grounding the capacitor bank on a grounded system results in the lowest switching overvoltages, as may be seen by comparing the values of the grounded and ungrounded cases of Table III.

4. Effect of interconnecting neutrals of switched and unswitched banks. The unswitched bank under this condition has the tendency of holding the neutral of the switched bank at ground potential, and as the ratio of unswitched to switched capacity increases, the grounded case is more nearly approached. (Refer to cases VII and IX of Figure 10.)

Full-scale tests demonstrated that delta-connected or wye floating neutral capacitors up to 10,000 kva can be handled with standard breakers without creating the abnormal overvoltages indicated by the analysis. This appears to substantially satisfy present-day system requirements. Above these values a

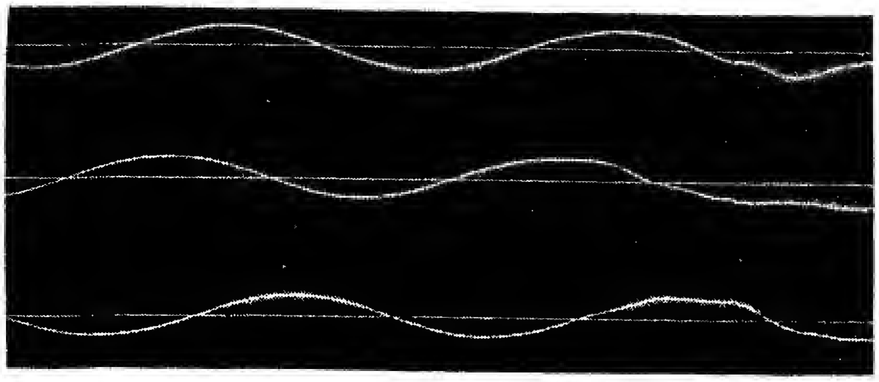

Figure 11a. Cathode-ray oscillogram showing the capacitor voltages to ground attending the interruption of a three-phase 6,500-kva bank with the Magne-blast air circuit breaker

See test 14 on Table IV

point is reached where restriking together with the attendant overvoltages becomes more probable, thus presenting a field for further development should the requirement greatly expand.

Capacitor Discharge During Short Circuit

When a short circuit occurs on the load side of a large capacitor bank, the capacitor discharges its energy into the fault—in some applications—along with the flow of short-circuit current. (See figure in Table V.) The question naturally arises regarding the extra duty, if any, required of the circuit breaker through which both of these currents flow. A study of the problem reveals that the most severe case of the above consideration concerns the closing of the breaker upon such a fault with immediate opening. The concern regarding this case is dispelled when it is realized that the maximum capacitor energy is "dumped" when the fault is initiated at the crest value of the system voltage. Under these conditions, the short-circuit current which flows is at its lowest value, namely the symmetrical value. In this case the highly damped capacitor discharge is practically over with the arrival of the first crest of normal-frequency short-circuit current. See Figure 13a.

If, on the other hand, the maximum short-circuit current is developed by initiating the fault at the zero point of the voltage wave, the capacitor charge is zero and hence contributes nothing. See Figure 13b.

Analysis shows that this latter case develops the maximum thermal and magnetic effects. Since this is a normal function of the breaker, it follows that the presence of the capacitor cannot add to the maximum closing duty of the breaker. It should be pointed out, in

Figure 13b. Fault initiated close to the minimum point of generated voltage

Minimum capacitor charge. Note the low capacitor contribution in the presence of the displaced short-circuit current. See test 3, Table V

addition to the above, that the presence of the shunt capacitor on the bus materially aids the circuit breaker in its duty by lowering the rate of rise of recovery voltage. This last deduction does not hold if the breaker is attempting to clear a L-G fault on a system that is susceptible to high arcing-fault voltages. Other[2] investigations indicate that on these systems the reduction of the ratio of capacitive zero-sequence reactance to the positive-sequence inductive reactance tends to give the more severe overvoltages if restrike occurs. These conditions however, are rare and can be eliminated by properly grounding the system. In order to determine breaker operation when performing this function, as well as an attempt to get higher inrush currents in the interests of completeness, tests were conducted in which short circuits were produced by closing breakers upon the fault and tripping with no time delay. Two oscillograms are shown demonstrating the above relationships. Figure 13a shows a fault initiated near the peak of generated voltage. Note that the high-frequency capacitor discharge is so short that, with the arrival of the first peak of the symmetrical short-circuit current, little of the capacitor discharge remains. Figure 13b shows a fault initiated near the zero of generated voltage, giving rise to a displaced fault. Note the insignificant contribution made by the capacitor. Table V shows a partial list of the tests made under these conditions. The above considerations show that the interrupting duty on a circuit breaker is not increased by the presence of a large shunt bank on the bus side. In no case did the breakers in this series of tests exhibit abnormal stress.

Appendix A. Sequential Energizing of a Three-Phase Ungrounded Wye Capacitor Bank—Inrush Current

Considering the circuit given by Figure 1a, switch a may be closed with no electrical effect. The maximum current in phase ab may be obtained by closing switch b at a time when the voltage across it, E_{ab}, is a maximum. Thus

$$i_a=-i_b=\frac{\sqrt{3}E\cos\omega t}{2\left(pL+\frac{1}{pc}\right)}=\frac{(1-a)E_a}{2Z(p)} \qquad (1)$$

where E = line-to-neutral generated voltage in phase a.

The voltage across the open switch c is

$$a^2E_a-\{E_a-i_aZ(p)\} \qquad (2)$$

which with equation 1 substituted is

$$E_a\left(a^2-1+\frac{1}{2}-\frac{a}{2}\right)=\frac{3a^2}{2}E_a=-1.5E\sin\omega t \qquad (3)$$

It is interesting to note that the voltage across the last switch to close has no natural-frequency component, even though the current flowing in phases b and c at this time does have. This may be written

$$E_{sw_c}=-1.5E\sin(\omega t'+\theta) \qquad (4)$$

where

$\theta=\omega\Delta t$, and Δt is the time elapsed between the closing of switches b and c. Considering the effect of this voltage by itself,

$$i_c=\frac{-1.5E\sin(\omega t'+\theta)}{1.5Z(p)} \qquad (5)$$

At any time after Δt the total current in phases a and b is

$$I_{aT}=i_a-\frac{i_c}{2}$$

$$I_{bT}=-i_a-\frac{i_c}{2} \qquad (6)$$

Since I_{bT}, the total current in phase b, will be the largest, the operational expression for I_{bT} given by equation 6 will be solved.

$$-i_{bT}=\frac{\sqrt{3}E\cos\omega t}{2Z(p)}-\frac{E\sin(\omega t'+\theta)}{2Z(p)} \qquad (7)$$

The solution of this is

$$I_{bT}=I_0\left[\frac{\sqrt{3}}{2}\sin\omega t-\frac{\sqrt{3}}{2}\sqrt{X_C/X_L}\sin\omega_0 t+\frac{1}{2}\cos(\omega t'+\theta)-\frac{1}{2}\cos\theta\cos\omega_0 t'+\frac{1}{2}\sqrt{X_C/X_L}\sin\theta\sin\omega_0 t'\right] \qquad (8)$$

where

$I_0=\frac{E}{Z}$ = normal capacitor current per phase

$X_C=\frac{1}{\omega C} \qquad X_L=\omega L$

$\omega_0=\omega\sqrt{X_C/X_L}$ = natural frequency of the circuit

t terms are components of i_b, the current before switch c is closed

t' terms are components of $\frac{i_c}{2}$ the additional current after switch c is closed

Since the natural-frequency components of equation 8 have large coefficients by comparison with the forced frequency components, the latter may be neglected to simplify the task of determining the value of θ which will give the largest total component of current in phase b. The natural-frequency components are

$$I_{NF}=\sqrt{X_C/X_L}\left[-\frac{\sqrt{3}}{2}\sin\omega_0 t+\frac{1}{2}\sin\theta\left(\sin\omega_0 t\cos\frac{\omega_0}{\omega}\theta-\cos\omega_0 t\sin\frac{\omega_0}{\omega}\theta\right)\right] \qquad (9)$$

Putting $dI_{NF}/d\theta$ equal to zero permits the value of θ to be found which will give maximum I_{NF}. This will not be far from that which will put the two components of equation 9 inphase which, for a natural frequency of 5 is $\theta=180/5=36$ degrees.

If $\theta=36$, $I_{NF}\max=\sqrt{X_C/X_L}\ 1.12$

If $\theta=40$, $I_{NF}\max=\sqrt{X_C/X_L}\ 1.18$

Adding 1.0 to $\sqrt{X_C/X_L}\ 1.18$ to allow for fundamental frequency components of equation 9 gives

$$I_{bT}=I_0(5.9+1.0)=6.9I_0$$

which is 15 per cent higher than $I_{\max}$ determined for simultaneous switching.

Appendix B. Capacitor De-Energizing Analysis; Capacitor Voltage upon Restrike

Case 2. Part of Bank Unswitched

Referring to Figure 8, just before restrike, at $t=0$, the voltage existing across the switch $=-E(1+\cos\omega t)$ neglecting the rise in voltage of point a due to i, flowing through L. The effect of closing the switch (restriking) may be obtained by applying this voltage to the operational impedance of the circuit, and the switch current is

$$i_2=EC_2\frac{\omega_0^2}{\omega_1^2}\left[\frac{p(\omega_1^2+p^2)}{(\omega_0^2+p^2)}+\frac{p^3(\omega_1^2+p^2)}{(\omega_0^2+p^2)(\omega_2^2+p^2)}\right] \qquad (10)$$

where

E = crest value of generated voltage

$$\omega_1^2=\frac{1}{LC_1},\quad \omega_2^2=\frac{1}{LC_2},\quad \frac{1}{\omega_0^2}=\frac{1}{\omega_1^2}+\frac{1}{\omega_2^2}$$

The change of voltage of capacitor C_2 due to the restrike is $\Delta e_{c2}=i_2/pC_2$ for which the solution is

$$\Delta e_{c2}=E\frac{\omega_0^2}{\omega_1^2}\left[\frac{\omega_1^2}{\omega_0^2}+\ -\frac{\omega_1^2}{\omega_0^2}+1+\frac{\omega_1^2-\omega_0^2}{\omega^2-\omega_0^2}\right)\cos\omega_0 t+\frac{\omega_1^2-\omega^2}{\omega_0^2-\omega^2}\cos\omega t\right] \qquad (11)$$

If the natural frequency ω_0 is assumed very large compared with ω, then at $t=\pi/\omega_0$

$$\Delta e_{c2}=2E\left[\frac{C_1+2C_2}{C_1+C_2}\right] \qquad (12)$$

and the capacitor voltage after restrike is

$$E_{c2}=E-\Delta e_{c2}=E\left[\frac{-C_1-3C_2}{C_1+C_2}\right] \qquad (13)$$

For case II, where $C_1=0.2$ microfarad and $C_2=0.5$ microfarad, $E_{c2}=(-17/7)E$. This value may be obtained by conservation of charge—the sum of the charges on the capacitors after restrike is the same as before, hence immediately after restrike

E of both capacitors =

$$\frac{Q_T}{C_T}=\frac{(-C_1+C_2)E}{C_1+C_2}=-\frac{3}{7}E$$

The equalized capacitor voltage must still change through $2C_2/C_1+C_2\,E$ to arrive at the

Application of Vacuum-Tube Oscillators to Inductive and Dielectric Heating in Industry

J. P. JORDAN
ASSOCIATE AIEE

I. Introduction

THE knowledge that metals could be heated inductively and that nonconductors could be heated dielectrically dates from the earliest experiments with electricity. In the last few years inductive and dielectric losses, which have long been obstacles in the electrical industry, have been profitably employed in a new industrial tool powered by high-frequency motor-generator sets and vacuum-tube oscillators. Low-frequency inductive heating has been used in specialized melting applications for approximately 20 years and for some surface hardening work for the last ten years. However with the advent of the new equipment and knowledge of its use, it is no longer a highly restricted application but is ready to handle thousands of heating processes throughout the industry. Hence, it is felt that a short review of the theory of inductive and dielectric heating, together with a description of the vacuum-tube circuits used and some of their applications, would be of value at this time.

II. Classification of Equipment

Inductive heating can be roughly segregated by frequency into three classes. The first class covers applications to 1,000 cycles. It is almost entirely used for forging and melting steel and nonferrous metals either directly or indirectly (that is, by heating electrically conductive crucibles). Power requirements range from a few watts to thousands of kilowatts generated by motor-generator sets. It is being widely used to produce many of the specialized alloys demanded for war equipment.

The second class covers frequencies from 1,000 to 12,000 cycles almost entirely generated by rotating machines with power ratings of from 20 to 1,200 kw. The applications in this group cover practically all heating processes—surface hardening, forging, brazing, soldering, melting are all included. One to three thousand cycles are used for melting nonferrous alloys, for surface-hardening relatively large parts, and for some forging applications. The new 9,600-cycle generators are being used successfully for surface-hardening relatively small parts where the contours need not be too closely followed, and where the depth of case need not be too small. Widely used for brazing and soldering of other high-resistance metals, inductive heating is more difficult to apply to the heating of copper, brass, and other low-resistance alloys.

The third group for inductive heating covers all applications from 50,000 cycles to 1,000,000 cycles. Generation is almost entirely restricted to spark-gap and vacuum-tube oscillators. Spark-gap type of equipment can be built for frequencies from 50,000 cycles to 200,000 cycles and for power outputs up to 25 kw. Vacuum-tube equipment, while having no theoretical frequency or power limitation, is most economically applied at frequencies over 150,000 cycles and at power outputs up to 200 kw.

In the dielectric heating field the vacuum-tube oscillator is the only source capable of producing sufficient power at the frequencies necessary. From 1,000,000 to 30,000,000 cycles have been used at powers up to 200 kw.

III. Theories Involved

Before taking up some of the applications in greater detail, it might be well to review some of the fundamental theories involved. Any charge to be heated inductively can be thought of as a short-circuited secondary winding of a transformer, the primary being the heater coil. The currents produced in the charge heat it by resistive and hysteresis losses according to the well established theory of eddy currents. The heat generated is confined to the surface of the parts by the skin-effect phenomena. The depth of penetration varies inversely with the square root of frequency, directly with the specific resistance of the material, and, in the case of magnetic materials, inversely with the permeability.

With nonmagnetic metals the heat is generated in this superficial volume throughout the heating cycle, varying only as the resistance of the metal changes

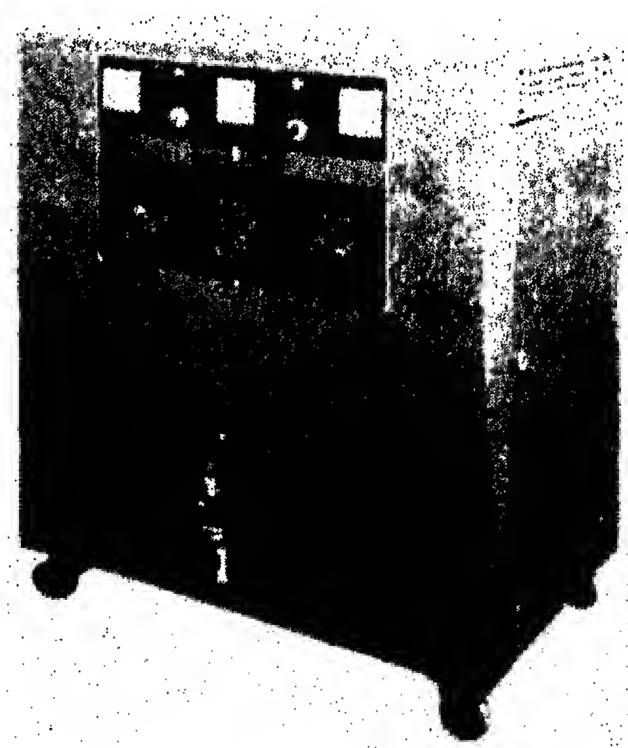

Figure 1. Five-kilowatt power oscillator for high-frequency induction heating

Paper 42-154, recommended by the AIEE committee on industrial power application for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 4, 1942; made available for printing July 29, 1942.

---

system voltage, and in changing through the inductance it will overshoot this amount and become a negative maximum of

$$\left(\frac{2C_2}{C_1+C_2}+1\right)E=\frac{C_1+3C_2}{C_1+C_2}E$$

which agrees with equation 13.

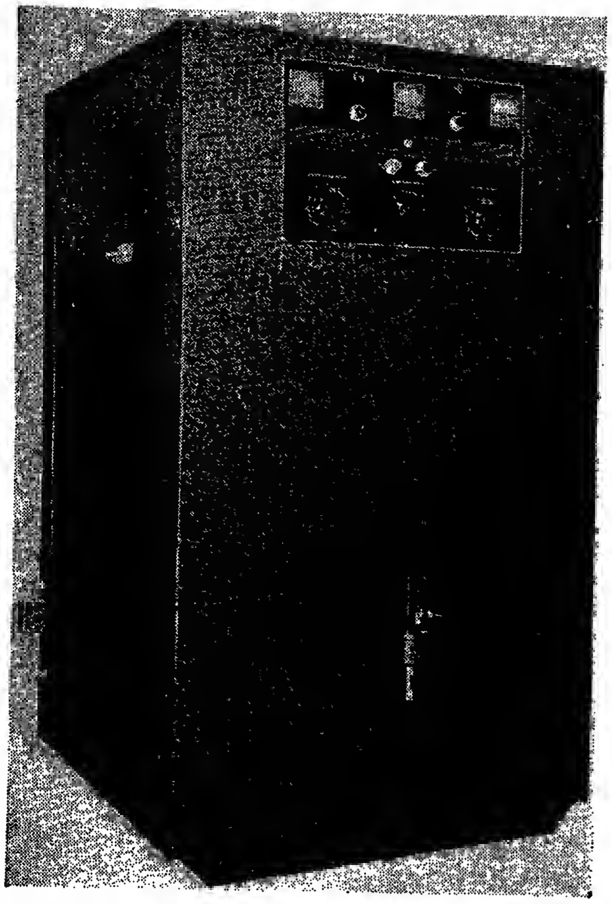

Figure 2. Fifteen-kilowatt power oscillator for high-frequency induction heating

with temperature—the core of the charge being heated largely by thermal conduction. Thus silver and copper are difficult to heat because of their low specific resistance and the resulting small depth of penetration. In magnetic materials the depth of the heated layer, which is very small due to the effect of the high permeability, increases rather abruptly at the temperature above which the material becomes nonmagnetic. Simultaneously, the power being absorbed in the original layer is reduced. Therefore steel with a high permeability and high specific resistance is readily heated in a thin surface layer while below the critical temperature, whereas above this temperature the power absorbed is less, and the depth of penetration considerably greater.

Because of these effects, the majority of steel parts can be readily surface-hardened at the intermediate frequencies by heating the surface inductively and quenching when the desired penetration has been achieved. Much higher frequencies are required for irregular parts where the contour must be followed closely, where coupling is difficult because of shape or small size, and where extreme localization of the heat is a necessity. To heat readily the low-resistance metals such as silver, copper, aluminum, and brass, the magnetic flux densities required at the intermediate frequencies are difficult to obtain, whereas the higher frequencies allow the use of more normal flux densities.

In dielectric heating the material to be heated is placed between two electrodes, and voltage applied at a frequency above 1,000,000 cycles. The whole forms a high-loss capacitor. The theory of dielectric losses is somewhat complex and is not yet thoroughly understood. However for most materials the heat developed is roughly proportional to the frequency and voltage applied and to the power factor of the dielectric. The entire mass is uniformly heated throughout, provided the electric field is uniform.

IV. Vacuum-Tube Circuits

The vacuum-tube oscillators used in the high-frequency field are of the simplest possible type. Radically departing from the usual radio construction practice; they are truly an industrial tool. Mechanically they are ruggedly built to withstand normal factory usage. Electrically they have been greatly simplified to provide the maximum reliability. The circuits most generally used are the Colpitts and the coupled-grid self-excited oscillator. In either of these circuits, the alternating supply voltage is stepped up by means of a power transformer to a voltage in the neighborhood of 7,500 volts to 15,000 volts and then rectified by a suitable bank of mercury vapor rectifier tubes. The direct current thus obtained supplies the oscillating circuit which consists primarily of a grid-controlled vacuum tube shunted across a parallel resonant circuit. The tube acts as a very rapidly operating switch. When this switch operates at the fundamental frequency of the parallel resonant circuit, it transmits power surges at this frequency by effectively short-circuiting the line once each cycle. Thus the voltage across the oscillation capacitor and inductance is alternately reduced and increased, setting up a circulating current in the resonant circuit.

To assure that the tubes operate at the desired frequency, their control grids are excited directly from the resonant circuit. This excitation voltage is obtained by several methods. In the Colpitts circuit (Figure 3) the excitation voltage is obtained by a direct tap on the oscillation capacitor, while in the coupled-grid circuit (Figure 4) it is developed in a coil inductively coupled to part of the oscillation inductance. All direct current is prevented from appearing in the resonant circuit by means of blocking capacitors. In both of these circuits the heater coil is usually in series with the parallel resonant circuit and forms part of the oscillation inductance. Since the frequency of operation is primarily determined by the constants of the resonant circuit, it will shift slightly as the inductance of the heater coil changes with load, thus always assuring operation at resonance and reducing fluctuations in the output current. For some applications requiring higher coil currents than are economically obtainable with a resonant circuit, an air-core transformer is used to step up the current.

V. Applications—Inductive Heating

This type of equipment can be applied to a great variety of heating problems. In the case of a small one-quarter-inch shaft the central portion was used as a bearing surface while the ends were riveted over to hold it in position. The overall length was approximately $1^1/_4$ inches. The problem was to harden the bearing surface while leaving the ends unaffected. Previously, this was achieved by copperplating the ends and then casehardening the exposed parts by carburizing—a lengthy and expensive process. To apply induction hardening, a small coil was wound which was approximately the length of the desired hardened area. The part was centered in this coil, and the whole was immersed in water. Power at a frequency of 500,000 cycles was applied. As the steel heated up, a film of steam formed around that area, protecting it from the cooling action of the water.

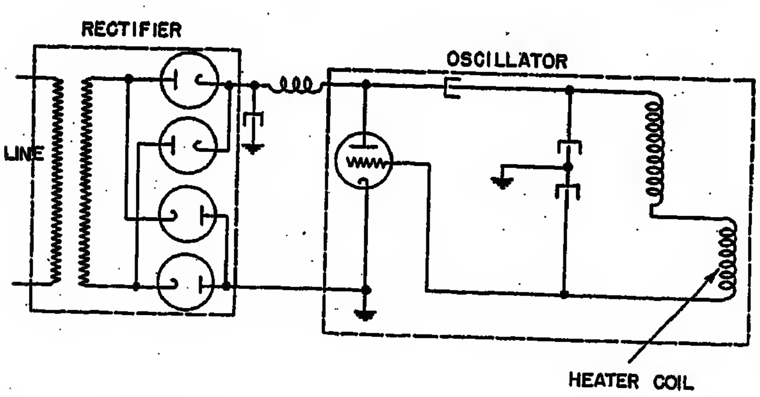

Figure 3 (left). Basic Colpitts oscillator circuit as used for induction heating

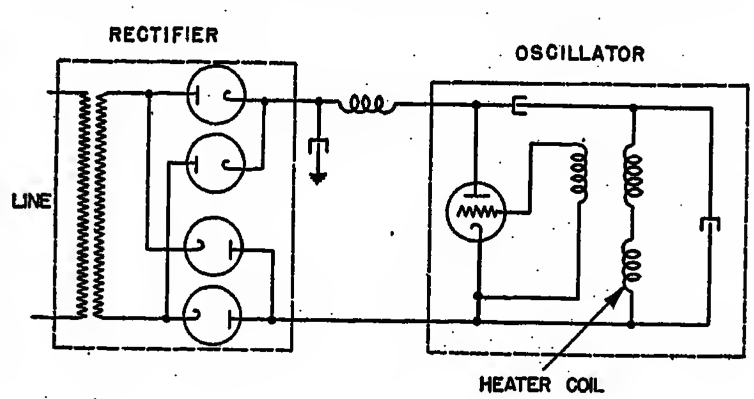
Figure 4 (right). Basic coupled-grid oscillator circuit as used for induction heating



But, when power was removed, this vapor envelope collapsed, allowing the water to rapidly quench the part. The entire cycle was complete in $3^1/_2$ seconds, and a satisfactorily hardened area obtained. Approximately four kilowatts output was used.

Curiously enough, in surface-hardening split pipe-threading dies an external coil can be used to harden the inside teeth. This is possible, because the induced currents must travel in a closed loop. Since there is no continuous external path around the circumference of a split die, the currents must travel completely around the inside of the die before returning to the outside surface. Thus such a die can be located inside a coil and, with proper heating and quenching cycles, can be hardened on both the inside and outside surfaces simultaneously, leaving a soft tough core.

In applying inductive heating to brazing, the usual procedure consists of assembling the fluxed parts using a preformed piece of brazing alloy between the parts. The advantages of the use of this method are speed, cleanliness, simplicity, and localization of heat. No experienced operators are necessary, and the method is admirably suited to automatic or semiautomatic operation.

In assembling the stator punchings of a small motor, the shell holding them had previously been spun over on either end. However, in using this method, the punchings had a tendency to work loose. To solve the problem, one end of the shell was spun over, the stator punchings assembled in position, and a thick washer placed over the end. A groove in the washer accommodated a ring of silver solder adjacent to the shell. The use of torch heating was impractical, because the heat conducted to the punchings tended to carbonize the insulating varnish. However, by using high-frequency induction, the heat could be so localized and the time interval used so short, that little heating of the punchings took place. Also, since the entire brazing operation could be performed while in a press, no loosening was encountered.

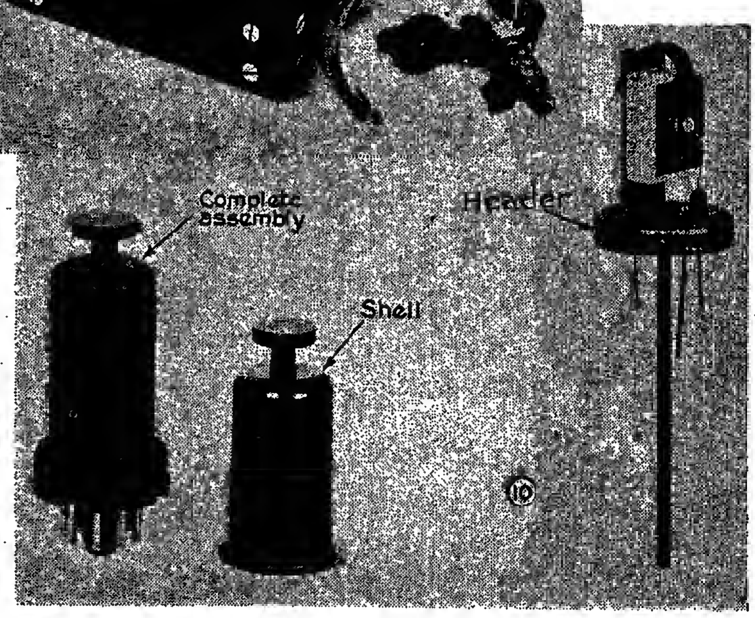

Figure 10. Metal-tube-type crystal unit

Shell soldered to header assembly by inductive heating

to be sealed in a glass bushing required two heating operations. First, the copper stud had to be silver-brazed to a nickel-steel alloy cup using a gas torch. Then, after spraying the rim of the cup with a suspension of finely divided glass in alcohol, the whole was fired in a muffle furnace to fuse the glass preparatory to sealing it into the insulator. These two operations are performed simultaneously, and a much more uniform product achieved by the induction heating method. The coil used is so proportioned that, as the proper temperature is reached for brazing at the joint, the flange is at the fusing temperature of the glass. The entire operation is complete in five seconds.

In the assembly of Calrod heating units the bushings and terminals are brazed in place. A great variety of metals must be heated since nickel-silver, copper, brass, and steel are all used for various applications. Also, the Mycalex insulating pieces must not be overheated or damage will result. Although the steel parts could be successfully heated using intermediate frequencies generated by rotating machines, high-frequency vacuum-tube equipment is used to obtain flexibility of operation throughout the range of materials used. Preformed silver solder rings are used. All operations being automatically controlled, there is no possibility of overheating or burning of the pieces. A further application of this machine has been the reclamation of short pieces of tubing previously regarded as scrap, since efforts to braze them together had been expensive and in many cases resulted in a weak joint. However, because of the uniformity of the brazed joint and the automatic operation made possible by inductive heat, these pieces are now being used successfully.

Because soft soldering is a low-temperature operation amenable to the use of resistance heating, only high-production items of an unusual nature have previously been attempted by induction methods. However, with the present-day enforced use of high-temperature soft solders, this application has been expanding rapidly.

In the manufacture of crystals as used in radio apparatus, one form of the crystal assembly is mounted on a header and enclosed in a shell very similar to the familiar small metal radio tube. The shell is soft-soldered to the base or header. This operation was performed in the past by pretinning the flange on the shell and the rim of the base and making the final joint in a ring burner, adding such solder as was necessary. However, the products of combustion of the gas used sometimes condensed on the crystal surface and seriously affected its operation. Also, the heat transmitted through the supporting bracket occasionally cracked the crystal. By heating inductively, the heat is entirely confined to the rim, and the operation considerably speeded up.

VI. Applications—Dielectric Heating

Dielectric heating of nonconducting materials is the newest application in the field and shows great promise of rapid development. Already one large unit has been placed in operation curing the glue in plywood with promise of many other such installations.* Several unsuccessful trials have been made to cure rubber by this method, but the applications to plastics, ceramics, and insulating compounds are progressing rapidly.

Not only will this type of heat reduce the time of curing of many plastic parts (a reduction in the case of thick laminated plastic insulating compounds of from hours to minutes), but it will allow the use of some types of plastics in forms previously impossible because of the difficulty of properly curing the material. Within the next two years it is expected that considerable progress will be made in this direction.

VII. Closure

A word of caution regarding the application of this type of equipment. The rotating machine and the high-frequency oscillator supplement but cannot replace each other. It is neither economically nor theoretically sound to attempt to heat large regularly shaped steel parts by use of oscillators, nor is it wise to use rotating machines of high power to heat a small irregular part where a low power oscillator could be applied. There is little overlapping of their respective fields of application, but, because of the great number of factors which must be considered, no broad definitions of their fields can be made. Thus each application must be judged on its own merit.

Energy Flow in Electric Systems—the *Vi* Energy-Flow Postulate

JOSEPH SLEPIAN
FELLOW AIEE

Synopsis: The conditions which a valid postulated electric-energy flow must satisfy are given and are stated to be insufficient for its unique determination. The commonly used *Vi* energy-flow postulate is shown by examples to be not generally valid, but by adding a simple term it can be made equally valid with other valid energy-flow postulates. Various examples are given of the application of this corrected energy-flow postulate. On power systems the engineer commonly limits his use of the uncorrected *Vi* postulate to applications where the correcting term should have a negligible net effect. Various examples of such use are discussed.

I. Introduction

AMONG power electrical engineers the following postulate as to electric-energy flow is extensively used. Let V be the electric potential at any particular point, referred to some arbitrarily chosen point of zero potential. Let i be the current density at that point. V, of course, is a scalar quantity, having magnitude but no associated direction in space; i is a vector, having magnitude and also direction in space. The product Vi is a vector and is postulated to describe or represent the density of a flow of electric energy in watts per square centimeter, V being in volts and i in amperes per square centimeter. In particular, the point in question may be a point in the cross section of a linear conductor or cable. The postulated electric-energy-flow density may be integrated over the section of the conductor to give the total postulated energy flow along the conductor. If, as is usually the case, the potential V is constant over the section of the conductor, then the total postulated energy flow will be VI, where I, a vector, is the total current flowing over the section of the conductor. This will be the reading of an instantaneous wattmeter connected into and to the conductor at that point. The average in time of this quantity VI will be the reading of the usual wattmeter at that point.

What are the phenomena which can be actually observed which justify or make valid the energy-flow postulate, if it is valid? They are the following. At some points in space electric energy is being generated or created. By that is meant that energy of some other well-known, recognizable, and measurable form is disappearing, and at the same time electric manifestations are taking place there, such as the flow of currents, the appearance of electric fields, and so forth. Thus, in a generator chemical energy of a pile of coal is disappearing, or potential energy of water in a reservoir is lessening in amount. In a discharging battery chemical energy is disappearing. In a thermocouple heat energy at the hot junction is disappearing at a rate greater than the heat energy appearing at the cold junction.

At other points in space recognizable and measurable forms of energy are appearing or being created, with simultaneous electric manifestations. In an electric oven heat is appearing in measurable amount. In an electric motor, mechanical energy is appearing as, perhaps, in the increasing potential energy of a rising elevator. In an electrochemical plant the chemical energy stored in matter is being increased.

Also, at various points in space electric and magnetic fields make their appearance, and it is found necessary, if the law of conservation of energy is to remain true, to assign a stored electromagnetic energy to these fields. It is commonly said: "It takes work to produce these fields." Where, as in the core of a reactor, there is a magnetic field, it is customary to assign a stored energy per cubic centimeter of amount $(10^{-7}/8\pi)H{\cdot}B$ joules where H is the magnetic intensity, and B is the magnetic induction in gauss. Where, as in the dielectric of a capacitor, there is an electric field, it is customary to assign a stored energy per unit volume of $^1/_2\, E{\cdot}D$ where E is the electric intensity in volts per centimeter, and D is the electric induction in coulomb-centimeters. In empty space, these assigned stored energy densities are respectively $\frac{10^{-7}}{8\pi}H^2$, and $\frac{1.11{\cdot}10^{-12}}{8\pi}E^2$ joules per cubic centimeter. If these energy densities are integrated over all space, they give correctly the total energy which must be regarded as stored in the electromagnetic field if the law of conservation of energy is to remain true.*

At the various points of space this stored electromagnetic energy will be appearing or disappearing accordingly as the electric and magnetic fields are increasing or decreasing in intensity.

The postulated energy flow may be said to be substantiated, made valid, justified, or established if it properly co-operates with or fits in with these observable phenomena which have just been described. Where electric energy is being generated, the postulated energy flow must show energy flowing away and in proper amount. In regions where electric energy is being consumed, the postulated energy flow must make energy approach in proper amounts. At places where electric and magnetic fields are changing, and with them the associated stored energy, the postulated energy flow must make approach or recede the proper amounts of energy.

Paper 42-141, recommended by the AIEE committee on basic sciences for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted February 9, 1942; made available for printing May 29, 1942.

JOSEPH SLEPIAN is associate director of research, research laboratories, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

* It turns out that these energy densities are not the only ones which may be assigned to the various points of space, which will integrate to the correct total electromagnetic energy. See, for example, reference 1. Therefore, these stored energy densities do not have a unique validity. However, in this paper, only these assumed energy densities will be considered in their relation to postulated energy flow.

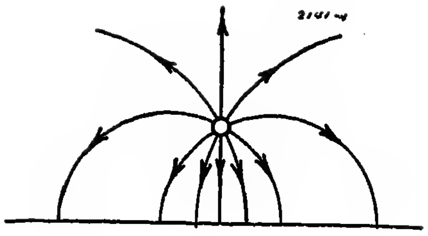

Figure 1 (left). Field E_1 in plane perpendicular to line

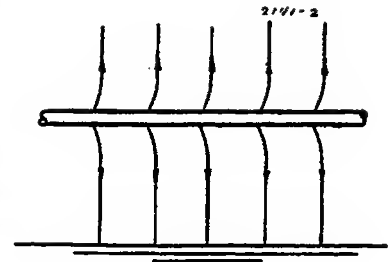

Figure 2 (right). Field E_1 in plane through line

The conditions establishing the validity of the postulated energy flow may be stated more exactly in this way. Construct a closed geometric surface anywhere in the electric system. Determine the postulated energy-flow density at every point of the surface. Integrate over the whole surface, obtaining the postulated total energy flow outward through the surface. This total energy flow out must correspond to the total changes taking place within the region enclosed by the surface. That is, the total energy flow out through the surface calculated according to the postulate must equal the excess of the rate of generation of electric energy over the sum of the rate of consumption and rate of increase of storage of electric energy within the surface.

It will be evident at once to the trained mathematician, and after a little study to the more lay engineer, that the conditions just given are not sufficient for determining uniquely an energy flow. For the postulate must merely direct the energy from the various generation points to the various consumption points, in their totality; which generation point is to feed which consumption point, and by what route, is completely undetermined so far as concerns any phenomenon which can be actually physically observed. Infinitely many postulates may be devised which will all be equally valid and equally well established by the conditions which have been described, and which are the only conditions available for defining an energy flow.

Actually, a postulated energy flow other than the *Vi* postulate, which is the subject of this paper, is very widely used, and not merely in abstract theory but for practical calculations, by radio engineers and physicists. This is the Poynting vector postulate about which there is an extensive literature.† We will not stop for a description of this Poynting vector postulate in detail at this stage. Suffice it to say that it is in its details completely different from the *Vi* postulate. In general, in an electric system it will lead energy from any particular generation point to a consumption point other than that to which it will be led by the *Vi* postulate, and where it leads energy from the same generation point to the same consumption point, it will in general do so by a different route.

† For description of energy flow in usual electric-power machines, according to the Poynting vector postulate, see Slepian, *Electric Journal*, volume 16, July 1919, page 303.

Calling attention to the lack of uniqueness of the validity of any and all valid energy-flow postulates is not however the primary purpose of this paper. It is rather to examine the *Vi* postulate and to determine whether it in itself is valid or established in the only physically verifiable sense which has been just described. The completely general validity of the Poynting vector postulate has been established (with the formulas for stored electromagnetic energy given above) by mathematical derivation from Maxwell's equations. The validity of the *Vi* postulate can then be determined most conveniently by checking by well-known mathematical operations whether it is equivalent to the Poynting vector postulate in the sense already explained. This has been done in another paper.[1]

It turns out that the *Vi* postulate is not generally valid, that is, it is not generally equivalent to the Poynting vector postulate. By adding a simple term, however, a new or enlarged *Vi* postulate may be given which is generally valid. It so happens that as usually used by electric-power engineers the contribution of this added term is negligibly small. Hence, no error is committed by the use of wattmeter readings in the usual way for the usual and proper purposes by the engineers of electric-power systems.

Without going into the detailed mathematics, this paper will show how the simple *Vi* postulate fails in many simple cases. It will describe the term which must be added to make the enlarged *Vi* postulate universally valid and will show in simple cases how this term makes complete the *Vi* energy-flow picture. It will show also that this term makes a negligible contribution in the usual use of wattmeters on power systems for usual proper purposes. To do these things, however, it is necessary to examine somewhat carefully the meaning of the electric potential V, the current density i, and the nature of the electric field.

II. The Electric Potential, V

The potential difference between two points is frequently defined as the integral of the electric force from the one point to the other, or, in other words, as the work which must be done in moving a unit positive charge from the one point to the other. This is equivalent to saying that it is the reading of a suitable voltmeter connected to the two points in question.

For d-c systems, where electric and magnetic fields are steady and unchanging, this definition is satisfactory. In this case the electric-field intensity is the negative gradient of the potential so defined. In this case also the simple *Vi* postulate is generally valid.

In this d-c case, the electric field and the potential of which it is the negative gradient can be calculated from the distribution of charges. If there are no dielectrics, the potential V is given by

$$V=\iiint \frac{\zeta}{r}dv \qquad (1)$$

where ζ is the charge density at any variable point, r is the distance from this variable point to the point at which the potential is being determined, and the integration is carried out through all space. If dielectrics are present, then a term must be added under the integral of equation 1, giving the effect of the polarization density in the dielectrics, but for simplicity we shall leave this out of the formula, as it can be readily supplied by those readers sufficiently trained to feel the lack of it. The electric field is then given by

$$E=-\text{grad } V \qquad (2)$$

In the case of an a-c system, however, the definition of the potential given at the beginning of this section fails. The work done in moving a unit charge from one point to another is no longer uniquely determined. The work done is different according to the path chosen in going from the one point to the other. For example, the work done in moving a charge from a point near the core of a transformer to a point diametrically opposite, by a path half way round the core,

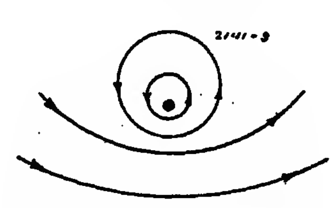

Figure 3 (left). Magnetic field around line

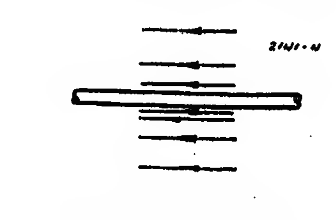

Figure 4 (right). Induced electric field E_2

will be different from the work done if the charge is moved from the one point to the other in the other direction round the core. If a suitable voltmeter is connected between the two points, the reading will be different according to whether the leads go round the core by the one path or the other.

We may however define a function calculated from the observable distribution of charges (and polarizations of dielectrics) by means of equation 1. We shall call this the Maxwell scalar potential,‡ V_M, so that

$$V_M=\int\int\int\frac{\zeta}{r}dv \tag{3}$$

Of course, the electric field is not the negative gradient of this scalar potential

$$E\neq-\text{grad } V_M \tag{4}$$

In fact E is not the gradient of any potential.

We may regard the electric field E as made up of a superposition of two fields, E_1 and E_2,

$$E=E_1+E_2 \tag{5}$$

where

$$E_1=-\text{grad } V_M \tag{6}$$

E_1 may be said to be the field produced electrostatically by the charges defining V_M.

If a charge is moved around in a closed path, the work done against the component field E_1 is necessarily zero, since E_1 is the gradient of a potential. If there is a net work, not zero, done by the charge in going round the closed path in the total field E, it must be the work done against the component field E_2. Thus the integral of E_2 around a closed path is in general not zero. By Faraday's law, this integral, sometimes called the induced electromotive force, is equal to $1/10^8$ times the rate of change of the enclosed magnetic flux, the units of electric field and magnetic flux being the usual volts per centimeter and maxwells.

The lines of force of the field E_2 cannot terminate on any charge, since equations 3 and 6 make E_1 bring to or from all the charges all the corresponding lines of force, thus leaving no charges for the lines of E_2 to terminate upon. The lines of force of E_2 then must form closed loops, linking varying magnetic flux. E_2 may then be said to be the electric field induced by the varying magnetic field, and to have no electrostatic character.

‡ Physicists now more generally use the retarded scalar potential of Lorentz. Except for very long lines in power systems, or high frequencies, this potential will differ very slightly from the scalar potential of Maxwell, which is used here because of its simpler description.

Mathematically the defining properties of E_1 and E_2 are as follows:

$$\text{div } E_1=-4\pi\zeta,\ \zeta \text{ in appropriate units} \tag{7}$$

$$\text{div } E_2=0 \tag{8}$$

$$\text{curl } E_1=0 \tag{9}$$

$$\text{curl } E_2=-1/10^8\frac{\partial B}{\partial t} \tag{10}$$

It appears that the potential used by electric-power engineers is precisely the Maxwell scalar potential which has just been described.

For example consider a single transmission line parallel to the surface of a good conducting earth, which is taken as having zero potential. The charges on the line by themselves, if they were unvarying, would produce the field E_1 with lines of force lying nearly completely in planes perpendicular to the line, as in Figures 1 and 2. The slight curvature in the lines of force of E_1, and their inclination to the line, shown in Figure 2 somewhat exaggerated, are due to the charge density on the line decreasing from left to right, due to the decreasing "potential" of the line.

The current in the line, produces the magnetic field shown in Figure 3, the lines of magnetic force lying in planes perpendicular to the line. If the current is increasing, the magnetic field also increases and induces an electric field E_2 whose lines of force are nearly parallel to the line as in Figure 4. This field is strongest at the line, where it is nearly equal, and opposite in direction to the component of the field E_1 which is parallel to the line. The parallel component of the net field, E, at the line is that required by the ohmic resistance of the line to the current it is carrying. The total field E is the sum of the electrostatic field E_1 and the induced field E_2.

To determine the potential at a point 1 in the line, the power engineer connects a voltmeter from that point to the ground immediately below. That is, he integrates the electric force along a path in the plane perpendicular to the line. Since such a path is perpendicular to E_2, he essentially integrates the field E_1 alone and, therefore, by equation 6, determines the Maxwell scalar potential, V_M, at the point 1 of the line.

To determine the potential at a second point 2 in the line, the engineer connects his voltmeter from the point 2 to the earth immediately below, and not to the earth point used for getting the potential at point 1. To find the potential difference between points 1 and 2, the engineer takes the difference between the potentials so determined. He does not connect a voltmeter from point 1 to point 2 with leads running parallel to and along the line. If he did, the field E_2 would contribute to the integral of E from 1 to 2 and he would get a result differing from that obtained by his usual procedure. He would say that this last procedure would give him only the resistance drop in the line, whereas his usual procedure gives him the total (resistance plus inductance) drop in the line. It is clear then that the power engineer uses the Maxwell scalar potential. Therefore, subsequently in this paper, the subscript M will be dropped from the V symbol for potential, it being understood that the Maxwell scalar potential is that which is meant.

III. The Corrected Vi Postulate

The appearance of the induced field E_2 is one of the features which distinguishes the variable-state or a-c system from the steady-state or d-c system. If E_2 is absent or negligibly small, then the usual energy-flow postulate,

$$P_1=Vi \tag{11}$$

is generally valid, provided i includes displacement currents as well as conduction currents, as will be explained in the next section. If however, E_2 is not absent, equation 11 becomes invalid. Then the following energy-flow postulate,

$$P_2=Vi+\frac{10}{4\pi}[E_2\times H] \tag{12}$$

is generally valid. The bracket symbol in equation 12 indicates the vector product of E_2 and H, whose meaning will be explained later in examples. The two terms in P_2 may be called respectively the conductive and inductive components of the postulated energy flow.

IV. The Current Density i—Example of Variable-State System Where P_1 Is Valid

To see how the inclusion of displacement currents in i makes P_1 valid as long as E_2 is absent, consider the following example:

A sphere of radius R, far removed from other objects, is charged to potential V_o. It is then surrounded by a spherically symmetrical radial electric field, with $V=V_oR\frac{1}{r}$, and $E=V_oR\frac{1}{r^2}$ where r is the distance from the center. There will then be a stored energy density, $T_e=\frac{1.11\cdot10^{-12}}{8\pi}E^2$ $=\frac{1.11\cdot10^{-12}}{8\pi}V_o^2R^2\frac{1}{r^4}$ joules per cubic

centimeter in the space around the sphere.

Now let the sphere be joined by a fine high-resistance wire to the remote ground. The sphere slowly discharges by the conduction current through the wire. The small current flowing produces a magnetic field, but let us suppose it is so small that we may neglect the stored energy which is associated with it and also the small induced field E_2 which it produces by its slow change.

The stored energy in the electrostatic field slowly disappears, and a corresponding amount of heat appears in the wire. The valid energy-flow postulate, $P_1=Vi$ must show energy flowing from the space where it is initially stored to the wire where it appears as heat.

In the wire itself, let the total conduction current be I. At a point where the potential is V_a, the postulate P_1 asserts that there is an energy flow in the wire equal to V_aI watts away from the sphere. At a more remote point on the wire, where the potential is V_b, the energy flow in the wire is V_bI, watts away from the sphere. V_bI is less than V_aI, the difference being $(V_a-V_b)I$. But if ζ_{ab} is the resistance of the wire in ohms between points a and b, $V_a-V_b=\zeta_{ab}I$, and $(V_a-V_b)I=\zeta_{ab}I^2$ which is precisely the joulean heat developed in the wire between a and b. Thus the postulate $P_1=Vi$ shows energy flowing from the sphere down the wire where it appears as heat at the proper places and in the proper amounts.

But the valid postulate $P_1=Vi$ must also show how the energy stored in the electrostatic field arrives at the sphere so that it may be directed thence into the wire. The displacement current density comes to the rescue for this purpose.

Where an electric field E is varying, in free space, a displacement current density is defined as $i=\frac{1.11\cdot10^{-12}}{4\pi}\frac{\partial E}{\partial t}$ amperes per square centimeter. In the present example E is decreasing so that there is a displacement current density flowing inwards towards the sphere given by $i=\frac{1.11\cdot10^{-12}}{4\pi}R\frac{dV_o}{dt}\frac{1}{r^2}$. The total displacement current flowing inwards over the surface of a sphere of radius r_a will be $4\pi r_a^2 i=1.11\cdot10^{-12}R\frac{dV_o}{dt}$. The potential at r_a being $RV_o\frac{1}{r_a}$ volts, there is a total energy flow inwards across the surface, according to the Vi postulate, of $1.11\cdot10^{-12}R^2V_o\frac{dV_o}{dt}\frac{dV_o}{dt}\frac{1}{r_a}$ watts. Across a more remote sphere, of radius r_b, the total energy flow inwards is $1.11\cdot10^{-12}R^2V_o\times\frac{dV_o}{dt}\frac{1}{r_b}$. The flow inwards across the inner sphere exceeds the flow inwards across the outer sphere by $1.1\cdot10^{-12}R^2V_o\frac{dV_o}{dt}\times\left(\frac{1}{r_a}-\frac{1}{r_b}\right)$ watts. This should be equal to the rate of decrease of the energy stored in the shell between the two spherical surfaces.

But integrating the stored energy density, $T_e=1.11\cdot10^{-12}V_o^2R^2\frac{1}{r^4}$ over this spherical shell, we get $\frac{1.11\cdot10^{-3}}{2}V_o^2R^2\times\left(\frac{1}{r_a}-\frac{1}{r_b}\right)$ joules. The rate of change of this energy, $1.11\cdot10^{-12}V_o\frac{dV_o}{dt}R^2\left(\frac{1}{r_a}-\frac{1}{r_b}\right)$ checks exactly with the assertion of the Vi postulate in the preceding paragraph.

Figure 5 shows diagrammatically this flow of the stored energy to the sphere and thence to the wire according to the Vi postulate. For comparison, Figure 6 shows the energy flow according to the Poynting vector postulate.

V. Example of Failure of Simple Vi Postulate

Consider a long straight linear conductor of circular section and radius R. Let a current flow in it which is increasing at a constant rate, $I=I_ot$. Let the return circuit be the parallel-plane good conducting ground a considerable distance below the conductor.

There will be a magnetic field surrounding the conductor as in Figure 3, and this field will be increasing in strength at a constant rate. The stored energy associated with this field and distributed in the space will also be increasing. A valid energy-flow postulate must show a flow of energy into these regions where the stored energy density is increasing.

A potential drop (Maxwell scalar potential drop) will exist along the line, called by the engineer the inductive drop along the line. Neglecting the ohmic resistance of the line this potential drop will be constant in time. Associated with this distribution of potential on the line will be an electrostatic field E_1 as pictured in Figure 2. This field will be constant in time.

The steadily increasing magnetic field of Figure 3 will induce an electric field E_2 as pictured in Figure 4. This induced field E_2 is also constant in time.

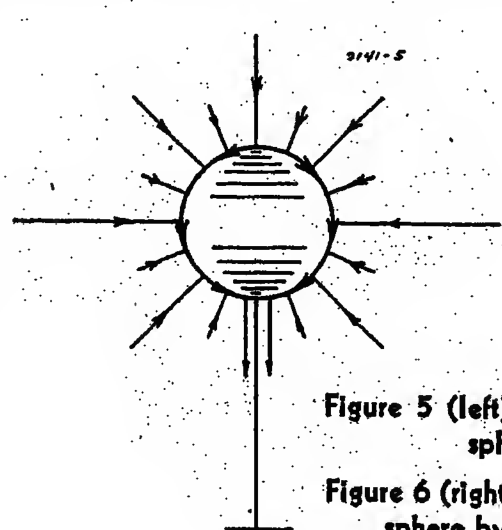
Let us apply the simple $P_1=Vi$ postulate to this case. It shows an energy flow in the line at each point of an amount VI watts, where V is the potential at the point. Everywhere else, other than in the line, the current density is zero. There is no displacement current in the space because the electric fields E_1 and E_2 are constant in time. The simple $P_1=Vi$ postulate then shows energy flowing in the line and nowhere else.

Consider a short length of the line. Because the potential at the entering end is larger, the energy flow entering the section is greater than that leaving the section. Hence, if the simple Vi postulate is valid, there should be appearing in the section an increasing amount of some form of energy, such as heat for example. But no such energy appears there! The simple Vi postulate fails!

Likewise, out in space the stored magnetic energy is increasing. The Vi postulate should show an energy flow bringing this stored energy to its proper position in space. It does not! It fails!

VI. Success of the Enlarged Postulate, $P_2=Vi+\frac{10}{4\pi}[E_2\times H]$, With Preceding Example

The bracket in the second or inductive term of the enlarged postulate, P_2, denotes the vector product of the induced electric field E_2 and the magnetic field H. This is a vector which stands perpendicular to both E_2 and H, with direction given by the right hand rule, that is, the direction of advance of a right-hand screw when



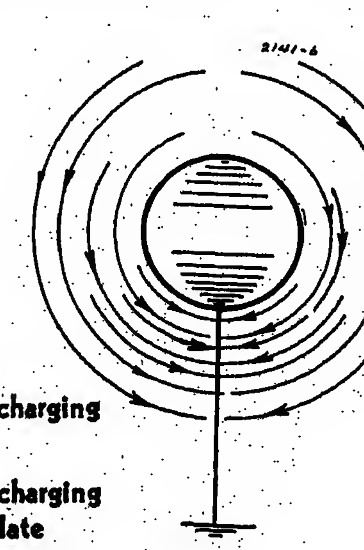


Figure 5 (left). Energy flow for discharging sphere by Vi postulate

Figure 6 (right). Energy flow for discharging sphere by Poynting vector postulate

turned in the sense which brings E_2 most quickly into line with H. Its magnitude is equal to the product of the magnitudes of E_2 and H, respectively, and the sine of the angle between them.

Let the induced electric field E_2 have the value E_{20} at the conductor itself. The (Maxwell scalar) potential gradient along the conductor will have the same magnitude as E_{20}, since we are neglecting the ohmic resistance of the line, but will be oppositely directed.

Let the length of the portion of the line we are considering be l centimeters. The potential drop through this portion will then be $l|E_{20}|$, $|E_{20}|$ being the magnitude of the vector E_{20}. The first or conductive term of P_2 then will give an excess of energy entering the one end of the line

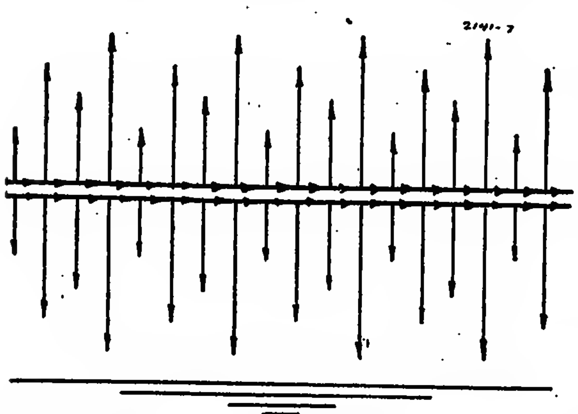

Figure 7. Energy flows about line carrying increasing current by P_2 postulate

portion over that leaving the other end by an amount equal to $l|E_{20}|I$ watts.

At the surface of the line, the magnetic field H_o is perpendicular to the line and E_{20} and has the magnitude $|H|_o=\dfrac{2I}{10R}$. The second term of P_2 then shows an energy-flow density leaving the conductor surface of $\dfrac{10}{4\pi}|E_{20}|\dfrac{2I}{10R}=\dfrac{1}{2\pi}|E_{20}|\dfrac{I}{R}$ watts per square centimeter. Multiplying by the area of the surface of the line, $2\pi Rl$, we find the second term showing an energy flow out of the line of an amount $l|E_{20}|I$ watts. Comparing with the preceding paragraph we see that the enlarged postulate P_2 calls for the appearance in the line of heat or other energy of amount zero! In the line P_2 succeeds!

In the space outside the line, while the first term of P_2 shows zero energy flow, the second or inductive term shows energy flow radially outwards into space. It is not difficult to show that this radial flow is of just the proper amount to account for the increasing magnetic energy stored there. Figure 7 shows diagrammatically the energy flow about the line according to P_2.

P_2 succeeds everywhere! It must, since it has been shown in the paper of footnote 1 that it is equally valid with the Poynting vector postulate.

VII. Energy Flow in Transformer

It is instructive to trace the flow of energy in a transformer according to the simple and enlarged Vi postulates. The simple Vi postulate fails, of course. The enlarged postulate succeeds because of its inductive term.

In each turn of the primary of the transformer, there is a potential drop equal to the induced voltage per turn, V_t, if the resistance drop is neglected. According to the simple Vi postulate then, more energy flows into the turn than out by an amount V_tI_p watts, where I_p is the primary current. The simple Vi postulate then makes $V_tn_pI_p$ (n_p=number of primary turns) watts disappear in the primary, apparently causing energy to be annihilated.

Similarly, the simple Vi postulate calls for the apparent creation of energy in the secondary at the rate $V_tn_sI_s$ watts.

The second term of the enlarged Vi postulate avoids this apparent distressing destruction of energy in primary and creation of energy in secondary by providing an energy flow from primary to secondary.

Between the primary and secondary coils there will be a magnetic field perpendicular to the coil wires, Figure 8. This field will have magnitude approximately $|H|=\dfrac{4\pi}{10}\dfrac{n_pI_p}{l_1}$ where l_1 is the length of the coil. Between the coils there will also be an induced electric field E_2 with lines of force remaining parallel to the coil wires and perpendicular to H. The magnitude of E_2 will be approximately $|E_2|=\dfrac{V_t}{l_2}$ where l_2 is the perimeter of a turn.

According to the second term of P_2, then, there is an energy flow from primary to secondary of $\dfrac{10}{4\pi}[E_2\times H]=\dfrac{V_tn_pI_p}{l_1l_2}$ watts per square centimeter. Multiplying by l_1l_2, the total area carrying this energy-flow density, we get $V_tn_pI_p$ watts carried across from primary to secondary by the second term of P_2, which is just the energy brought into the primary by the first term Vi.

VIII. Relationship Between Poynting Vector Postulate and P_2

The Poynting vector postulate asserts the presence of an electric-energy-flow density given by

$$P=\frac{10}{4\pi}[E\times H] \text{ watts per cm}^2 \tag{13}$$

It differs from the enlarged Vi postulate, P_2 in making all the energy flow inductive, and none conductive.

This suggests that the resolution of the energy flow into a conductive and inductive component as in P_2 is largely arbitrary. This is true.

Let V' be any *arbitrary* scalar function of position in space. Let E_1' be a vector function of space defined by

$$E_1'=-\text{grad } V' \tag{14}$$

Let E_2' be defined by

$$E=E_1'+E_2' \tag{15}$$

Then it is readily shown that the energy flow postulate

$$P_2'=V_i'+\frac{10}{4\pi}[E_2'\times H] \tag{16}$$

is equally valid with P and P_2.

This bears out the statement made in the introduction that infinitely many valid energy-flow postulates may be devised.

The Poynting vector P, and the corrected Vi postulate P_2, are special cases of equation 16, obtained by respectively taking $V'=0$, and taking for V' the electric potential V.

IX. Validity of Simple Vi Postulate for Usual Proper Purposes on Power System

The power-system engineer postulates an energy flow in his lines given by connected wattmeter readings and with this postulate carries on his usual technical and commercial operations. This postulate is identical with the simple Vi postulate (except for the omission of displacement currents) which we have seen is not generally valid. The postulate can be made valid by the addition of the inductive term of P_2. Hence, since the engineer is successful in his usual operations, we conclude that he limits himself to those applications where the contribution of the inductive term of P_2 is negligible.

We have also seen that even the valid enlarged Vi postulate, P_2, is not uniquely valid. Hence, again since the engineer is successful in his usual operations, we conclude that he normally limits himself to those questions for which all valid postulated energy flows will give the same

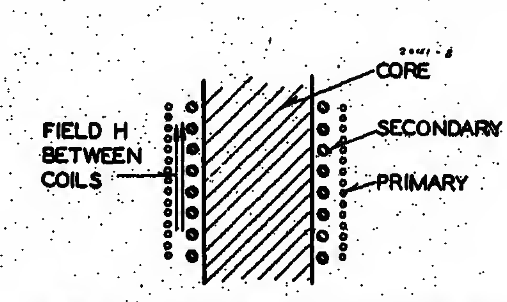

Figure 8. Magnetic field in transformer

Correct connection

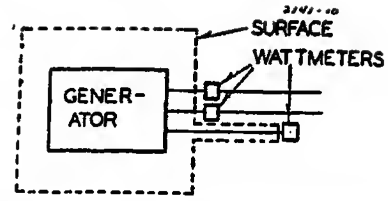

Figure 10. Energy of generators by wattmeters

Incorrect connection

answer. In referring back to the introduction, there is only one question to which all valid energy-flow postulates give the same answer, namely, the following: In a given region of space, in which there may be any and various kinds of electric apparatus, what is the excess of the total electric-energy generation over the sum of the total energy consumption and the increase in electric-energy storage?

Before giving examples, it is well to point out one use of wattmeter readings which is frequently made and which does not involve the energy-flow postulate at all. It is for determining the loading or heating of lines.

Now, the heating of a line certainly does not depend on any so intangible and intrinsically indeterminable a thing as a postulated energy flow. The heating is determined only and entirely by the current through it, and this is measured unequivocally by an ammeter. However, from the wattmeter reading the engineer, if he knows the usual voltage and power factor of the line, can make an estimate of what the current may be and thus estimate the loading or heating of his line. But in doing this the engineer is really using the wattmeter, together with his other knowledge of the line, as a kind of devious ammeter. Regardless of how he may colloquially refer to energy or power or the line, he knows that the heating of the line is determined by the current magnitude only.

As a first example, consider the determination of the energy generated by a generator. The engineer places wattmeters in all the leads coming from the generator, adds their readings algebraically, and asserts that number so obtained is the desired generation. He will be right if the inductive term of P_2 makes no contribution.

Surround the generator by a closed surface passing through the points in the leads where the engineer connected his wattmeters (Figure 9). The validity of P_2 ensures that, when integrated over this closed surface, it will give the net rate of energy generation in the generator since the energy stored remains constant. The conductive term, Vi, of P_2, will be zero everywhere in the surface except over the sections of the generator leads. This term integrated over the surface will equal the sums of the wattmeter readings. E_2 and H which enter into the inductive term, $\frac{10}{4\pi}[E_2 \times H]$ of P_2, will each be negligibly small on the surface, except in the neighborhood of the leads. There, as explained in sections *V* and *VI* and shown in Figure 3, E_2 is parallel to the leads and therefore perpendicular to the surface. H however will lie parallel to the surface. Hence $\frac{10}{4\pi}[E_2 \times H]$ lies entirely parallel to the surface and makes zero contribution to the total energy crossing the surface by the P_2 postulate. Hence P_2 integrated over the surface equals the sum of the wattmeter readings, and the engineer's usual use of wattmeters for determining the energy generation of a generator is justified.

It is clear from this discussion that the validity of the use of wattmeters alone in

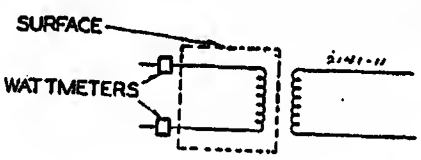

Figure 11 (left). Determination of loss in primary of a transformer

the preceding example depends on the points of attachment of the wattmeters to the leads lying in a surface which is perpendicular to the E_2 field. The engineer is aware of this. If one of the wattmeters is displaced along one of the leads from its proper position, as in Figure 10, the engineer knows that the sum of their readings will no longer equal the rate of energy generation in the generator. Ordinarily he will say that this is due to the inductive action of the leads, each on the other. This paper describes this situation by observing that the inductive term of P_2 in this case asserts a flow of energy not zero over the portion of the enclosing surface, which lies parallel to the leads.

Another example: The engineer will not attempt to determine the losses in the primary coil of a transformer by means of wattmeters alone. In referring to Figure 11, showing a transformer diagrammatically, it is clear that for a surface which encloses the primary alone, there will necessarily be some portions across which the inductive term of P_2 will also assert there is an energy flow, as explained in section VII, and this energy flow must be added algebraically to the wattmeter readings to obtain the primary losses. However, the engineer will not hesitate to determine the total losses in a transformer alone, since in that case an enclosing surface may be drawn such that across it the inductive term of P_2 will assert zero energy flow.

A last example: Two power systems, A and B, operate with an interconnecting transmission line, in which wattmeters are properly placed. The engineer advises that the owners of these systems make payments to one another depending on the sum of the readings of these wattmeters. What is the physical basis on which the engineer makes his recommendation?

Referring to Figure 12, a surface may be drawn through the points of connection of the wattmeters and enclosing completely the system A, such that the contribution to the energy flow across the surface according to postulate P_2 of the inductive term is zero. The contribution of the conductive term will of course equal the sum of wattmeter readings. Hence we may conclude that the sum of the wattmeter readings equals the excess of the generation in system A over the sum of all the loads and losses in system A.

Similarly, a surface may be drawn

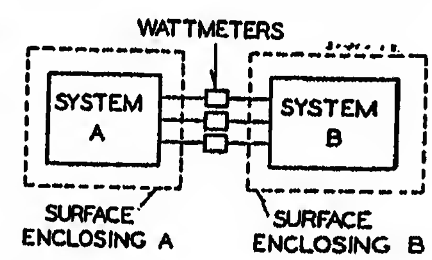

Figure 12. Power systems interconnected

through the wattmeter connections and enclosing the system B, which will justify the statement that this same sum of the wattmeter readings also equals the excess of the sum of the loads and losses over generation in system B.

Because of this numerical relationship between the wattmeter readings and the balance between generation, loads and losses on the two respective systems, the engineer makes his recommendation that the owners of system B compensate the owners of system A. The engineer may in addition make some irrelevant assertions concerning energy flow in the transmission line, while a physicist may equally irrelevantly speak of an energy flow from A to B through space.

The owners of the systems are indifferent to these reflections of engineer and physicist. Their esthetic tastes may perhaps be more like that of the engineer so that they may prefer an energy flow postulate P_2 which makes some of the energy (but not all) flow in wires, to one like P, where nearly all of the energy flows in space and quite remotely from the wires.

Power-System Interconnection in Quebec

W. R. WAY
MEMBER AIEE

I. Introduction

THE main purpose of this paper is to describe the development of a major interconnected system located in the province of Quebec.

By means of a study, based on prewar data when stable conditions existed, and by suitable illustrations and explanations, it is aimed to show how it has been possible, through interconnection of three important hydroelectric systems, to increase the combined firm power capacity far beyond the sum of the capacities of the individual systems if operated independently. It will be brought out that the diversity in load characteristics and hydraulic conditions makes it feasible to accomplish this result and to effect other desirable economies on these systems, which are dependent solely on power supply from hydroelectric plants.

The possibilities of system consolidation had been under study for some years, but the war, with the urgent demand for more firm power, forced the issue to a conclusion, involving combined power resources of nearly 4,000,000 horsepower as indicated in Table I.

Reference will also be made to certain engineering features and operating practices of these systems, which may prove to be of interest.

II. Description of Geographical Areas

In leading up to a detailed analysis of the present interconnected system, it is thought desirable to describe briefly the areas under consideration.

The Montreal Area. This area is considered as including the territory in the immediate vicinity of Montreal Island on which is located the city of Montreal. Power is supplied by the Montreal Light, Heat, and Power Consolidated principally from two power developments on the St. Lawrence River. The plants of the Montreal Island Power Company and of the Canadian Light and Power Company also feed into this area.

Originally, in the year 1900, electric service was supplied by a number of small isolated power companies, not interconnected in any way and each serving its own independent district. In most cases standby steam plants were necessary to guard against the frequent interruptions to the supply from the hydroelectric plants because of ice trouble, breakdown, and other causes.

In 1902 the Montreal Light, Heat, and Power Consolidated was formed and acquired jurisdiction over most of the isolated systems in and near Montreal. It was soon realized that for reasons of economy, and to secure better service, some consolidation of systems or interconnection between plants was essential.

While some immediate constructive steps were taken in this direction, it was found that parallel operation was difficult or in some cases impossible because of the different frequencies, these being 66, 60, and 30 cycles. Furthermore, some systems were two-phase, while others were three-phase, and even direct-current. Eventually by compromising on 63 cycles, tying in through frequency changers, increasing the 30-cycle frequency to 31.5 cycles, and adopting three-phase alternating current, a common operating base was obtained, but this did not necessarily indicate parallel operation of the combined systems. Actually it was not until 1923 that all the subsystems of the Montreal area were operated completely in parallel.

The Shawinigan Area takes in the territory on both sides of the St. Lawrence River from Montreal to Murray Bay, some 80 miles below Quebec City, and is served mainly by the Shawinigan Water and Power Company, the Quebec Power Company, and the Southern Canada Power Company.

The Saguenay Area in the Lake St. John region is served mainly from plants on the Saguenay River by companies under the control of the Aluminum Company of Canada, Ltd.

III. Load, Output, and Hydraulic Characteristics of the Individual Systems

In the *Montreal Area* the St. Lawrence River is the chief source of power and has a flow which is unusually uniform, the average mean flow being 220,000 cubic feet per second, while the maximum and minimum recorded flows are 318,000 cubic feet per second and 173,000 cubic feet per second respectively. The heads involved are from 26 to 80 feet; comparatively long headrace canals are found, with the main difficulties in power output being caused by ice jams or other forms of ice trouble, occurring during the months of January and February. A typical hydrograph is shown in Figure 1.

The nature of the load in the Montreal area is that which might be expected in any large metropolitan area, with weekday load factor in the winter months of the order of 68 per cent and an annual load factor of 47.5 per cent during the prewar period. Maximum peak loads occur in the months of November or December, with a definite tapering off during the summer months. This is well

Paper 42-150, recommended by the AIEE committees on power transmission and distribution and power generation for presentation at the AIEE Pacific Coast convention, Vancouver, B. C., Canada, September 9–11, 1942. Manuscript submitted June 4, 1942; made available for printing July 9, 1942.

W. R. WAY is assistant general superintendent of the Shawinigan Water and Power Company, Montreal, Quebec, Canada.

The author acknowledges the assistance of J. R. Hango of the Saguenay Transmission Company, Ltd., and Cooper Antliffe of the Montreal Light, Heat, and Power Consolidated in the preparation of this paper.

But what actually moves the owners of A to expect compensation is the physically observable fact that the generation in A exceeds the sum of the energies billed for at all the loads in A plus the losses in A. Likewise the owners of B are persuaded to make compensation by the physically observable fact that the total energy generated in B is less than the sum of the energies billed for at all the loads in B plus the losses in B. These same physically determinable facts as to location and magnitude of electric-energy generation and consumption, which basically are those alone in which owners of power systems are interested when engaged in "exchanges of energy," are also the only physically determinable facts on which the infinitely many valid energy-flow postulates will agree. The engineer is quite right in choosing one of them, namely $P_2 = Vi + \frac{10}{4\pi}[E_2 \times H]$, for determining the magnitude of the so-called "exchange of energy," and applying it under such a condition that the second term may be neglected, and determining the effect of the first term by wattmeter readings.

illustrated by comparing the typical daily load curves shown in Figure 2.

The chief need consequently is peak power for short periods during the winter months, while during the remainder of the year large and variable amounts of surplus energy and power are indicated, particularly during the months of April to November inclusive, with no immediate market available.

From the point of view of output, the gross primary kilowatt-hours sold in this entire area for 1941 were 3,341,902,000, while the corresponding maximum system peak load for primary power was 586,200 kw.

In March 1942, there was available 60-cycle capacity horsepower to the extent of 650,000 horsepower apart from that available from the Shawinigan Water and Power Company under the 160,000-horsepower contract.

In the Shawinigan Area the St. Maurice River is the most important source of power. It has a drainage area of 16,000 square miles and is suitably equipped for good regulation, having a number of storage reservoirs with a total storage of 13,000 square-mile-feet. This gives an indication of the extent to which the river is regulated and the possibilities of storing water for the combined system.

By using these storages, the regulated flow (Figure 1) can usually be maintained at 22,000 cubic feet per second, as compared with the unregulated minimum flow of 6,000 cubic feet per second. The maximum flow now experienced is of the order of 120,000 cubic feet per second which occurs early in May. As a result plants on this river have little difficulty in maintaining a high rate of output, excepting during the high tail-water period when in certain cases the plant output is markedly reduced. It so happens, however, that in the month of May the Montreal area is in a position to rectify this condition to a great extent, so that from the hydraulic standpoint, there is some diversity between the Montreal and Shawinigan areas.

From the load standpoint the Shawinigan system firm load is of an unusually high load factor, being of the order of 92 per cent on a week day, with an annual load factor under prewar conditions of 71 per cent. The type of firm load includes paper mills, aluminum production, carbide and carborundum furnaces, and asbestos mills, as well as a few steel plants.

Until recently, on account of the important paper-mill load which required the supply of quantities of process steam, large amounts (maximum peak over 500,000 horsepower) of surplus energy were supplied to electric boilers to replace coal-fired steam at the mills. This surplus was not only that obtainable from the Shawinigan area proper but also included secondary power purchased from neighboring companies.

Output characteristics of the Shawinigan system during the year 1941 included gross kilowatt-hour sales of 6,270,760,543 kilowatt-hours with a maximum 60-cycle firm peak of 868,000 kw. In March 1942 this area was served by 30-cycle and 60-cycle capacity to the amount of 1,154,500 horsepower aside from the 100,000-horsepower firm power contract with the Saguenay Power Company.

In the *Saguenay Area*, the Saguenay River is fed from a watershed area of 28,100 square miles. The hydrograph of this river (Figure 1) is somewhat similar to that of the St. Maurice River but is fortunately different as to the time of occurrence of the high water period, thus indicating advantages from interconnection with the St. Maurice River plants.

Prior to 1941 no storage reservoirs on this watershed had been constructed for regulating the flow of the Saguenay River, but Lake St. John itself (6,080 square-mile-feet usable storage) is utilized to the greatest practical extent from December to March inclusive.

Regarding load characteristics: before the war, power developed in the Saguenay area was utilized principally for the production of paper and aluminum and to supply the 100,000-horsepower firm power contract with the Shawinigan Water and Power Company. During periods of excess energy, the surplus was utilized for electric steam generation, the output for this purpose attaining at times the value of 375,000 horsepower. Since 1940, on account of the tremendous increase in demand for firm power, the electric boiler load has been discontinued.

The gross output of the plants in the Saguenay area during 1941 was 4,538,000,000 kilowatt-hours with a maximum firm peak of 639,000 kw. To serve this area, as in March 1942, there was capacity normally available to the extent of 1,000,000 horsepower.

IV. Possibilities of Maximum Utilization of Resources by Interconnection

In order to illustrate how the differences in the system characteristics of the three areas, could be utilized fully, a study has been made and a series of curves (Figure 3) prepared to show the peak (kilowatt) possibilities, while the kilowatt-hour problem is set out in Table II. The data have been based on *normal prewar conditions in 1939*, when interconnection was being considered.

The system in each area is analyzed graphically (Figure 3) to show its maximum available generator capacity (*G*),

Table I. Output Data of Plants Associated With Interconnection

	Total Rated Turbine Output (Horsepower)	Size of Largest Unit (Horsepower)	Number of Units
Montreal area supplied chiefly by Montreal Light, Heat, and Power Consolidated	968,000	53,000	45
Shawinigan area supplied chiefly by Shawinigan Water and Power Company	1,089,500	44,500	48
Saguenay or Lake St. John area supplied chiefly by Aluminum Company of Canada, Ltd.	1,850,000	85,000	28
Miscellaneous Companies	80,000	6,000	20
Total	3,987,500 horsepower		

Maximum rated capacity operated in parallel (2,586,000 horsepower) 1,930,000 kw.

power available (P) as influenced by hydraulic conditions, and maximum firm load (L) which could be carried if operated as a completely independent system. To simplify the study, no allowance for reserve has been made to take care of load growth or frequency regulation.

From Figure 3A it may be noted that in the *Montreal area*, the comparatively steady power output from the St. Lawrence River plants having no storage facilities and the metropolitan load of low load factor are not an ideal combination from the point of view of matching available power facilities and load requirements. In the summer months, even at time of peak load, over 100,000 kw surplus output is indicated, while an additional 100,000 kw is available for about seven hours each day after midnight. This unfavorable situation results in surplus energy being available to an amount of over 800,000,000 kilowatt-hours per year (item 1, Table II; see also Figure 2).

In the *Shawinigan Area*, with its large storages and regulating possibilities on the St. Maurice River, it is possible to convert the entire available annual energy into firm load irrespective of daily or seasonal requirements (item 2, Table II). The curves (Figure 3B) also show that the maximum feasible firm load that may be carried at the normal 71 per cent yearly load factor is also just equal to the limit set by reduced system generator capacity during the high tail-water period.

Under these conditions, except for two months during the spring flood period, there is a minimum of about 60,000 kw reserve generator capacity. This reserve is admirably suited to assist in converting daily or seasonal surplus energy of adjacent areas into firm power by storing such surplus energy in the St. Maurice River storage reservoirs and returning it as firm power during the winter months to satisfy peak requirements. Additional generator capacity on the St. Maurice River would permit extension of this scheme.

In the *Saguenay Area*, using average runoff for the $4^1/_2$ winter months, the maximum possible firm load to be carried is dependent on the fixed storage capacity of Lake St. John. This results in a large amount of idle generator capacity during the winter months (Figure 3C) and large surplus summer energy (item 3, Table II).

The idle generator capacity during the winter months, combined with Lake St. John storage facilities, is useful in assisting in the conversion of surplus night energy in the Montreal area into firm power. Furthermore, part of the summer surplus energy may be stored in the reservoirs of the St. Maurice River and taken back during the winter months and thus be converted into firm power.

These curves indicate that if each of the systems in the three areas were to be operated independently:

(*a*). The firm loads which each system could carry successfully would be limited definitely to the values indicated by the load curves (see Figures 3A, 3B, 3C), on account of limiting local conditions.

(*b*). The equivalent energy (kilowatt-hours) consumed by such individual firm loads would be restricted to the values given in Table II.

Such isolated system operation would leave a fair portion of the combined total resources unused, or inefficiently used, as indicated by the following:

(*a*). 1.7 billion kilowatt-hours of idle energy (from a firm-power viewpoint) equal to over 18 per cent of the total energy available. This corresponds to 260,000 kw (74.6 per cent load factor) of unused potential firm power (Table II).

(*b*). Spare generator capacity and spare power could be made available to all areas at

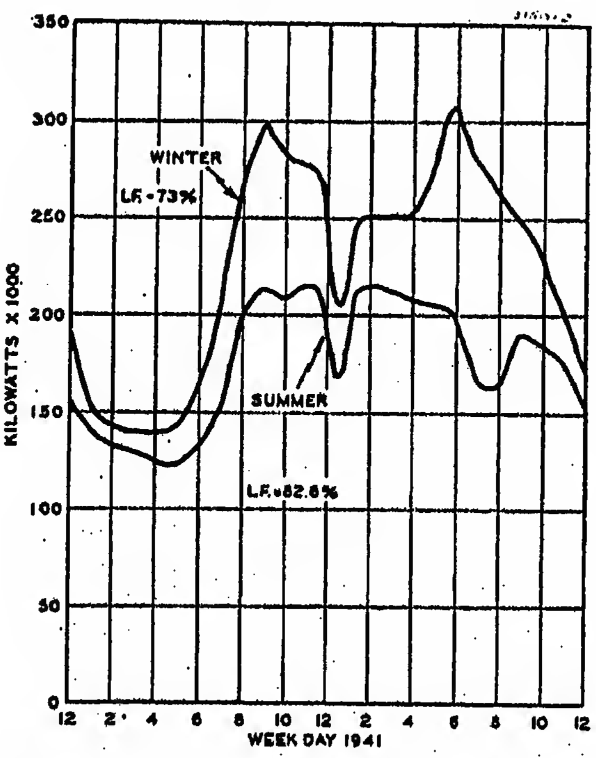

Figure 2. Typical summer and winter week-day (1941) firm load curves, Montreal area

Taken in combination with steady output of St. Lawrence River plants, the large amounts of surplus energy available for conversion into firm power are apparent

their critical periods during the year, because of the diversity in individual system power resources and load characteristics (Figure 3D).

These unused resources illustrate what potential possibilities a flexible interconnection of the three systems would offer for complete utilization of combined resources.

While it is not represented that this study is complete, and without attempting to describe in detail any specific coordination scheme or outline its practical execution, which would be most difficult without knowledge of how and where the reclaimed firm power would be used, it is submitted that the study does give a measure of the benefits to be derived from interconnection and justifies the following conclusion:

"By suitably interconnecting the three areas to permit free interchange of power, energy, and reserve generating facilities, by utilizing the Shawinigan facilities to store offpeak energy from neighboring areas, and by installing possibly 125,000 kw additional generating capacity on the St. Maurice River to permit returning the stored energy as firm power during the winter months, it is found possible to convert almost all of the surplus energy of the combined system into firm power.

"Thus a total of 260,000 kw of additional firm power may be gained (Table II, item 5), based on the combined system firm load factor under normal conditions of 74.6 per cent. This is illustrated by the curves Figure 3E. The capital expenditure involved for additional generating capacity and suitable tie-line connections has been estimated to be approximately $38 per kilowatt of firm power reclaimed, as against $100 to $125 per kilowatt for new power developments."

Apart from the low cost and more efficient use of resources, it was realized that proper interconnection would be expected to result in better operating flexibility, increased service security, and a number of miscellaneous advantages, such as:

The actual situation in this respect in 1939 was:

(*a*). More complete utilization of surplus energy and less combined reserve generating capacity required.

(*b*). Better regulation of load, frequency, and voltage.

(*c*). Full advantage taken of diversity in load and hydraulic conditions.

(*d*). Better maintenance schedules of equipment possible.

(*e*). Deferment of individual system additions to generating plants.

V. Prewar Conditions

Although from many such studies and frequent discussions, the advantages of adequate system interconnection were well known, there was no economic justification for proceeding, during the prewar period, with the execution of any plan until the reclaimed power could be sold as firm power.

(*a*). Each system had large amounts of surplus power and energy available and was

able to derive some revenue from the sale of such power to electric boilers, while firm load growth was proceeding normally.

(*b*). Since the Montreal and Shawinigan areas were interconnected in a limited manner, a portion of the surplus energy in Montreal area was utilized for electric-boiler load on the Shawinigan system.

(*c*). The Shawinigan and Saguenay areas were not interconnected, but some 30,000 kw to 50,000 kw were being interchanged, when desirable, by transferring blocks of load from one area to the other on the 60-kv system.

(*d*). Companies had to abide by commitments and contractual obligations in regard to new plant construction, and, therefore, there was no incentive to defer construction programs and to obtain prime power from neighboring companies by interconnection.

VI. Changed Conditions Caused by the War

With the advent of the war, there was an urgent and immediate demand for large amounts of additional firm power for defense industries. This abnormal demand was not confined to any one area but was most pronounced in the Saguenay and Shawinigan areas. As a result, some form of co-ordination involving proper system interconnection was immediately sought because of the attractive prospect of providing additional firm power in the shortest time at minimum cost.

Compared to the studies previously made on a prewar basis, war conditions modified the situation to some extent, and the actual trend for full development and utilization of total power resources, was along the following lines:

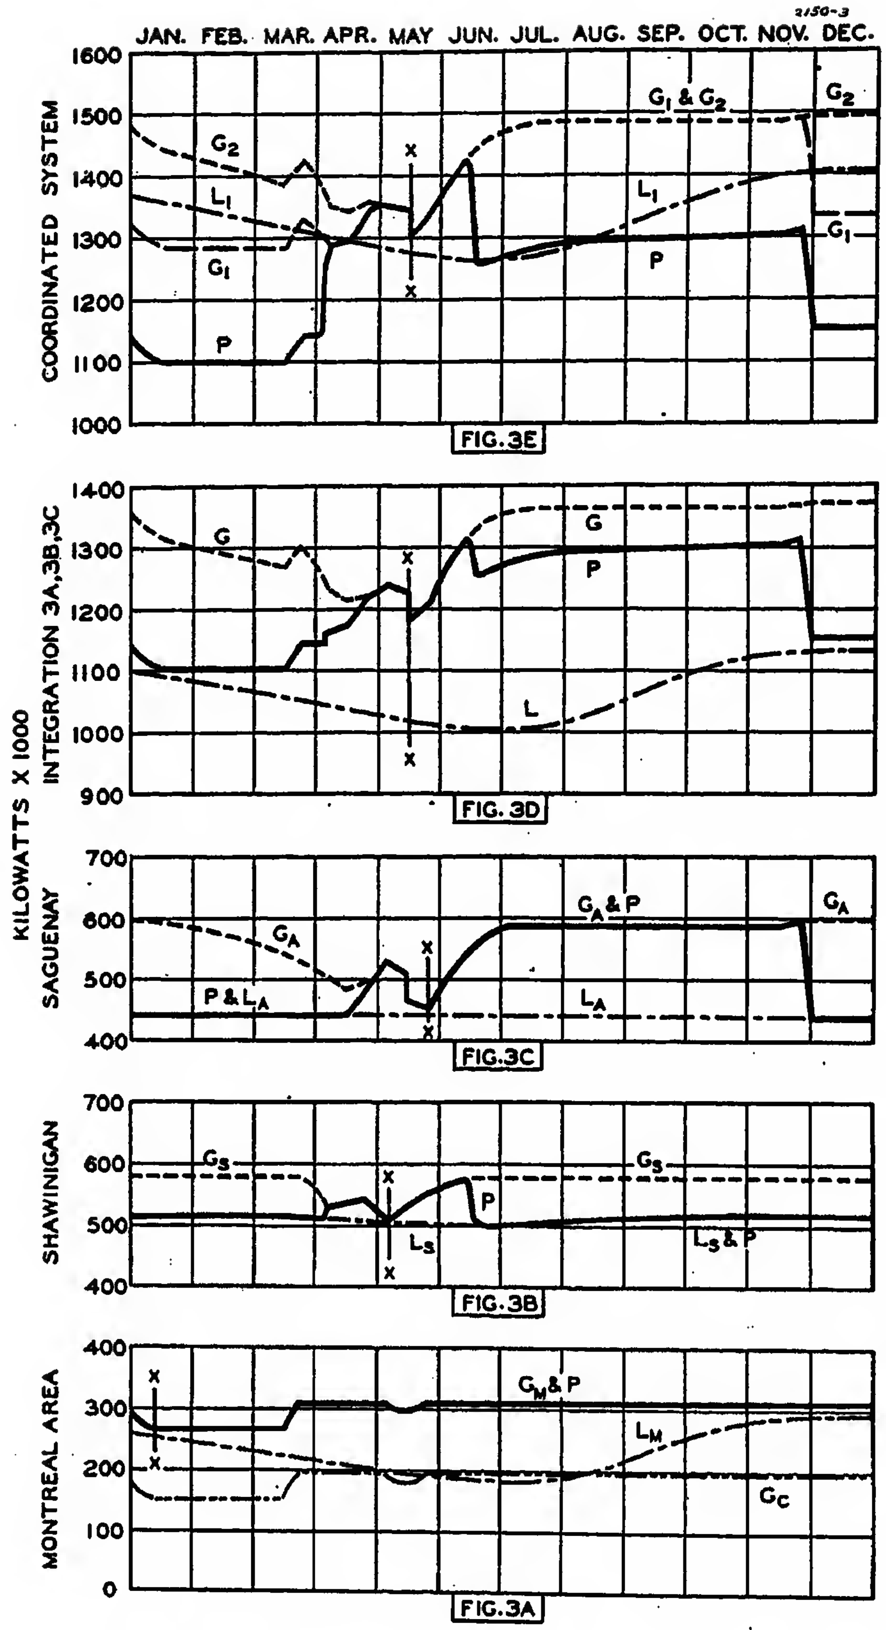

Figure 3. Curves to illustrate graphically the results of co-ordination study based on actual prewar system data

P=available firm power on a *daily* basis of at least normal system load factor. The variable shape of the curve is caused by water shortage or high tail-water conditions

G_M, G_S, G_A= maximum possible generator output at any instant on the individual Montreal, Shawinigan, and Saguenay systems respectively, as influenced by variable heads and flow conditions

G_C=actual Montreal area generator capacity, 1939, apart from Shawinigan contract

G=integration of G_M, G_S, and G_A, $G_2 = G + 125{,}000$-kw maximum system generator output with energy backing on a daily basis

$G_1 = G_2 - (G_A - P)$ = maximum system generator output with energy backing (normal-system firm load factor) from *seasonal* storage

L_M, L_S, L_A=maximum practical firm-power demand (at normal load factor) on the Montreal, Shawinigan, and Saguenay systems, respectively, and as dictated by maximum generator output at the critical point $X-X$ or shortage of water

These curves follow the typical or normal annual trend on the system concerned

L=integration of L_M, L_S, L_A

$L_1 = L + 260{,}000$ kw=estimated firm peak demand (at normal-system load factor) which could be successfully carried on the fully co-ordinated system

$X-X$=Critical points of generator reserve [since the Montreal Light, Heat, and Power Consolidated contract supply from Shawinigan Water and Power Company is duplicated in the output figures of each company (Figures 3A and 3B) a correction in the form of a deduction of 120,000 kw, (160,000 horsepower) has been made in the integrated curves (Figures 3D and 3E) to obtain the true result]

1. In the *Montreal area* there were immediately available some 825,000,000 kilowatt-hours of surplus energy annually which could be converted into prime power by utilizing Shawinigan storage. Such energy was available in the largest amounts during the summer months and during nights and week-

To utilize this energy necessitated increased back-feed from the 110-kv Montreal system and resulted in the installation (January 1942) of a 110-kv oil-filled underground cable seven miles long.[1] This eliminated the restriction or "bottleneck" in power flow through the 60-kv ring system and through the two 30,000-kva transformer banks in the city of Montreal and increased the transfer ability by over 100,000 kw.

2. In the *Shawinigan area* it was necessary to provide means for handling the increased feed-back from the Montreal area, as well as to store a portion of it, and transmit the remainder to the Saguenay area. This required certain changes on the system and included these items:

(*a*). Additional transformers and voltage regulating equipment were installed in certain districts to permit interchanging the full amount of power and to enable the reactive to be controlled.

(*b*). A number of additional storage projects were started on the St. Maurice River which, when completed, will provide additional capacity of 285 square-mile-feet equivalent to 16,000 horsepower years.

(*c*). To transmit the reclaimed firm power to the Saguenay area, a 220-kv transmission line was built and placed in operation December 1940. This line serves as a means of permanently interconnecting the Saguenay system with the Shawinigan and Montreal systems.

3. The *Saguenay Companies* decided on immediate industrial expansion and complete development and local utilization of power resources in the Saguenay area, as well as arranging for absorbing all available surplus power in the Shawinigan and Montreal areas. Physically, the program included:

(*a*). The construction of two storage reservoirs which, when completed, will provide the means of converting surplus summer energy in the Saguenay area into firm power. Storage capacities are estimated to be 2,460 and 5,360 square-mile-feet respectively and should permit an increase in the regulated flow of the Saguenay River from 32,000 to 45,000 cubic feet per second.

Table II. Study of Kilowatt-Hour Resources and Load Requirements

Based on Normal Prewar Conditions 1939

Item No.	Maximum Feasible Firm Loading If Operated as Isolated Systems: Annual Peak Demand, Kw	Annual Load Factor (Per Cent)	Equivalent Firm Energy Kwhr×10⁶	Total Practical Energy Available Annually Kwhr×10⁶	Surplus Energy Available Annually Kwhr×10⁶
1. Montreal area	293,000	47.5	1,220	2,045	825
2. Shawinigan area	520,000	71.0	3,240	3,600	360
3. Saguenay area	440,000	93.0	3,580	4,100	520
Total	1,253,000	73.0	8,040	9,745	1,705
* Less Montreal Light, Heat, and Power Consolidated contract	120,000		620	620	
4. Integration of items 1, 2, and 3. Net =	1,133,000	74.6	7,420	9,125	1,705

5. Combined surplus energy, if properly utilized and if converted into firm power, would be equivalent to:

$$\frac{1,705,000,000}{8,760\times 0.746}=260,000 \text{ kw}$$

6. Percentage of total energy resources reclaimable as firm power $=\frac{1,705}{9,125}=18.6$ per cent

* Since Montreal Light, Heat, and Power Consolidated contract supply from Shawinigan Water and Power Company is duplicated in the output of each company, its deduction is necessary to obtain a true result.

(*b*). Completion of a second double-circuit 154-kv line.

The result has been that with the provision of these facilities a rapid and fairly complete exploitation of all available power and energy resources in these areas has been accomplished with minimum outlay and in minimum time, providing as well additional generator reserve, improved operating flexibility, and service security.

As an illustration of the actual results obtained in combined system output, a typical daily firm-power peak load curve (Figure 4) for January 1942 has been plotted and shows how fully the resources are being utilized for firm-power purposes. It is to be noted that on the individual systems the margin of generator reserve is very limited, whereas on the combined system fairly large reserves are available excepting at time of maximum system peak.

VII. Analyzer Studies and Increased Fault Currents

Anticipating the tying up of the Saguenay and Shawinigan systems over the 220-kv tie line, a number of studies were made on an a-c network analyzer to determine among other matters:

(*a*). The magnitude of fault current at different locations.

(*b*). Possibilities of automatic reclosing and single-phase switching on the 154-kv and 220-kv lines.

(*c*). Degree of stability.

These studies indicated that the interconnection materially increased the magnitude of the fault currents at the interconnecting points.

In most cases, existing oil circuit breakers were capable of meeting the increased duty, but in certain localities it was found necessary to modify existing breaker designs in order to increase the rupture duty and to reduce operating times.

Where new circuit breakers were found to be necessary, there was a tendency to adopt the air-blast breaker for 69-kv, 132-kv, and 220-kv service. The type of air-blast breaker generally adopted was developed by engineers of the Montreal Light, Heat, and Power, Consolidated after several years of development work and field tests. However, also on the system may be found European designs of 11-kv, 154-kv, and 220-kv air-blast circuit breakers, as well as 69-kv and 138-kv "oil-poor" breakers. Circuit-breaker performance is considered satisfactory, although in some instances it has been necessary to modify designs slightly.

VIII. Stability and High-Voltage Automatic Reclosing

In the matter of automatic reclosing of high-voltage lines, actual experience gained over a period of eight years with an installation on two long 187-kv lines indicates that under many transient faults returning the faulted circuit to service promptly by automatic means has prevented the loss of the second line due to the systems falling out of synchronism.

Studies on the analyzer of the Shawinigan-Saguenay 220-kv tie line indicated that with a line-to-ground fault on the line cleared in five cycles, using conventional three-phase switching, and reclosing automatically in 20 cycles, the resulting swing curves showed every indication that stability would be maintained. Since the subsequent line loading is much higher than that used in the studies, attention is now being directed to complete a study of single-phase switching. In due course it is expected that some definite progress will be made in a practical application.

On the two 187-kv circuits, now operating at 154 kv, a few cases of instability have been experienced caused primarily by line short circuits in the Saguenay area and under unusually heavy load conditions. Such operations were not unexpected, and, considering the transmission constants and excessive loading, completely stable operation under all types of faults is not anticipated.

Continual efforts are being made to improve system protection so as to reduce time of fault clearance, with the object of improving stability.

IX. 220-Kv/165-Kv Transformation

In order to connect the 220-kv Shawinigan system to the Saguenay system (operating at 154 kv to 165 kv) and to permit a load of 150,000 kw to be carried it was necessary to consider carefully the transformation problem.

Originally, two obvious ideas were considered:

(*a*). The installation of three 50,000-kva conventional double-winding 220-kv/165-kv three-phase transformers with a limited-capacity tertiary winding.

(*b*). The installation of two 75,000-kva 220-kv/165-kv three-phase autotransformers.

In the case of the conventional-type transformers, it was found that 50,000

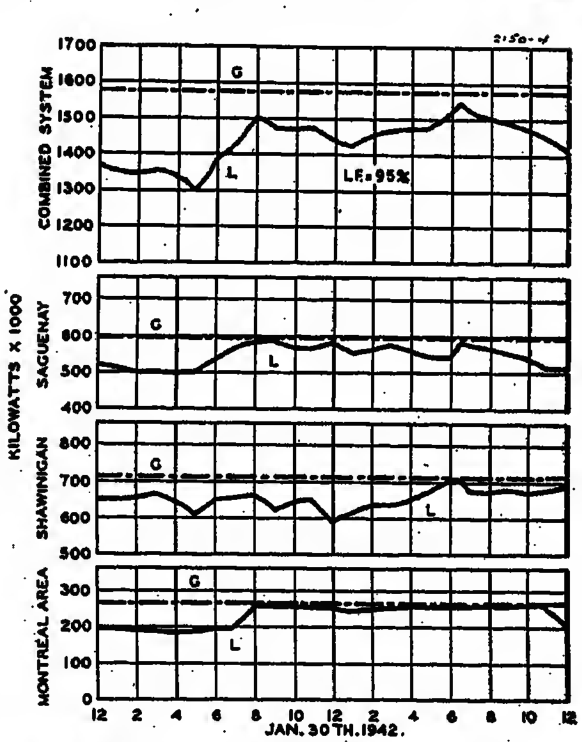

Figure 4. Actual daily load curve, interconnected systems, January 30, 1942, showing how available resources have been fully utilized for firm power purposes

kva was the largest size that could be handled from the point of view of transportation and servicing, and this would have required the purchase of three such units.

Regarding the use of autotransformers, because of their inherent lighter weight, it was possible to obtain from the manufacturer units of 75,000-kva rating so that only two transformers were required.

However, a third proposal was suggested, diagram of which is shown in Figure 5. This scheme was found to be practical by the manufacturer and was eventually used. The fundamental idea was to make use of the fact that there were already existing two 45,000-kva banks of 165-kv star to 66-kv delta. Since the problem was to transmit power from the 220-kv system to the 165-kv system, two three-phase "series" transformers were installed, each having a name-plate rating of 18,750 kva, 220 kv–55 kv/60 kv 196.8*A*, and supplied with a number of suitable voltage taps. The setup is really a scheme whereby use is made of the core structure of the existing 45,000-kva transformers in conjunction with the "series" transformers by electrically coupling at 60 kv, so as to simulate the effect of an autotransformer in the combined unit. By this means, the weight and rating of the additional transformer equipment may be considerably reduced without impairing the kilovolt-ampere transfer ability between 220 kv and 165 kv. Furthermore, the use of this idea results in a marked decrease in impedance and transformation losses between 220-kv, 165-kv, and 60-kv systems, as compared with the alternative schemes.

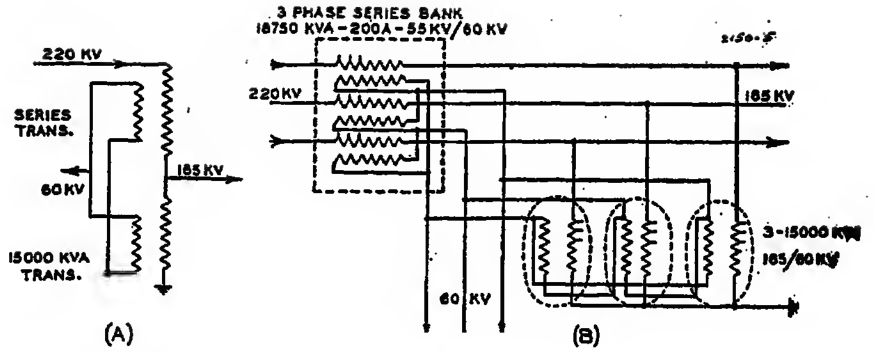

Figure 5. Diagram to illustrate method of interconnecting 220-kv system to 165-kv and 60-kv systems using series transformers

A. Development of one phase

B. 220-kv/165-kv/60-kv transformation

From the point of view of costs the percentages were:

Three 50,000-kva conventional-type three-phase transformers........	100 per cent
Two 75,000-kva autotransformers..	70 per cent
Two 18,750-kva series transformers (150,000 kva equivalent)..........	57 per cent

More than a year's operation on these three-phase series banks has demonstrated the success of the arrangement and it has been found that loads of 190,000 kw have been transmitted from 220 kv to 165 kv without undue heating.

X. System Protection

When interconnecting large systems, the need for instantaneous and selective zone protection assumes special importance, to reduce the hazard of permanent power arc damage and system instability, since in many instances troubles pyramid.

Fortunately, on this high-voltage network and particularly on the Shawinigan system, the matter of such relay protection had been given unusual attention. The double step impedance principle, with its features of instantaneous fault clearance to within 80 per cent to 90 per cent of the line length, was conceived, developed, and applied as early as 1920 for the clearance of phase-to-phase and ground faults. General application of the instantaneous differential-current zone protection, to generators, transformers, and station bus bars quickly followed.

With the adoption of high-voltage network distribution came the problem of instantaneous protection for the short tie lines. This led to the development and successful application of a number of differential-current pilot-wire schemes, using a separate control cable for the pilot wires. Subsequently, the directional impedance interlock principle was developed, with available communication circuits being used as a control channel.

Recently commercial carrier-current relaying, combined with a simplex communication, has been used in conjunction with some important high-voltage trunk lines to provide selective instantaneous clearance.

For transformer and regulator protection, in addition to differential schemes and supplemented by residual current features, gas-detector relays are being used. The pressure element is arranged to trip the associated circuit breakers, while the gas element operates an alarm.

For standby or backup protection, the impedance principle has been adopted almost exclusively since its initial development because of its effectiveness under all operating conditions and irrespective of the amount of system generator capacity connected. This is in contrast to the shortcomings, in these respects, of the inverse definite time overload protection previously used.

At controlling points, automatic oscillographs and high-speed recording voltmeters are utilized, as well as transmission-line fault locators, to ensure sufficient available data so that each case of trouble may be fully investigated and proper remedial measures applied.

To ensure proper over-all functioning of the protective schemes, the practice of making "primary" checks and tests on new protection installations is standard.

Concluding this section, it is apparent that without the progress and development just outlined in regard to protective schemes, interconnection of systems would have been a hazardous venture with added service difficulties, rather than the increased service reliability actually obtained.

XI. Basic System-Operating Principles

The general principles underlying the operation of the combined systems may be summed up as follows:

(*a*). To assure satisfactory parallel operation, each company undertakes as far as possible and with a practical spirit of co-operation to maintain load, voltage, and frequency conditions which are most suitable to the common interest, keeping in mind, of course, local problems and obligations to customers.

(*b*). Firm power contracts existing prior to interconnection remain in full force and effect.

(*c*). Operating agreements have been made to cover the supply or purchase of surplus energy.

(*d*). It is the objective of all companies concerned to ensure maximum utilization of all available power resources to assist in the war effort. Equitable energy rates have been agreed upon to make this result possible.

So far, any unusual operating matters which have arisen and which were not covered by agreement, have been promptly and satisfactorily rectified by the operating managements of the respective companies.

XII. Control of Voltage and Reactive

Constant voltage is required at the load in the Saguenay and Montreal areas and on the 60-kv busses. In addition, however, when the following items have

been considered, it will be realized that a definite reactive control problem exists:

(*a*). Between the Montreal area and the Shawinigan area, involving the four 110-kv circuits, the load may have to vary between 120,000 kw *delivered to* Montreal and 130 kw *fed back from* Montreal.

(*b*). The load transmitted over the upper St. Maurice 220-kv line varies from 100,000 kw to 250,000 kw and is delivered at the receiving point at approximately 100 per cent power factor, so that most of the reactive kilovolt-amperes of the two generating plants feeding this line is used in transmission and is not available therefore for the load.

(*c*). The load transmitted from Quebec to Lake St. John in the Saguenay area may vary between 25,000 kw and 150,000 kw, and at Lake St. John it is frequently necessary to supply 50,000 kva; that is, the power is received at a leading power factor.

(*d*). System load reductions of the order of 45 per cent occur each Sunday when mills shut down.

(*e*). Only one synchronous condenser (30,000-kva capacity) is available on the system installed at Quebec.

This whole matter of voltage and reactive control was given attention in the a-c network-analyzer studies, and as a result, it was decided to install "on-load" tap-changing gear on all transformers in the Shawinigan area where a tie exists between the 220-kv system and the 110-kv Montreal system, as well as on a customer's 110-kv bank.

So far, with some extra supervision required, use of these facilities has enabled voltage levels to be maintained by proper generator field manipulation, as well as by occasional use of vented hydroelectric units as synchronous condensers, and by changing taps at controlling points when dictated by marked changes in loading conditions.

XIII. Frequency Regulation, Load Control, and Reserve Generation

Normally, generating stations in the Montreal area are operated on base load, with frequency controlled by either Shawinigan or Saguenay systems. Automatic frequency control is available and is used on two generating stations in the Shawinigan area. With manual control no difficulty has been experienced in holding frequency to plus or minus 0.1 cycle and synchronous time to a maximum error of ten seconds. This may not be as close regulation as many other systems obtain but is found to be quite satisfactory in this case. Manual control of frequency has been made more convenient to the operator by bringing the governor motor control to miniature keys on the operator's desk.

Automatic tie-line load control is not used and is not considered essential at the present time, although it would be a definite operating convenience. The long distances between exchange points and generating stations make the application of automatic tie-line control both difficult and expensive.

At the generating station on frequency control, it has been the custom in the past to try to maintain a minimum amount of spare equivalent to a 30,000-kw unit during the peak period, and to retain in service at other generating stations a sufficient number of units to carry the allotted load efficiently, consistent with flow and head conditions, so that when the need arose, an additional 30,000 kw–50,000 kw could be picked up by running wide open temporarily. However, present practice is to utilize, as far as possible, most of the normal generator reserve for supplying urgent defense loads. This results occasionally in the necessity of dropping blocks of electric furnace load or grinder motors as a temporary means of maintaining suitable frequency.

XIV. Summary and Conclusions

1. The interconnected system described and supplied solely from hydroelectric plants must be considered as one of the major power systems on the continent, having resources of nearly 4,000,000 horsepower (developed or under construction), of which 2,586,000 horsepower are now operating in parallel.

2. It is to be noted that while operating as individual systems or areas, the hydraulic power resources and load requirements of each group were not ideally matched, it was found that when viewed as a combined system, these characteristics were quite complementary, thus enabling much more complete firm-power utilization of total energy resources.

3. Under normal prewar conditions, undoubtedly this interconnection of systems would have been delayed in its execution, but because of the immediate demand for more firm power for defense industries, it became imperative and economically feasible to proceed, therefore in effect making available for firm power over 18 per cent of the total combined energy resources which otherwise would have been wasted or sold as secondary power to electric boilers. This estimated gain in firm power output is apart from that obtained from additional sources as given in section VI.

4. Because of the necessity of producing and utilizing every available kilowatt-hours for defense purposes, operating procedure has changed, resulting in larger ranges in frequency and voltage regulation and less generator reserve.

Control of reactive kilovolt-amperes is successfully accomplished mainly by generator field adjustment and use of transformer tap-changing equipment, with the assistance of a single 30,000-kva synchronous condenser.

Three-Winding Transformer Ring-Bus Characteristics

G. W. BILLS
ASSOCIATE AIEE

C. A. MacARTHUR
NONMEMBER AIEE

SUCH hydroelectric projects as the Boulder Dam, Grand Coulee, and that proposed for the St. Lawrence River present serious power limit and short-circuit problems. Each of these developments will be capable of producing over 1,000,000 kw, part of which for each case must be transmitted over 200 miles. Any method which will increase transient stability and lower fault currents should be carefully investigated; this paper presents the investigation of such a method.

Statement of Problem

To obtain optimum use of transmission lines between a generating station and a load center, it is desirable to parallel the circuits in such a manner that the loss of a line or section of a line will result in the least disturbance. In general, this is done by bussing the lines together and sectionalizing at one or more points.

However, to bus lines on the sending and receiving ends imposes very severe requirements on switching equipment. For example, the 287.5-kv Boulder Dam–Los Angeles lines require 287.5-kv breakers with interrupting capacities of 2,500,000 and 3,500,000 kva. Even on 230-kv systems circuit breakers with interrupting capacities of 2,500,000 kva are in use.

High-voltage bus reactors may be used to reduce short-circuit currents, but besides being costly, they tend materially to increase the reactance between the sending and receiving ends of the system after the loss of line or line section. It is probable, even though the fault currents on the circuits are reduced by the addition of reactors to the bus, that the dynamic power limit would be decreased because of the added impedance.

The use of reactors in the transformer neutrals to reduce ground-fault currents may interfere with relaying and imposes higher-voltage stresses on equipment. Also, for three-phase faults neutral reactors have no effect on fault currents and thus do not increase the power limit for such disturbances.

Paper 42-153, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 1, 1942; made available for printing July 24, 1942.

G. W. BILLS and C. A. MACARTHUR are both with the Bonneville Power Administration, Portland, Oreg., as assistant engineers in the system engineering department.

Description of Studies

Three-winding transformers connected so as to form a ring on the low-voltage side, as shown in Figure 1, lower short-circuit currents by making use of the reactance between low-voltage windings. To determine the transient power limits and fault currents of a system using this ring-bus arrangement, studies were made on an a-c network analyzer. For comparison similar studies were made on the same system with a standard high-voltage bus, as shown in Figure 2.

The studies prove that the transient stability limits are higher and the fault currents are lower for the three-winding transformer ring-bus system. A very interesting result was that the transient stability limits for the above system are almost independent of the reactance between low-voltage windings as it varies from zero to 40 per cent.

The basic system for the studies consisted of four 230-kv transmission lines 185 miles in length connecting a hydroelectric plant to a load center. The load center was connected through a short line to an infinite bus. The generating plant consisted of eight identical 60-cycle machines, each of 55,000-kva capacity. Each generator had a direct-axis transient reactance of 44 per cent and a WR^2 of 132,500,000 pound-feet squared.

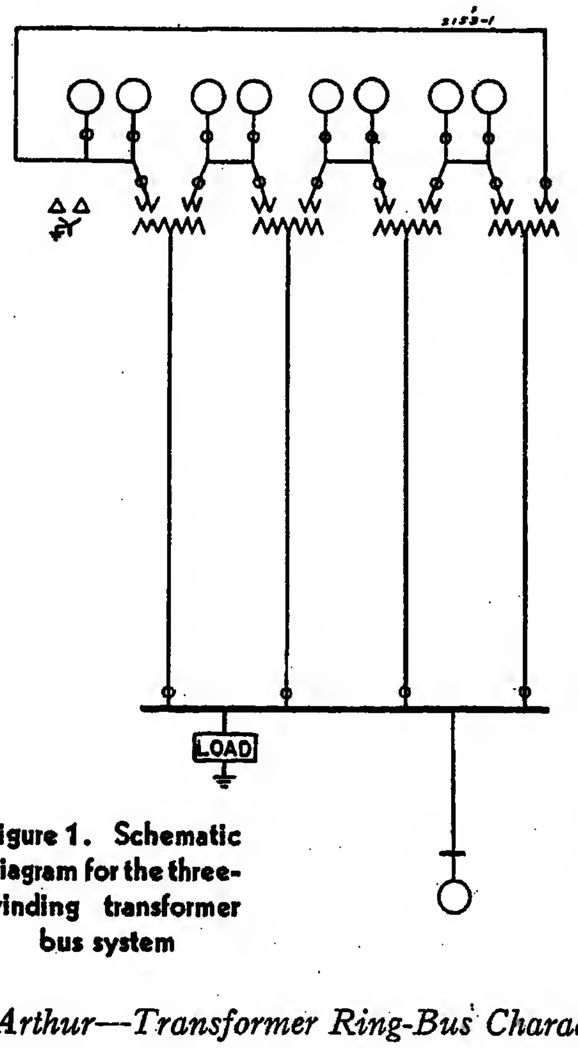

Figure 1. Schematic diagram for the three-winding transformer bus system

For the three-winding transformer ring bus the transformer banks were rated 110,000/110,000/150,000 kva at 13.8/13.8/230 kv and connected delta, delta, wye-grounded. With the low-voltage windings paralleled, the through reactance of the transformers was 11 per cent on a 150,000-kva base.

For the standard bussing arrangement the transformer banks were rated at 110,000 kva, 13.8/230 kv and connected delta, wye-grounded. The reactance was 11 per cent on a 110,000-kva base. Transformer banks rated at 110,000 kva but having a reactance of 11 per cent on a 150,000-kva base were also used.

The various sytems were placed on an a-c network analyzer and studies made of short-circuit and transient-stability characteristics. Faults were applied on a generator bus and also on the sending end of a transmission line. For the three-winding transformer ring bus the reactance between the low-voltage windings was varied from zero to 40 per cent.

The results of the short-circuit studies, shown in Figure 3, indicate that the severity of three-phase short circuits on the generator bus of the transformer ring-bus system can be made as low as that of the standard bus system. This is accomplished by using low-voltage windings having a reactance between them of at least 42 per cent.

By not bussing the transformers on the high-voltage side, the severity of faults on the transmission lines near the generating station are very greatly reduced. This materially reduces system disturbances resulting from the line faults.

Transient-stability limits for the two standard bus systems were found for both three-phase and two-phase faults on the lines near the sending end. For these and all stability studies a total clearing time of $4^1/_2$ cycles was assumed.

Similar studies were made on the three-winding transformer bus system as the reactance between the low-voltage windings was varied from zero to 40 per cent.

The power-limit values from Figure 4 show that the standard systems are much less stable in all cases. For example, the best standard system carries at least 36,000 kw less than can the transformer ring-bus system.

B_2—Double-line-to-ground fault on a transmission line near sending end

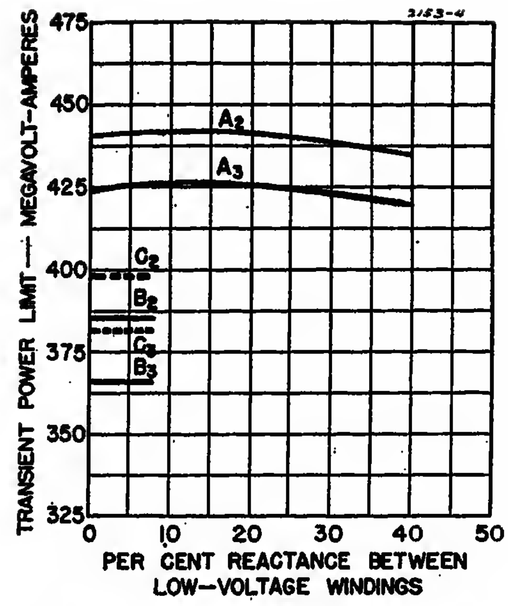

Figure 4. Transient-stability limits

Curves *A* for the three-winding transformer ring-bus system as follows:

A_3—Three-phase fault on transmission line near sending end

A_2—Double-line-to-ground fault on transmission line near sending end

Curves *B* for the standard system with 11 per cent transformers on a 110,000-kva base as follows:

B_3—Three-phase fault on transmission line near sending end

B_2—Double-line-to-ground fault on a transmission line near sending end

Curves *C* for the standard system with 11 per cent transformers on a 150,000-kva base

C_3—Three-phase fault on a transmission line near sending end

C_2—Double-line-to-ground fault on a transmission line near sending end

It should be kept in mind that the assumed clearing time is almost the minimum possible for 230-kv systems. Longer clearing times would increase the difference in stability limits between the systems and so favor the ring-bus system.

The rise in power limits for the ring-bus system as the transformer reactance increases from zero to 15 per cent is explained by the decreasing severity of the faults. At 15 per cent reactance the effect of the bus reactance in decreasing synchronizing power between the generators becomes larger than that due to decreased fault currents, and the power limits tend to drop when the reactance is increased. However, the variation in power limit is small, being less than two per cent over the entire range; thus higher reactances between low-voltage windings may be used, resulting in greatly reduced currents for generator bus faults.

Conclusions

While a detailed economic study is beyond the scope of this paper, it may be mentioned that three-winding transformers with the ranges of reactance used in this study may be obtained for the same price as standard three-winding transformers. The increase in cost of the three-winding transformers over the smaller capacity two-winding transformers is partially offset by the elimination of high-voltage breakers.

However, on transient stability and short-circuit considerations the three-winding transformer ring bus offers very definite advantages for systems of large magnitudes.

Inverse Functions of Complex Quantities

HERBERT B. DWIGHT
FELLOW AIEE

FORMULAS for inverse functions of complex quantities, such as $\sin^{-1}(x+iy)$, are of use in several branches of electrical engineering. Calculations for transmission circuits require them, particularly in connection with communication circuits. Integration of expressions involving complex quantities can involve inverse functions. They are encountered also in conformal transformations.

In presenting the formulas in this paper, it is necessary to specify angles with sufficient detail to avoid ambiguity and the liability of incorrect results. Also, all of the appropriate multiple values should be included. It is not always obvious by inspection that two different complex values are only values of different branches of the same function and are both correct.

In all cases, numerical examples are given as illustrations.

Inverse Sine $\sin^{-1}(x \pm iy)$

Let

$$\sin^{-1}(x+iy) = u+iv$$

where x, y, u, and v are real quantities and $i=\sqrt{-1}$.

$$\sin(u+iv) = (x+iy)$$

$$\sin u \cosh v = x \tag{1}$$

$$\cos u \sinh v = y \tag{2}$$

Squaring equations 1 and 2 and putting

$$\sin^2 u = 1 - \cos^2 u$$

and

$$\cosh^2 v = 1 + \sinh^2 v$$

there is obtained, by eliminating $\sinh^2 v$ $\left(\text{put } \sinh^2 v = \dfrac{y^2}{\cos^2 u}\right)$

$$\cos^4 u - (1-x^2-y^2)\cos^2 u - y^2 = 0 \tag{3}$$

from which

$$\cos^2 u = \tfrac{1}{2}[1-x^2-y^2 \pm \sqrt{(1-x^2-y^2)^2+4y^2}] \tag{4}$$

Since u is real and $\cos^2 u$ is positive, the positive value of the root is taken.

The quantity under the radical sign may be factored, and is

$$\{(1+x)^2+y^2\}\{(1-x)^2+y^2\} \tag{5}$$

From equations 4 and 5

$$\sin^2 u = \tfrac{1}{2}[1+x^2+y^2 - \sqrt{\{(1+x)^2+y^2\}\{(1-x)^2+y^2\}}]$$
$$= \tfrac{1}{4}[\sqrt{(1+x)^2+y^2} - \sqrt{(1-x)^2+y^2}]^2$$

$$\sin u = \pm\left(\frac{p-q}{2}\right) = \frac{\pm 2x}{p+q} \tag{6}$$

where $p = \sqrt{(1+x)^2+y^2}$ (positive value) (7)

$q = \sqrt{(1-x)^2+y^2}$ (positive value) (8)

The second solution in equation 6 is obtained by rationalizing the numerator. It involves the sum of two quantities instead of the difference and so allows more convenient precise computation.

Since v is real, $\cosh v$ is positive, as may be seen from the series expansion. Therefore, by equation 1, $\sin u$ is the same sign as x. This allows $\pm$ in equation 6 to be changed to $+$. Therefore

$$u = \sin^{-1}\frac{2x}{p+q} \tag{9}$$

Take the principal value of u, that is, the value between $-\pi/2$ and $\pi/2$. Since u lies in this range, $\cos u$ is positive.

The following expression corresponding to equation 3 can be obtained by eliminating $\cos^2 u$

$$\sinh^4 v + (1-x^2-y^2)\sinh^2 v - y^2 = 0$$

$$\sinh^2 v = \tfrac{1}{2}[x^2+y^2-1 \pm \sqrt{(1-x^2-y^2)^2+4y^2}]$$

The quantity under the radical sign is the same as equation 5 so that

$$\cosh v = \pm\tfrac{1}{2}(p+q)$$

Since v is real, the positive value is to be taken.

$$v = \cosh^{-1}\frac{p+q}{2} \tag{10}$$

Since $\cos u$ is positive, then by equation 2, $\sinh v$ and v are the same sign as y. This may be secured by writing

$$\sin^{-1}(x \pm iy) = \sin^{-1}\frac{2x}{p+q} \pm i\cosh^{-1}\frac{p+q}{2}$$

where y is positive and the positive value of $\cosh^{-1}$ is taken (see reference 1, page 58, and reference 2, page 264).

For any angle θ, there are angles $2k\pi+\theta$ which are the same as θ in all respects, and there are angles $(2k+1)\pi-\theta$ which have the same sine, where k is a positive or negative integer or 0. These can be combined by stating that angles having the same sine as θ are

$$n\pi + (-1)^n\theta \tag{11}$$

where n is an integer or zero. Therefore

$$\sin^{-1}(x \pm iy) = n\pi + (-1)^n \sin^{-1}\frac{2x}{p+q} \pm i(-1)^n\cosh^{-1}\frac{p+q}{2} \tag{12}$$

taking the principal value of $\sin^{-1}$ and the positive values of $\cosh^{-1}$ and of the radicals p and q. The quantity x may be positive or negative, but the quantity y is positive.

Note that if $y=0$ and $x>1$, $q=x-1$ and $p+q=2x$. If $y=0$ and $x<1$, $q=1-x$ and $p+q=2$.

An alternative computation may be made by means of the well-known formula

$$\sinh^{-1} m = \text{logn}\,(m+\sqrt{m^2+1}) \tag{13}$$

where logn denotes natural logarithm. Let

$$\sin^{-1} A = u$$

where A and u are complex quantities

$$\sin u = A$$
$$iA = \sinh iu$$
$$iu = \sinh^{-1} iA$$
$$\sin^{-1} A = -i\sinh^{-1} iA + 2k\pi$$
$$= -i\,\text{logn}\,(\pm\sqrt{1-A^2}+iA)+2k\pi \tag{14a}$$
$$\text{or } = i\,\text{logn}\,(\pm\sqrt{1-A^2}-iA)+2k\pi \tag{14b}$$

The two solutions of equation 14a indicated by $\pm$ correspond to the two angles θ and $\pi-\theta$ which have the same sine. The second or alternative form, equation 14b, is identical with equation 14a. The expression involving $+$ in equation 14b is obtained from that involving $+$ in equation 14a by rationalizing the numerator in equation 14a. In practice, the form should be used which involves the numerical sum of quantities instead of the difference, thus giving more convenient precise computation.

Square Root $\sqrt{(x \pm iy)}$

In the computation just described, the square root of a complex quantity is required. It may be expressed as follows:

$$\sqrt{(x+iy)} = \pm\left[\sqrt{\left(\frac{m+x}{2}\right)} + i\sqrt{\left(\frac{m-x}{2}\right)}\right] \tag{15}$$

Paper 42-158, recommended by the AIEE committee on basic sciences for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9-11, 1942. Manuscript submitted April 30, 1942; made available for printing July 27, 1942.

HERBERT B. DWIGHT is professor of electrical machinery, Massachusetts Institute of Technology, Cambridge, Mass.

$$\sqrt{(x-iy)}=\pm\left[\sqrt{\left(\frac{m+x}{2}\right)}-i\sqrt{\left(\frac{m-x}{2}\right)}\right] \quad (16)$$

where x may be positive or negative, y is positive
and

$$m=+\sqrt{(x^2+y^2)} \quad (17)$$

The positive square roots of $(m+x)/2$ and $(m-x)/2$ are used (see reference 2, page 260).

An alternative method is to express the complex quantity in the polar form

$$r\angle\theta=re^{i\theta}=r(\cos\theta+i\sin\theta) \quad (18)$$

where, if the complex quantity is $x+iy$

$$r=+\sqrt{(x^2+y^2)},\ \cos\theta=\frac{x}{r}\text{ and }\sin\theta=\frac{y}{r} \quad (19)$$

Then

$$\sqrt{(x+iy)}=\pm\sqrt{r}\underline{/\theta/2}$$
$$=\pm\sqrt{r}\left(\cos\frac{\theta}{2}+i\sin\frac{\theta}{2}\right) \quad (20)$$

The angle θ may be in any one of the four quadrants, depending on whether x and y are positive or negative quantities. The angle is not specified according to the principal values of $\tan^{-1}$ and $\cos^{-1}$, and so forth, though the numerical value of θ may be conveniently found by using a table of tan or $\tan^{-1}$ and then determining the quadrant for θ by equation 19.

Logarithm logn (x+iy)

In using equation 14, the logarithm of a complex quantity is required. This is computed as an inverse function of e^z.

Let

$$\text{logn}(x+iy)=u+iv$$
$$e^{u+iv}=e^u(\cos v+i\sin v)$$
$$=x+iy$$

$$e^u\cos v=x \quad (21)$$

$$e^u\sin v=y \quad (22)$$

Squaring and adding

$$e^{2u}=(x^2+y^2)$$

Let

$$r=\sqrt{x^2+y^2}$$

The positive value of the root is to be taken since u is real and e^u is positive.

The angle v is to be specified with sufficient completeness so that the numerical values of $\cos v$ and $\sin v$ will have the correct signs.

$$\text{logn}(x+iy)=\tfrac{1}{2}\text{logn}(x^2+y^2)+i(\theta+2\pi k) \quad (23)$$

where $\cos\theta=x/r, \sin\theta=y/r, r=\sqrt{(x^2+y^2)}$ and k is an integer or 0, the positive value of r being taken. The quantities x and y may be positive or negative (see reference 7, page 3).

The angle θ, according to this specification, is not always a principal value of $\cos^{-1}$, $\sin^{-1}$, or $\tan^{-1}$. If both x and y are negative, $\tan\theta$ is positive and the angle θ is in the third quadrant.

Another case where

$$\theta=\tan^{-1}\frac{m}{n}$$

is not a sufficient specification is in the equation

$$m\cos A+n\sin A=r\sin(A+\theta) \quad (24)$$

where $r=\sqrt{m^2+n^2}$, $\sin\theta=m/r$ and $\cos\theta=n/r$

(See reference 5, number 401.2).

Example 1. $\sin^{-1}(2+i3)$

$$p=\sqrt{(9+9)}=4.243$$
$$q=\sqrt{(1+9)}=3.162$$
$$p+q=7.405$$

$$\sin^{-1}\frac{4}{7.405}=\sin^{-1}0.540=0.570\text{ radian}$$

$$\cosh^{-1}\frac{7.405}{2}=1.983$$

Putting $n=0$ in equation 12,

$$\sin^{-1}(2+i3)=0.570+i1.983$$

Putting $n=1$

$$\sin^{-1}(2+i3)=3.142-0.570-i\,1.983$$
$$=2.572-i\,1.983$$

In this computation, tables of $\sin^{-1}x$, $\cosh^{-1}x$, and so forth, as in reference 6, for real values of x, may be used. To check,

$$\sin(0.570+i\,1.983)=0.540\times3.702+i\,0.842\times3.563$$
$$=2.00+i\,3.00$$

and

$$\sin(2.572-i1.983)=0.540\times3.702-i(-0.842\times3.563)$$
$$=2.00+i\,3.00$$

If the only purpose of the real part of the value of $\sin^{-1}(2+i3)$ is to take the sin, cos, or tan, or to add it to other angles which are given in degrees, then a trigonometric table in degrees might be used, but care would be needed in choosing an appropriate notation.

In using equation 14 to obtain $\sin^{-1}(2+i3)=\sin^{-1}A$

$$1-A^2=6-i\,12$$
$$=x-iy \quad \text{as in equation 16}$$
$$m=\sqrt{(36+144)}=13.42 \text{ by equation 17}$$
$$m+x=19.42,\ m-x=7.42$$
$$\sqrt{(1-A^2)}=\sqrt{\left(\frac{19.42}{2}\right)}-i\sqrt{\left(\frac{7.42}{2}\right)}$$

by equation 16, using the + sign

$$=3.116-i\,1.926$$
$$-iA=3\quad -i\,2$$
$$\sqrt{(1-A^2)}-iA=6.116-i\,3.926$$

Equation 14b is used instead of equation 14a so as to avoid the small difference of nearly equal quantities.

Let $6.116-i3.926=x+iy$ as in equation 23

$$6.116^2=37.4$$
$$3.926^2=15.4$$
$$52.8$$

$$\tfrac{1}{2}\text{logn }52.8=\tfrac{1}{2}(1.664+2.303)=1.983$$

The angle θ of equation 23 is in the fourth quadrant.

$$\tan(-\theta)=\frac{3.926}{6.116}=0.642$$

$$\theta=-0.571\text{ radian}$$
$$\text{logn}(x+iy)=1.983-i0.571 \quad \text{by equation 23}$$
$$\sin^{-1}(2+i3)=0.571+i1.983 \quad \text{by equation 14b}$$

The second solution is given by the − sign in equation 14a or 14b, the former being preferable.

$$-\sqrt{(1-A^2)}+iA=-6.116+i3.926$$

The angle θ of equation 23 is in the second quadrant.

$$\sin^{-1}(2+i3)=2.571-i1.983$$

The quantity $2k\pi$ may be added to either of these solutions.

Inverse Cosine $\cos^{-1}(x\pm iy)$

Let $\cos^{-1}(x+iy)=u+iv$

$$\cos(u+iv)=x+iy$$

$$\cos u\cosh v=x \quad (25)$$

$$\sin u\sinh v=-y \quad (26)$$

Squaring and eliminating $\sinh^2 v$,

$$\sin^4 u-(1-x^2-y^2)\sin^2 u-y^2=0$$

$$\sin^2 u=\tfrac{1}{2}[1-x^2-y^2\pm\sqrt{(1-x^2-y^2)^2+4y^2}]$$

Since u is real and $\sin^2 u$ is positive, use the positive value of the root.

$$\cos^2 u=\tfrac{1}{2}(1+x^2+y^2-pq)$$
$$\cos u=\pm\tfrac{1}{2}(p-q)$$

Since v is real, $\cosh v$ is positive, and $\cos u$ is the same sign as x, by equation 25. Then

$$\cos u=\tfrac{1}{2}(p-q)=\frac{2x}{p+q}$$

$$u=\cos^{-1}\frac{2x}{p+q}$$

Take the principal value, that is, the value between 0 and π. Then $\sin u$ is positive. Similarly

$$\sinh^4 v+(1-x^2-y^2)\sinh^2 v-y^2=0$$
$$\sinh^2 v=\tfrac{1}{2}[x^2+y^2-1+\sqrt{(1-x^2-y^2)^2+4y^2}]$$

taking the positive value of the root since $\sinh^2 v$ is positive.

$$\cosh^2 v=\tfrac{1}{4}(p+q)^2$$
$$\cosh v=\tfrac{1}{2}(p+q)$$

taking the positive value since v is real.

$$v=\cosh^{-1}\frac{p+q}{2}$$

Since $\sin u$ is positive, $\sinh v$ and v are the same sign as $-y$, from equation 26.

$$\cos^{-1}(x+iy)=\pm\left[\cos^{-1}\frac{2x}{p+q}+2k\pi-i\cosh^{-1}\frac{p+q}{2}\right] \quad (27)$$

where y is positive, taking the principal value of $\cos^{-1}$ and the positive values of $\cosh^{-1}$ and of p and q. Also

$$\cos^{-1}(x-iy)=\pm\left[\cos^{-1}\frac{2x}{p+q}+2k\pi+i\cosh^{-1}\frac{p+q}{2}\right] \quad (28)$$

taking the same values of $\sin^{-1}$ and $\cosh^{-1}$ as with equation 27. For p and q see equations 7 and 8.

The quantity x may be positive or negative. The quantity y is positive.

An alternative method is by use of the equation

$$\cosh^{-1} p=\pm\,\text{logn}\,(x+\sqrt{x^2-1})$$

Let $\cos^{-1} A=u$, a complex quantity.

$$A=\cos u=\cosh iu$$
$$iu=\cosh^{-1} A$$

$$\cos^{-1} A=-i\cosh^{-1} A=\mp i\,\text{logn}\,(A+\sqrt{A^2-1})+2k\pi \quad (29a)$$

$$\text{or }=\pm i\,\text{logn}\,(A-\sqrt{A^2-1})+2k\pi \quad (29b)$$

The second equation is obtained by rationalizing the numerator of the first and is to be used when it avoids the numerical difference of quantities.

Example 2. $\cos^{-1}(-2-i4)$

By equation 28, putting $k=0$

$$\cos^{-1}(-2-i4)=\pm[\cos^{-1}(-0.4385)+i\cosh^{-1}4.56]$$
$$=\pm[2.025+i2.198]$$

To check,

$$\cos(2.025+i2.198)=-0.4385\times4.56-i0.899\times4.45$$
$$=-2.00-i4.00$$

By the alternative method, let $A=-2-i4$

$$A^2-1=-13+i16$$
$$\sqrt{(A^2-1)}=1.952+i4.10$$
$$A=-2-i4$$

Using equation 29b to avoid the numerical difference of quantities

$$A-\sqrt{(A^2-1)}=-3.952-i8.10$$

In finding the logarithm of this, logn $r=2.20$, and the angle θ is in the third quadrant and is 4.258 radians.

$$\cos^{-1}(-2-i4)=\pm(-4.258+i2.20)+2k\pi$$
$$=\pm(2.025+i2.20)$$

putting

$$k=1.$$

Inverse Tangent $\tan^{-1}(x+iy)$

Let $\tan^{-1}(x+iy)=u+iv$

$$\tan(u+iv)=x+iy=i\tanh\frac{u+iv}{i}$$

since

$$\tan z=i\tanh(z/i)$$

$$\tanh\frac{u+iv}{i}=\frac{x+iy}{i}$$

$$v-iu=\tanh^{-1}(y-ix)$$

$$=\tfrac{1}{2}\,\text{logn}\,\frac{1+y-ix}{1-y+ix} \quad (30)$$

where logn denotes natural logarithm.

$$e^{2v}(\cos 2u-i\sin 2u)=\frac{1+y-ix}{1-y+ix}$$

Rationalizing the denominator

$$e^{2v}\cos 2u=\frac{1-x^2-y^2}{(1-y)^2+x^2} \quad (31)$$

$$e^{2v}\sin 2u=\frac{2x}{(1-y)^2+x^2} \quad (32)$$

Squaring, adding, and factoring the numerator

$$e^{4v}=\frac{(1+y)^2+x^2}{(1-y)^2+x^2} \qquad \text{by equation 5}$$

$$v=\frac{1}{4}\,\text{logn}\,\frac{(1+y)^2+x^2}{(1-y)^2+x^2} \quad (33)$$

Dividing equation 32 by equation 31

$$\tan 2u=\frac{2x}{1-x^2-y^2} \quad (34)$$

Let

$$2u=\pi-\tan^{-1}\frac{1+y}{x}-\tan^{-1}\frac{1-y}{x} \quad (35)$$
$$=\pi-\alpha-\beta$$

where the principal values of $\tan^{-1}$ are taken, that is, α and β are between $-\pi/2$ and $\pi/2$.

$$\sin(\pi-\alpha-\beta)=\sin(\alpha+\beta)$$
$$=(\tan\alpha+\tan\beta)\cos\alpha\cos\beta$$
$$=\frac{2}{x}\cos\alpha\cos\beta$$

which is the same sign as x, as it should be, from equation 32. Cos α and cos β are positive.

$$\cos(\pi-\alpha-\beta)=-\cos(\alpha+\beta)$$
$$=(-1+\tan\alpha\tan\beta)\cos\alpha\cos\beta$$
$$=(1-x^2-y^2)\frac{\cos\alpha\cos\beta}{x^2}$$

which is the same sign as $1-x^2-y^2$ and proportional to it (see equation 31).

The quantity $2k\pi$, where k is an integer, may be added to equation 35.

Therefore

$$\tan^{-1}(x+iy)=\frac{1}{2}\left\{(2k+1)\pi-\tan^{-1}\frac{1+y}{x}-\tan^{-1}\frac{1-y}{x}\right\}+\frac{i}{4}\,\text{logn}\,\frac{(1+y)^2+x^2}{(1-y)^2+x^2} \quad (36)$$

where the principal values of $\tan^{-1}$ are taken and where x and y may be positive or negative.

An alternative method of computation is by means of equation 31

$$\tan^{-1}(x+iy)=\frac{i}{2}\,\text{logn}\,\frac{1+y-ix}{1-y+ix}+2k\pi \quad (37)$$

Example 3

$$\tan^{-1}(-2-i4)=1.675-i0.2006$$

When computing this by equation 37, $k=-1$. Other values, given by adding $2k\pi$, are equally appropriate.

Inverse Hyperbolic Sine $\sinh^{-1}(\pm x+iy)$

Let

$$\sinh^{-1}(x+iy)=u+iv$$
$$x+iy=\sinh(u+iv)$$
$$=i\sin\frac{u+iv}{i}$$
$$y-ix=\sin\frac{u+iv}{i}$$
$$u+iv=i\sin^{-1}(y-ix) \quad (38)$$

By equation 12

$$\sinh^{-1}(\pm x+iy)=\pm(-1)^n\cosh^{-1}\frac{s+t}{2}+i(-1)^n\sin^{-1}\frac{2y}{s+t}+in\pi \quad (39)$$

where n is an integer or 0,
x is positive,
y is positive or negative

$$s=\sqrt{(1+y)^2+x^2}\ \text{(positive value)} \quad (40)$$

$$t=\sqrt{(1-y)^2+x^2}\ \text{(positive value)} \quad (41)$$

The principal value of $\sin^{-1}$ (between $-\pi/2$ and $\pi/2$) and the positive value of $\cosh^{-1}$ are taken.

Note that if $x=0$ and $y>1$, $s+t=2y$ and if $y<1$, $s+t=2$.

An alternative solution is

$$\sinh^{-1} A = \operatorname{logn}(\pm\sqrt{1+A^2}+A)+i2k\pi \tag{42a}$$

$$\text{or} \quad = -\operatorname{logn}(\pm\sqrt{1+A^2}-A)+i2k\pi \tag{42b}$$

The two solutions of equation 42a indicated by $\pm$ correspond to the two angles θ and $\pi-\theta$ which have the same sine. Logn $(A-\sqrt{A^2+1})$ is a value of $\sinh^{-1} A$ which differs from logn $(A+\sqrt{A^2+1})$ by logn (-1) or $i(2k+1)\pi$. Evidently one at least of the two values is complex, for any given value of A, whether A is real or complex.

The second or alternative form, equation 42b, gives the same results as equation 42a. It should be used when it enables one to avoid computing the numerical difference of two quantities.

Example 4

$$\sinh^{-1}(-2-i4) = -2.184-i1.097$$

putting $n=0$ in equation 39 or using the + sign in equation 42b.

Also $\sinh^{-1}(-2-i4)=2.184+i4.239$ putting $n=1$ in equation 39 or using the − sign in equation 42a.

The quantity $i\,2k\pi$ may be added to both these solutions.

The results may be checked by computing sinh, which gives $-2-i4$.

Inverse Hyperbolic Cosine $\cosh^{-1}(x+iy)$

Let $\cosh^{-1}(x+iy)=u+iv$

$$x+iy = \cosh(u+iv) = \cos\frac{u+iv}{i}$$

$$u+iv = i\cos^{-1}(x+iy)$$

If y is positive, by equation 28,

$$\cosh^{-1}(x+iy) = \pm\left[\cosh^{-1}\frac{p+q}{2} + i\cos^{-1}\frac{2x}{p+q}+i2k\pi\right] \tag{43}$$

Also, if y in the following equation is positive, by equation 29,

$$\cosh^{-1}(x-iy) = \pm\left[\cosh^{-1}\frac{p+q}{2} - i\cos^{-1}\frac{2x}{p+q}+i2k\pi\right] \tag{44}$$

The quantities p and q are positive and are given by equations 7 and 8. The quantity x is positive or negative.

The positive value of $\cosh^{-1}$ and the principal value of $\cos^{-1}$ are taken.

An alternative solution is

$$\cosh^{-1} A = \pm\operatorname{logn}(A+\sqrt{A^2-1})+i2k\pi \tag{45a}$$

or

$$= \pm\operatorname{logn}(A-\sqrt{A^2-1})+i2k\pi \tag{45b}$$

Equations 45a and 45b give the same results and the one which involves the numerical sum of two quantities should be used in any given case.

Inverse Hyperbolic Tangent $\tanh^{-1}(x+iy)$

Let

$$\tanh^{-1}(x+iy) = u+iv = \frac{1}{2}\operatorname{logn}\frac{1+x+iy}{1-x-iy} \tag{46}$$

$$e^{2u}\cos 2v = \frac{1-x^2-y^2}{(1-x)^2+y^2} \tag{47}$$

$$e^{2u}\sin 2v = \frac{2y}{(1-x)^2+y^2} \tag{48}$$

Squaring, adding, and factoring the numerator

$$e^{4u} = \frac{(1+x)^2+y^2}{(1-x)^2+y^2}$$

$$u = \frac{1}{4}\operatorname{logn}\frac{(1+x)^2+y^2}{(1-x)^2+y^2} \tag{49}$$

Dividing equation 33 by equation 32

$$\tan 2v = \frac{2y}{1-x^2-y^2} \tag{50}$$

Let

$$2v = \pi - \tan^{-1}\frac{1+x}{y} - \tan^{-1}\frac{1-x}{y} = \pi-\alpha-\beta \tag{51}$$

where the principal values of $\tan^{-1}$ are taken, that is, α and β are between $-\pi/2$ and $\pi/2$.

$$\begin{aligned}\sin(\pi-\alpha-\beta) &= \sin(\alpha+\beta)\\ &= (\tan\alpha+\tan\beta)\cos\alpha\cos\beta\\ &= (2/y)\cos\alpha\cos\beta\end{aligned}$$

which is the same sign as y, as it should be, from equation 48. Cos α and cos β are positive.

$$\begin{aligned}\cos(\pi-\alpha-\beta) &= -\cos(\alpha+\beta)\\ &= (-1+\tan\alpha\tan\beta)\cos\alpha\cos\beta\\ &= (1-x^2-y^2)\frac{\cos\alpha\cos\beta}{y^2}\end{aligned}$$

which is the same sign as $1-x^2-y^2$ and proportional to it (see equation 47). The quantity $2k\pi$, where k is an integer, may be added to equation 51.

Therefore

$$\tanh^{-1}(x+iy) = \frac{1}{4}\operatorname{logn}\frac{(1+x)^2+y^2}{(1-x)^2+y^2} + \frac{i}{2}\left\{(2k+1)\pi - \tan^{-1}\frac{1+x}{y} - \tan^{-1}\frac{1-x}{y}\right\} \tag{52}$$

where the principal values of $\tan^{-1}$ are taken and where x and y may be positive or negative (reference 3, page 115, and reference 5, number 715).

An alternative method of computation is to use equation 46 directly. Multiple values will be obtained since expression 23 for logn has a term $i2k\pi$.

Example 6

$$\tanh^{-1}(-2+i3) = -0.1469+i1.339$$

putting $k=0$ in equation 52

or $= -0.1469+i4.4806$

putting $k=1$.

The choice of the alternative formulas involving logarithms of complex quantities, which have been given in each case in this paper, depends to some extent on the practice and preference of each individual. While the algebraic logarithmic formulas are shorter to write than the others, the solution of the numerical problems in this paper has seemed longer by the logarithmic formulas.

The use of logarithmic formulas for obtaining results involving inverse functions is given in equations 125, page 71 and 428, page 179 of volume 2 of "Communication Networks," by E. A. Guillemin (reference 4).

A Practical Discussion of Problems in Transformer Differential Protection

P. W. SHILL
MEMBER AIEE

Synopsis: Some conditions which have to be met with in protecting transformers by the usual current-differential method produce special problems. Those involving the protection of interconnected wye or zigzag transformers and those involving Scott-connected transformers are dealt with at some length. There is also a discussion of tolerances in the selection of current transformers and the factors to be considered in the selection of relays for the purpose.

ELECTRIC-power systems are becoming more and more complex insofar as their protection is concerned. Until now there has been little difficulty in obtaining almost anything that one might desire for the usual run of problems, such as the protection of machines, transmission lines, transformers, and so forth. Even systems, which have grown to the point where they have generators, transmission lines, transformers, and other equipment with widely diverse characteristics connected together, have been successfully protected. The war has now changed things, so that today we are having to bring back into service various pieces of apparatus which have been considered obsolete, and which one hoped would remain in that class forever. To connect old apparatus into a well-designed power system and protect them both with equipment not too well-suited to the purpose is a real problem for the engineer responsible for relay protection. Often the circuit is needed in service very quickly, but the delivery dates for relays, current transformers, and so forth, cannot be promised for many months ahead. There is also the question of priorities.

It is quite probable that some old two-phase equipment will have to be rehabilitated and put back into service. For this reason, the question of the protection of Scott-connected transformers by the current-differential method should receive some attention.

While there have been on the market several types of relays and current transformers which, when properly applied, give very satisfactory results, we are now faced with the fact that we must use considerable ingenuity to "get by" with such things as we may have on hand or can procure readily.

A few years ago much time and money were spent on current-differential protections to see that the various component parts of the circuit were built as closely to their theoretical ideals as possible. Current transformers of exact special ratios and with matching characteristics were specially purchased and installed. Current-transformer cable connections were carefully tested so that their resistances might be closely matched. Relays of very special types were considered to be absolute essentials. In fact, there was, generally speaking, considerable superstition in some places about this type of problem.

Today, with our accumulated data based on experience and more accurate knowledge of those conditions which must be satisfied in order to ensure a reliable protection, many of the old ideas have been greatly modified, and we know that we can do things which at one time were considered to be quite hazardous to the continuity of service.

A transformer differential protection is much more likely to operate when it should not do so than not to operate when it should do so. So that, provided the relays are in working order and their current windings are not short-circuited, they will operate if they can get sufficient current at any time. The chief concern with differential relays is to see that they do not respond too readily to transient currents and to be sure that their multiple trip circuits are in an operable state at all times. So sensitive is the usual current-differential protection that a loose connection on one current-transformer wire has been known to operate the relay connected with it.

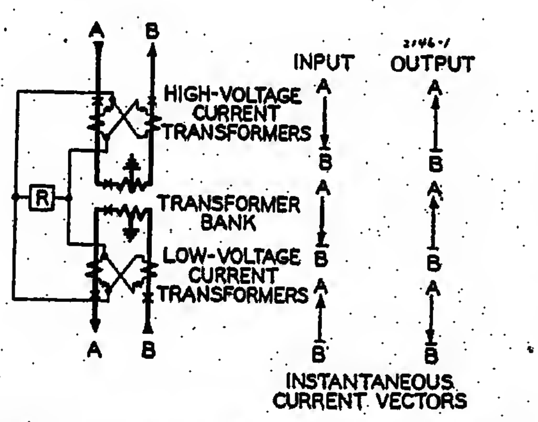

Figure 1. Single-phase transformer differential protection

The chief sources of trouble for which the designer must be on the watch when working up the studies for a differential protection are:

1. The possibility of the generating capacity of the system being so reduced under light load conditions that the fault current available in the protected zone may be insufficient to operate the relays.

2. The possibility that the relays may be so sensitive that they may operate during periods of transient differential currents, which may be produced by the magnetic characteristics of the transformer and of the current transformers, at times of switching, or of heavy faults which draw current through the protected zone but are themselves outside of it.

In the past there was some doubt about the suitability of bushing-type current transformers for use in differential current schemes. It is now accepted that, except in the cases of those with turn ratios too small to be reliable for any kind of use, bushing-type current transformers are as reliable as wound ones for relay work, especially when the relays are required to work, that is, during periods of heavy current flow due to fault conditions.

Fundamental Principles

Let us now review the more important basic conditions which must be satisfied in all reliable current-differential protective schemes for three-phase transformers.

1. Current transformers must be provided in every phase connection to the transformer or transformer bank, so that all current entering and leaving the windings by normal paths may be properly measured and accounted for in the balancing of the differential circuit.

2. Delta-connected transformer windings ordinarily are provided with current transformers with wye-connected secondary windings. They are the most accommodating of all circuits for which to provide differential protection, because, provided proper attention is paid to the ratio of the current transformers, it is immaterial whether their current-transformer secondary circuits be wye-connected or delta-connected.

3. Any transformer windings which are connected in wye or zigzag and are so arranged that current can return to any phase through a neutral connection will at times have some current returning which is not measured by the phase current trans-

Paper 42-146, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted May 25, 1942; made available for printing July 2, 1942.

P. W. Shill is relay protection engineer with the British Columbia Electric Railway Company, Ltd., Vancouver, British Columbia, Canada.

The author expresses his appreciation to L. B. Stacey for his suggestions on the scope and form of the paper, and to J. A. Polson for checking the manuscript and preparing the diagrams.

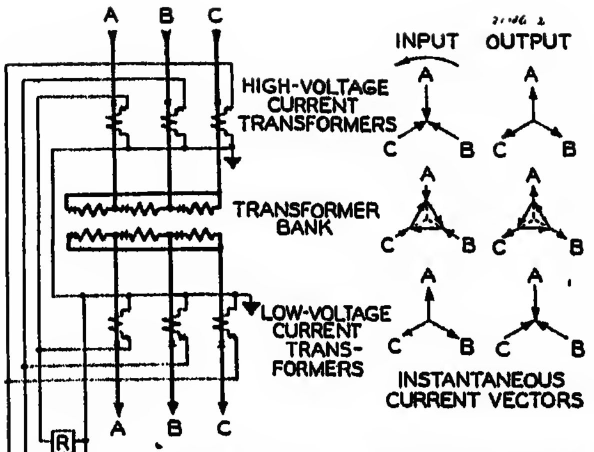

Figure 2. Three-phase delta-delta transformer-bank differential protection

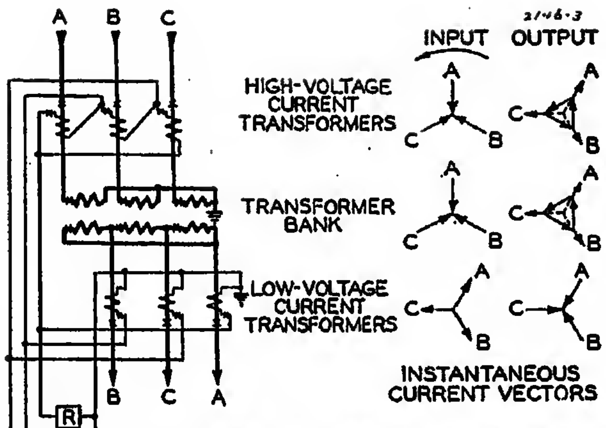

Figure 3. Three-phase wye-delta transformer-bank differential protection

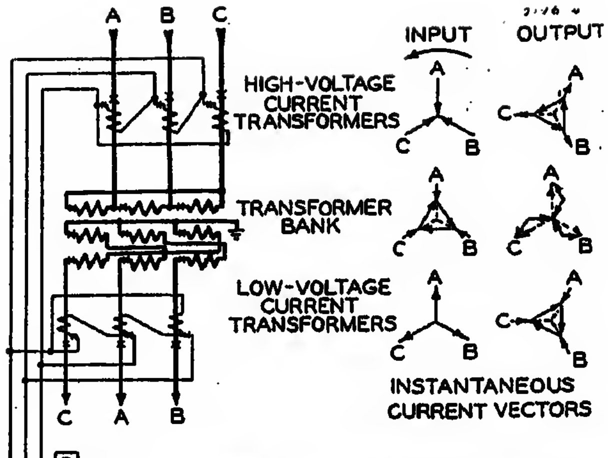

Figure 4. Three-phase delta-zigzag transformer-bank differential protection

formers. This would cause an unbalance in the differential circuit. This unbalance will take the form of zero-phase-sequence components in the current-transformer secondary circuits which measure the currents in the wye-connected or zig-zag-connected transformer windings. Currents which do not sum to zero in delta-connected current-transformer secondary circuits will circulate the difference current around the delta. This circulating current is for all practical purposes the sum of the zero-phase-sequence components and corresponds to the power current returning through the neutral connection. The currents leaving from the delta and entering into the differential circuit will be a true measure of the phase power currents and will balance out satisfactorily. Because of these facts, it is generally accepted that circuits connected to wye- or zigzag connected transformer windings *must* have a delta circulating path for the zero-phase-sequence components in their current-transformer secondary circuits. This is necessary to ensure that neutral currents will not upset the differential current balance and thus operate the relays for some external condition when there is no fault in the differentially protected transformer zone.

4. The instantaneous vector sum of all the currents from the current-transformer leads connected to the relay for any one phase should be as nearly as possible zero at all instants of time when no internal fault exists. For this reason the phase angles between all the currents must be theoretically either zero or 180 degrees, depending upon the relation of the power transformer windings to each other, when no internal fault exists.

5. The current transformers in all connections to the transformer bank must have their performance characteristics so well-matched that transient differential secondary currents may be held to a minimum at all times when no internal fault exists.

Conditions 1, 2, and 3 can usually be arranged without much difficulty. Conditions 4 and 5 are ordinarily speaking never possible to be achieved to within their closest theoretical limits.

Table I

Full Load of Transformer Bank=15,000 Kva 3-Phase

Current-Transformer Ratios Figured for 25 Per Cent Overload. Base 60 Kv

		Current-Transformer Ratios			
Kilovolts	Amperes	Required	Available	Current-Transformer Secondary Amperes	Normal Relay Current Amperes

g Equals $2,506 \times \sqrt{3}/5$ to compensate for the delta connection.

* Auxiliary current-transformers 15/5 amperes current step-down to compensate for the delta plus inverted delta connection.

The Current Connections

The simplest case of all is that of a single-phase two winding transformer as shown in Figure 1. The three-phase two-winding delta-delta-connected transformer bank shown in Figure 2 is quite commonplace. Another case quite as common is the wye-delta-connected transformer bank shown in Figure 3. These three cases serve to illustrate how conditions 1, 2, and 3 are usually satisfied.

It should be noted that no neutral current or ground fault current can return to the delta-connected windings of a transformer bank, except through the admittance of the windings from the cores to their conductors. This current is always of a very small magnitude and can be ignored for the purposes of studies in current-differential protection.

It should also be noted that by putting wye-connected current transformers on the delta side of the transformer bank and delta-connected current transformers on the wye side of the transformer bank, the phase angles of the secondary currents can quite easily be adjusted so that they will satisfy condition 4.

The case of the delta-zigzag transformer bank shown in Figure 4 is one of the newer ones to come up, and, as will be seen by a study of its vector diagrams, is a hybrid one. The phase relations of the high-voltage and low-voltage circuits are the same as those for a delta-delta-connected transformer bank. There is a path for zero-phase-sequence current through the neutral connection of the zigzag winding; therefore, the current transformers on this side must have their secondary circuits connected in delta. We must not shift the phase relations of the current-transformer secondary currents on the delta side, and so these current transformers must have their secondary windings connected in delta also. This differs from the arrangements shown in Figures 2 and 3.

The three-winding delta-zigzag-wye transformer bank, shown in Figure 5, presents an interesting problem. Let us look at the connections of the windings and from the foregoing discussion decide what the requirements will be for each set of windings of the transformer bank.

1. The high-voltage winding is delta-connected and, therefore, will have current transformers with wye-connected secondary windings.

2. The intermediate-voltage windings are connected in zigzag, and, therefore, the current transformers *must* be delta-connected.

3. The low-voltage windings are wye-connected, and, therefore, the current transformers *must* be delta-connected.

Now the vector diagrams for the transformer bank show that the intermediate-voltage and the low-voltage windings have their output currents 30 degrees out-of-phase with each other; therefore, they cannot ordinarily both have current transformers with delta-connected secondary circuits and at the same time have their phase angles adjusted to a balanced condition. Furthermore, the high-voltage windings and the intermediate-voltage windings have their output currents in-phase with each other, and, therefore, the phase angle must not be disturbed as would be the case with dissimilar current-transformer connections.

The high-voltage delta-connected windings, having wye-connected current transformers, will provide secondary currents which represent the phase angles of reference to which the secondary currents from the current transformers connected to the other two sets of power windings must be adjusted.

This difficulty can be overcome successfully by the arrangement shown in Figure 5. The current transformers in the leads to the zig-zag windings are connected in delta. This has provided the necessary circulating path for the zero-phase-sequence components, but it has shifted the phase angles of the currents. A set of auxiliary current transformers must now be used to shift the phase angles back again. It should be noted that normally there will be a one to three step-up in current from the secondary currents in the original current transformers to the output of the auxiliary current transformers into the differential-relay circuit. This factor and any other adjustments in ratio that may be necessary can be taken care of by selecting auxiliary current transformers of a suitable ratio.

To determine the ratio required let:

I_p = the current in amperes from the zig-zag windings of the power transformers

I_r = the current in amperes required for the current differential circuit

$R_1/1$ = ratio of the current transformers in the leads from the zigzag windings of the power transformers

$R_2/1$ = ratio of the auxiliary current transformers

Then

$$R_2 = \frac{I_p \cdot (\sqrt{3})^2}{R_1 \cdot I_r}$$

The low-voltage wye-connected windings present no difficulty. The delta-connected current transformers provide the necessary circulating path for any zero-phase-sequence components, while the phase angles of the secondary output currents are adjusted to match those from the high-voltage side.

A more complicated case is the one of the "Scott"-connected transformer bank as shown in Figure 6. It will be noticed that the worst possible condition for current-differential protection has been considered. The high-voltage circuit is three-phase four-wire. The low-voltage circuit is two-phase four-wire and also has the mid-points of the phase windings of the transformers interconnected and grounded. Here are possibilities of three-phase neutral current and also of two-phase neutral current. Obviously, the three-phase current transformers must have their secondary windings delta-connected.

The two-phase circuit presents the real problem. We have to achieve two things:

1. To arrange that the over-all ratio of the current transformers is such that the final output will be of the right magnitude for the current differential circuit.

2. To change these output currents from two-phase to three-phase.

Of course the fundamental idea must be the same as that of the "Scott" connection, but it is not so easily accomplished with current transformers as with power transformers. The transformer producing the current in the phase W-X is the teaser of the transformer bank. Therefore, the current transformers in the circuit W-X must perform the same function in the current-differential circuit, by producing the quadrature components for B and C phases as well as providing the current for A phase.

Three auxiliary current transformers are required: two of them must have three windings, the other needs only two windings.

The two three-winding current transformers are called phase-mixing transformers for want of a better name. As will be seen, one of them mixes phases W-X and Y-Z to produce a resultant current for B phase. Similarly, the other one mixes phases W-X and Y-Z to produce a resultant current for C phase. The difference between the two resultants is achieved by reversing the direction of the current Y-Z in one of the phase-mixing transformers.

The two-phase current transformers have no interconnection between phases W-X and Y-Z. Therefore, any two-phase neutral current components when passing through the auxiliary current transformers will produce three-phase zero-phase-sequence components in the output circuits.

By connecting the output windings of the auxiliary current transformers in delta, a circulating path is provided for the zero-phase-sequence components, and the phase angles of the output currents are adjusted to match those from the three-phase side.

Let us now get on to the determination of the current transformers required.

Let

I_h = the current in amperes in the three-phase side of the power transformers

I_l = the current in amperes in the two-phase side of the power transformers

$\left.\begin{array}{l} I_{w-x} \\ \text{and} \\ I_{y-z} \end{array}\right\} = \left\{\begin{array}{l}\text{the currents in amperes in the respective current-transformer secondary windings on the two-phase side}\end{array}\right.$

I_r = the current in amperes required for the current-differential circuit

$R_1/1$ = ratio of the current transformers in

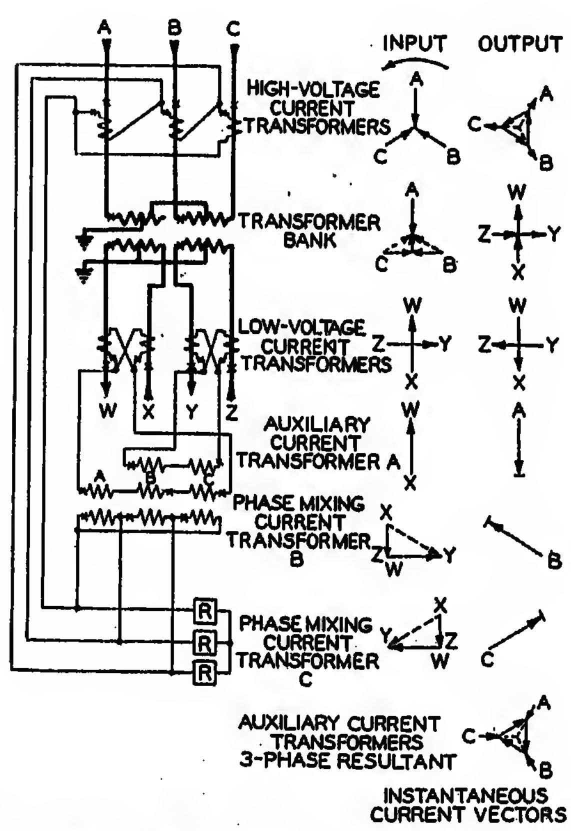

Figure 6. Three-phase to two-phase "Scott"-connected transformer-bank differential protection

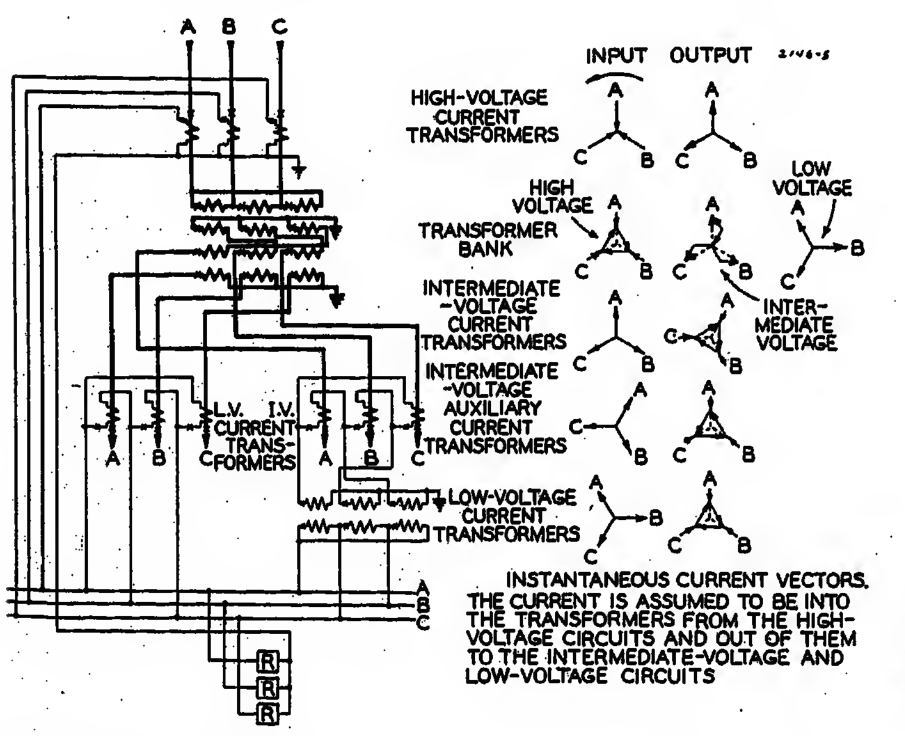

Figure 5. Three-phase delta-zigzag-wye transformer-bank differential protection

Table II

Full Load of Transformer Bank=5,000 Kva 3-Phase–2-Phase Current-Transformer Ratios Figured for 25 Per Cent Overload. Base 60 Kv

Kilovolts	Amperes	Phase	Current-Transformer Ratios: Required	Current-Transformer Ratios: Available	Current-Transformer Secondary Amperes	Normal Relay Current Amperes
63	46	3	100/5[g]	100/5	5	−0.2
61.5	47	3	102/5	100/5	5.1	−0.1
60	48	3	104/5	100/5	5.2	0
58.5	49	3	106/5	100/5	5.3	+0.1
57	51	3	110/5	100/5	5.5	+0.3
6.86	364	2	455/5	$\frac{1,000}{2}/5$†	4.55*	−0.65
6.6	379	2	474/5	$\frac{1,000}{2}/5$†	4.74	−0.46
6.34	394	2	493/5	$\frac{1,000}{2}/5$†	4.93	−0.27

g Equals $58 \times \sqrt{3}/5$ to compensate for delta connection.

* Three-phase current the same value after passing through phase-mixing current transformers.

† Two 1,000/5 current transformers with secondary windings in parallel = 500/5.

the three-phase leads of the power transformers

$R_2/1$ = ratio of the current transformers in the two-phase leads of the power transformers

$R_3/1$ = ratio of the auxiliary current transformer for A phase

then

$$R_1 = \frac{I_h \cdot \sqrt{3}}{I_r}$$

$$R_2 = \frac{I_r \cdot 2}{I_{w-x}} \text{ or } \frac{I_r \cdot 2}{I_{y-z}}$$

and

$$R_3 = \frac{I_{w-x} \cdot \sqrt{3}}{I_r}$$

Now when $I_{w-x} = I_{y-z} = I_r$

then the current input for B and C phases equals

$$0.866 I_{y-z} + j0.5 I_{w-x}$$

and the ratios of the phase-mixing transformers when expressed in terms of amperes will be

$$1.154 I_{y-z}/2 I_{w-x} \Big/ \frac{I_r}{\sqrt{3}}$$

This expression will hold good for any values of I_{w-x}, I_{y-z}, and I_r, even if they are not equal.

Generally speaking, a transformer differential protection should cover not only the transformer bank but as much more of the station equipment as possible. In Figure 7 there is shown an arrangement which can be considered as typical. Here there is shown a three-winding transformer together with its necessary circuit breakers and connections which are all included under the one differential protection. A fault anywhere in the circuits between the transformer and the six groups of current transformers, including the transformer itself, will cause the differential relays to operate. In large stations the bus bars indicated and the circuit breakers connected to them may be separated by considerable distances, so that the connections may include quite long pieces of cable. The differentially protected zone would then reach out to cover equipment situated all over the station installation.

Disturbing Factors

The foregoing discussion of the current-transformer circuits is based on the assumption that all instruments and machines with magnetic cores behave absolutely normally at all times. They do so only after the currents have reached their steady state. Unfortunately, they behave very abnormally during the times that transformers or machines are being cut in and out of service, and also during the times of heavy faults anywhere on the system which can greatly disturb the current conditions in any particular protected zone.

The most usual abnormal conditions are referred to as

1. Through-current transients.
2. Transformer charging-current transients.

Through-current transients are caused by faults which draw very heavy currents through the transformer bank, and the transient magnetic characteristics of the circuit are such that, for a few cycles, the current transformers on one side of the transformer bank do not deliver secondary currents which will balance those from the other side.

Transformer charging-current transients are caused by the inrush of the charging current of the transformer bank at the instant that the first circuit breaker closes. Obviously, the current must appear in the current transformers on one side of the transformer bank only when only one circuit breaker is closed. Fortunately this current persists for only a few cycles also.

Without discussiong these disturbing factors in further detail, let us say that the problem that confronts one from both of these conditions is to get the relays to ignore these transient currents and still remain sensitive enough and fast enough to clear any faults in their zone of protection before excessive damage can result from them.

Here again the war conditions enter into the picture. Old transformers often take very high charging inrushes of current. Current transformers of older types often have saturation curves and d-c time constants which differ widely from those which are built today. In fact, many of them were built when little attention was paid to standardization of performance. Therefore, one may be forced by circumstances to make use of current transformers which have characteristics differing very widely one from another. These conditions are almost sure to produce excessive current-transformer transient differential currents.

There are quite a few types of relays on the market which are arranged to be restrained during transient conditions and are designed on very sound theoretical

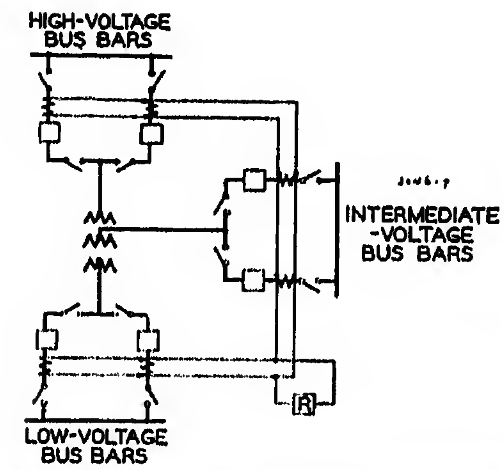

Figure 7. Grouping of current transformers for transformer-bank zone differential protection

Single-phase connections shown

bases for the purpose. Unfortunately, these relays are quite expensive to put into temporary installations. Also it is becoming more and more difficult to obtain relays of ordinary standard types, let alone those which are of quite special types, as these restrained relays are.

Tolerable Differential Currents

There are some compensating factors which help to simplify the problem. It is quite obvious that insofar as the relays are concerned, either the transformer charging current, or the through transient current will produce the greater differential current. Therefore, if we can restrain them for the greater current, we shall have no trouble with the smaller one.

In case of a fault in the protected zone, the damage done will be a function of the time that the fault persists and of the watts that are poured into it. If the impedance to a fault be high, and the power fed into it be therefore low, one may stretch out the time it may be al-

lowed to persist without doing any excessive damage.

It is quite usual in practice to find that current transformers cannot be arranged so that the differential current through the relays is zero at all times. There will almost always be some permanent differential current flowing which will be added to the true differential current under fault conditions. Insofar as the relays are concerned, this permanent differential current is the same as a permanent fault of very high impedance. A transient differential current will be the same as a transient fault, usually of relatively high impedance.

The Relays

Let us assume that one has not much choice of the current transformers and relays that one can obtain for any given differential protection. Let us assume also that, in a hypothetical case, mathematical investigation has yielded the following results for a normal five-ampere relay circuit on a 60-cycle system.

Maximum differential current due to through-current transients	—12 amperes for 20 cycles
Maximum differential current due to transformer charging-current transients	—15 amperes for 15 cycles
Normal 125 per cent load differential current through relays	—2 amperes
Maximum fault differential current under minimum system generating capacity	—5 amperes

If we can obtain both time delay and instantaneous relays of suitable types, we can adequately protect the transformer bank by using one instantaneous and one time relay per phase and set them as follows:

Instantaneous relay:	Pickup at 20 amperes
Time delay relay:	Pickup at 2.5 amperes Operate at 14 amperes in 30 cycles or at 17 amperes in 23 cycles.

The actual setting of the time-delay relay will depend upon its inherent characteristics. It must be determined by test. Let us suppose that for a given relay setting we get the following performance:

Operate at 14 amperes in 30 cycles.
Operate at 17 amperes in 15 cycles.

and for another setting we get

Operate at 14 amperes in 35 cycles.
Operate at 17 amperes in 23 cycles.

Then the second setting should be the one to be selected, because it gives ample time clearance for both through-current transients and transformer charging-current transients. The first setting comes too close to the anticipated time for transformer charging-current transients to persist and might result in false operations.

Almost always the fault current will be high enough to operate the instantaneous relay, but the time-delay relay is necessary to provide against faults at times when the short-circuit current to the fault would be sharply limited by the system setup. Transient currents will not operate the instantaneous relays, because they cannot reach a high enough value. They may, however, start the time-delay relays in operation, but they will die out before the relays can close their contacts. The low value of pickup current of the time-delay relays—0.5 amperes above the normal 125 per cent load differential current—will ensure that they will operate under minimum fault conditions and will not pick up under normal conditions. It is true that the time will be long in clearing, but the limited power available at the fault will limit the extent of the damage that can be done. Most manufacturers of relays now combine these two types of relays in one case.

In some places it is customary to use some sort of additional suppresser circuit to handle transient conditions. The suppresser circuit is usually arranged to shunt away part of the transient differential current from the usual percentage differential type of relays and slow up their action until the transient conditions have passed. This arrangement has one great disadvantage. There is no instant of time when a fault may show up in a transformer bank or its connections in the protected zone more than the one when the first circuit breaker closes and the charging current rushes in. A suppresser circuit makes the relays far less sensitive while it is in operation than they would be normally. Therefore, any fault developing before the suppresser circuit has timed itself out will require a much greater fault current to operate the differential relays than would otherwise be necessary. At times with low generator capacity in service this may cause a complete failure of the differential protection. Some suppresser circuits, which operate on straight voltage for their timing, could never time out during heavy faults in the protected zone, due to the voltage around the zone falling to a very low value, perhaps almost to zero.

On the whole, considerable tolerance can be allowed in the selection of current transformers and relays for current-differential schemes as will be seen from Tables I and II. Table I is worked out for a delta-zigzag-wye transformer bank such as the one shown in Figure 5. Table II is worked out for a "Scott"-connected bank as shown in Figure 6.

While it is always better to have instruments such as relays perform a function for which they have been especially designed, there are often quite a few applications for relays of certain types which were not contemplated at the time the relays were originally thought of. Fortunately, ordinary overcurrent relays can, with care, be made to suffice quite well for transformer differential protection, if time and money are important factors in getting the installation into service.

Conclusions

The most important and, in fact, the essential thing to make sure of in the design of a current-differential protective circuit is that the instantaneous directions of the various currents which must be matched are right and that they cancel out fairly well at the relays. This requirement naturally presupposes that there will be no phase-angle shifts between the currents coming into the relay for any one phase at any time. The exact balance of the magnitudes of the various currents is not very critical. The exact matching of the characteristics and ratios of the current transformers, which are used, is not necessary under ordinary circumstances. It may be necessary where unusually high sensitivity is required. While special types of relays for this work are normally available and give good results, it is not essential that one have anything but some reliable instantaneous and time-delay overcurrent relays in order to provide adequate protection in most cases. Necessary phase-angle shifts of currents, in order to adjust the instantaneous directions of the currents reaching the relays, can be made with auxiliary current transformers. These should have as low an internal burden as possible, in order not to upset the ratios of the power current transformers with which they are connected during heavy current periods. In current transformer circuits connected to transformer windings which have a return path for current through a neutral connection, a delta circulating path for the zero-phase-sequence components in the phase leads must be provided.

Some Air-Blast Circuit-Breaker Installations in Canada

H. W. HABERL
ASSOCIATE AIEE

R. A. MOORE
NONMEMBER AIEE

THIS paper gives a brief report on certain installations of air-blast circuit breakers now in service in Canada, including results of interrupting tests and operating experience.

There are in service in Canada 23 air-blast breakers of 69 kv, 138 kv, and 230 kv of the types illustrated. There are 37 breakers in service on 13 kv and 4 kv. These breakers are in service in ten different stations in various localities.

Figure 2 illustrates an installation of two 230-kv breakers in a station, carrying a load of about 250,000 kva per breaker. Two identical breakers are in service in another city.

Figure 4 shows six 138-kv breakers in a switchyard built for ten air-blast breakers. This switchyard was built in 1934, and 138-kv air-blast breakers have been in service continuously since that time in this installation.

Figure 5 shows three 138-kv air-blast breakers in a city station of 135,000-kva transformer capacity.

In Figure 6a is shown a 138-kv breaker in a downtown city station of 80,000-kva transformer capacity, fed by 120-kv underground cables. This station is built for air-blast breakers exclusively and will have an ultimate installation of 24 15-kv and 36 4-kv breakers.

Figure 7 shows one of two 110-kv breakers at a generating station in the north country (above latitude 48).

Air-blast breakers of 69-kv design are shown in Figure 8, in service in a city station of 40,000-kva transformer capacity. In Figure 11 is shown one of five 69-kv breakers in a terminal station where the short-circuit duty is 1,100,000 kva, this being the recorded interruption on test of one of these breakers in this station.

Air-blast breakers in service on 11-kv generator voltage are shown in Figures 13 and 14. Figure 15 shows a group of seven 4-kv breakers now in service in Western Canada.

Paper 42-157, recommended by the AIEE committee on protective devices for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 3, 1942; made available for printing July 24, 1942.

H. W. Haberl is protection and relay engineer, Montreal Light, Heat, and Power Consolidated, Montreal, Quebec, Canada.

R. A. Moore is switchgear engineer with the English Electric Company of Canada, Ltd.

Interrupting Tests

The type of 230-kv breaker illustrated has been tested at the station where these breakers are in service, located near the center of three large power systems operating in parallel with a combined generating capacity of about 2,750,000 horsepower. The maximum short-circuit duty at this location is 2,500 amperes at 230 kv or 1,000,000 kva, which is the recorded interruption on test of this breaker as shown in oscillogram, Figure 3.

The breaker is rated at 2,500,000 kva or 6,250 amperes at 230-kv three-phase, an amount of short-circuit current not available for test in Canada. However, this breaker has six interrupting elements in series per pole, and tests have been made on one of these elements interrupting 5,385 amperes with 58.8 kv across the element (see oscillogram Figure 6). This test voltage, 58.8 kv, is about 2.67 times the voltage impressed on each of the elements when interrupting a short-circuit current (assuming line-to-neutral voltage across each pole and equal voltage across each of the six elements in series). If the voltage across one pole is assumed to be 1.5 times line-to-neutral voltage, then the above ratio of 2.67 would become 1.78; that is (under the last assumption) the single element was tested at 1.78 times its rated voltage and interrupted 5,385 amperes which is 86 per cent of 6,250 amperes, its rated current. Multiplying 1.78 by 0.86 gives 1.54; that is, the test is an indication that the breaker would interrupt 6,250 amperes with a voltage across one element 1.54 times the normal (equally divided) voltage, and with a voltage across the same pole of 1.50 times the line-to-neutral voltage. It will be noted that the only extrapolation in the above is from 5,385 amperes test current to 6,250 amperes rated current, that is, an assumption of the same kilovolt-ampere capacity at 6,250 amperes. The assumption of 1.5 times line-to-neutral voltage across one pole is one which has been commonly used, and the assumption of 1.54 times the equally divided voltage across one element is believed to be more conservative than necessary. The oscillogram shows that the arc voltage (six arcs in series) is so low that it could be applied all across one element and be only a small fraction of 22 kv (the equally divided voltage across one element). Hence, if there is any practical inequality of voltages across the six elements, it could only occur after the interruption (and until the opening of the series isolating switch, while the blast of air is still passing between the contacts). The electrostatic field is quite uniform, being determined by the metal roof 30 by 48 inches, and a metal bedplate of the same size, 60 inches below it, supported on insulator stacks, about seven feet above the grounded structure. The insulating structure housing the contacts and arc chutes has a large horizontal cross section. The six sets of contacts occupy identical locations in this structure. Such conditions are conducive to uniform division of potential across the contacts.

Tests on the 69-kv breaker (oscillogram Figure 9) also have a bearing on the interrupting capacity of the 230-kv breaker. The interrupting element in the 69-kv breaker is the same as in the 230-kv breaker, except that the width of the 69-kv contact (and arc chute) is eight inches instead of five inches as in the 230-kv breaker. The 69-kv breaker has interrupted 10,000 amperes on a three-phase short circuit on a 63-kv circuit, which test subjected the single element of the 69-kv breaker to a transient voltage of

The 138-kv breaker has three of these 22-kv elements in series per pole, and the 230-kv breaker has six of these elements in series per pole

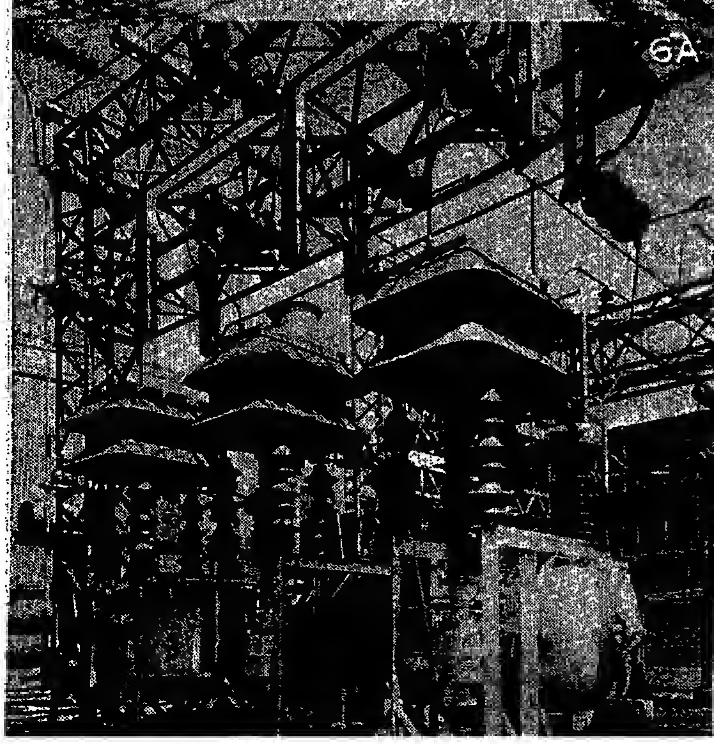

Figure 6a. 138-kv breaker on an underground 120-kv cable-fed substation located in a downtown area
This breaker is within ten feet of a busy street

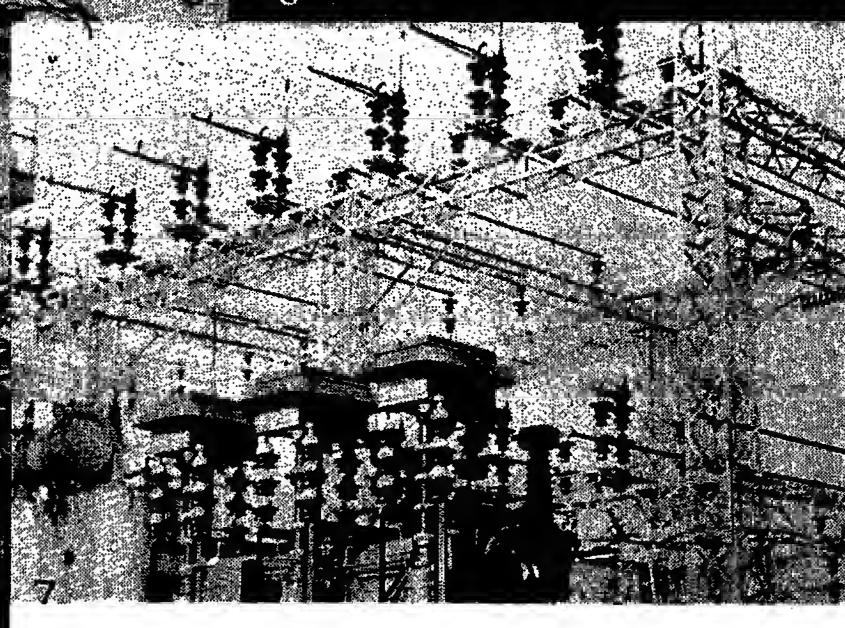

Figure 7. Two 110-kv breakers at generating station in northern Quebec
These breakers have two interrupting elements in series per pole. Addition of one interrupting element per pole would increase voltage rating to 138 kv and interrupting capacity to 2,000,000 kva

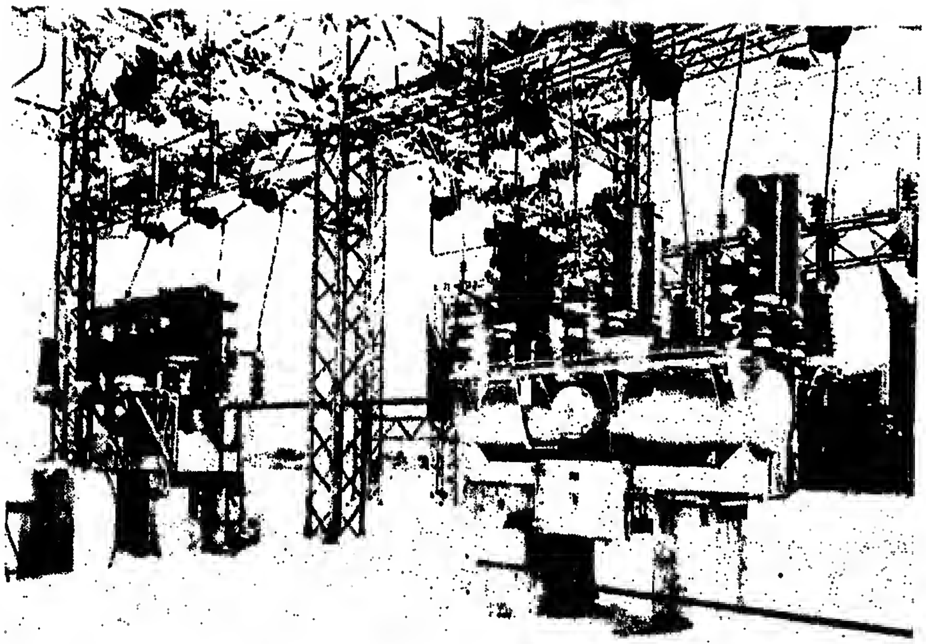

Figure 8. Two 69-kv breakers in city station

Switchyard laid out for nine of these breakers. Each pole has one interrupting element eight inches wide; otherwise the same as the elements in 138-kv and 230-kv breakers, which are five inches wide

36.4 kv. Reducing 36.4 kv in the ratio of five inches to eight inches gives 22.75 kv as the voltage at which the five-inch element should interrupt 10,000 amperes. If the voltages are divided equally in the 230-kv interruption, each element would be subjected to only 22 kv, but assuming 1.5 times line-to-neutral voltage across one pole, then one element would be subjected to 33 kv. Reducing 10,000 amperes interrupted on test, in the ratio of 22.75 kv to 33 kv, gives 6,900 amperes as the interruption at 230 kv, which is 2,750,000 kva. In this case we are interpolating, from the higher test current of 10,000 amperes to the lower current (6,900 amperes) which would justify a slightly higher kilovolt-ampere rating than we have assumed in the voltage ratio calculation.

It will be noted that none of the tests on this style of interrupter showed what is the maximum interrupting capacity. Each of the tests was simply made at the maximum current and voltage available, and none of the tests indicated that the interruption was near the limit of capacity of the breaker.

The 138-kv breakers illustrated have identically the same interrupting elements as the 230-kv breakers, with three elements in series per pole (instead of six). The tests above referred to are, therefore, directly applicable to the 138-kv breaker. The current-interrupting rating is practically the same (6,250 amperes), and the voltage per element is practically the same.

Tests were made also on the 69-kv breaker by applying 58.8 kv across one pole, interrupting 5,580 amperes, which was the maximum current available. The significance of these tests is the liberal overvoltage capacity shown (see oscillogram Figure 10).

In general the tests on all of the breakers above referred to have shown arcing time of one-half cycle. The contacts have shown negligible burning and did not require cleaning up before putting them in service. The arc did not extend outside of the cooling grid. All of the tests were "make-break" and the disconnecting switch contacts making the short circuit performed satisfactorily (the motion of the switch blade being very fast), the arc was not objectionable, and the contacts did not require cleaning up.

The tests were witnessed by disinterested visiting engineers from various power companies, and there was general agreement that no distress was shown in the interruptions.

Operating Experience

Service experience with air-blast breakers in Canada (and the United States) dates from 1934 when the first 138-kv breaker was put in service in the switchyard of a large generating station. It remained in service continuously for about six years interrupting all short circuits satisfactorily. Its isolating switch was very slow, and the workmanship on its interrupting contacts was relatively crude, finally resulting in overheating while carrying load, and it was superseded by breakers of improved design and workmanship. Breakers of the later style have been installed in the same station, and there are now six installed. This first installation demonstrated that there were no serious difficulties in operating and maintaining air-blast breakers of that voltage outdoors in a location subject to climatic extremes of moisture and temperature. The activated alumina twin air dryers installed in that station in 1934 are still in satisfactory operation serving six breakers. The early experience showed the importance of extracting the oil vapor as well as the moisture from the compressed air. There was much improvement made in the detailed technique of determining when the alumina needed reactivating; the color-changing alumina was a practical help, but not essential; the experienced operators got along quite well with the plain white product. The oil vapor (from the lubrication of the compressor pistons) requires a good tight woolen blanket to filter it out. If the blanket does not fit tightly in the container, the oil vapor will blow by. If oil vapor is allowed to pass into the breaker valves (especially the pressure-reducing valve), it will cause the small parts to stick. Consideration has been given to the use of oilless compressors, using carbon piston rings, but the maintenance of the carbon rings and extra cost of such compressors does not appear attractive nor justified. The

Figure 9. Three-phase "make-break" test on 69-kv breaker in 63-kv circuit, interrupting maximum current available 10,000 amperes, equals 1,090,000 kva

Opening time 3 3/4 cycles, including one-half-cycle arcing (see text for additional tests indicating higher interrupting capacities)

woolen filter has been found quite satisfactory.

There are now in service in Canada 23 air-blast breakers of 69, 138, and 230 kv, in seven different localities. Their service record is equivalent to about 21 "breaker years."

In one instance certain new-style arc-chute details were installed without sufficient interrupting tests, because of the desire to meet promised shipping dates, and certain new parts were found necessary after the tests. In other instances, water had accumulated in the air piping and was not blown out before connecting the breaker, resulting in a flashover in one of the small porcelain "closing" tubes, requiring only replacement of the tube. Aside from such experience, the straight work of installing air-blast breakers does not require any greater skill or labor than installing oil breakers; in fact, the absence of any mechanical linkage between poles of the air-blast breakers eliminates the close mechanical adjustments required in installing oil

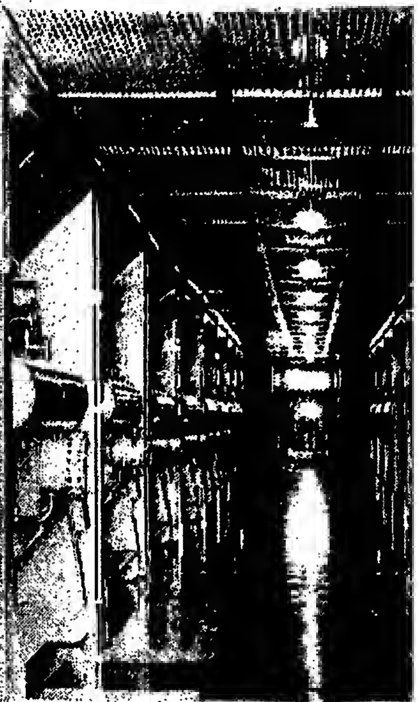

Figure 13. Delle breakers installed in a large power-house

Main generator and transformer breakers operating on 11 kv rated 1,000,000 kva. This station is completely equipped with air-blast breakers

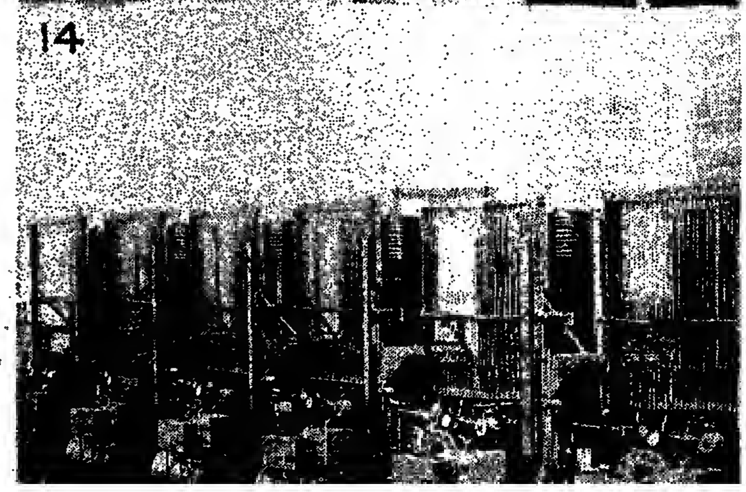

Figure 14. Factory picture, English Electric Company (Canada) of Delle breakers for four-kilovolt service

These breakers are now in service in western Canada

breakers. Also there is no item in the air-blast job corresponding to the job of filtering large quantities of oil during installation of oil breakers.

In the 69-kv, 138-kv, and 230-kv breakers herein illustrated the contacts and other parts requiring occasional inspection are very accessible. The contacts can be removed and replaced in a small fraction of the time required for corresponding inspection of oil-breaker contacts.

In these breakers the interrupters are supported on standard switch-type insulators (the same as used for bus supports and disconnecting switches). The breakage of the porcelain on such supports does not impair their mechanical strength, and there is no danger of the interrupter falling.

In the experience of several years of testing various styles of interrupter contacts and arc chutes to determine their interrupting limitations, the observers have been impressed with the fact that a failure to interrupt does not result in serious damage. After such a failure to interrupt, the contacts require resurfacing or replacement of arcing tips, certain parts of the arc chute require cleaning up or replacement, but the remainder of the breaker remains intact.

The 138-kv and 230-kv breakers illustrated are readily adaptable to single-pole operation (automatically opening and reclosing one pole only to clear a line-to-ground fault), because there is no mechanical connection between the three poles. The 69-kv breakers have mechanical connection, but this can readily be dispensed with in case single-pole operation is desired.

The opening time (including arcing time) of the 138-kv breaker is within three cycles. The other two breakers take about three quarters of a cycle longer in opening. This can be shortened by about one cycle in the case of the 69-kv breakers by omitting the mechanical tie between the poles. The opening time is also influenced to some extent by the adjustment of certain small valves controlling the opening and closing of the blast valve, so that the opening time of the blast valves and the breaker can be somewhat reduced below the above figures.

Regarding closing time, the breakers as now adjusted take about 12 cycles to close in the case of the 69-kv breaker, about 15 cycles for the 138-kv, and about 19 cycles for the 230-kv. This time is also susceptible of reduction by certain adjustments.

In cases where extremely fast reclosing is desired, this can be arranged by certain adjustments which advance the time of shutting off the blast and applying closing air pressure, it being unnecessary to wait until the isolating switch has completed its opening motion.

It has been noted that all of the tests recorded by the oscillograms were "make-break" interrupting tests. The construction of these breakers is such that the opening and clearing time is the same whether the operation is a "make-break" or a "break" performance, as the breakers are provided with pneumatic tripfree valves.

As shown by the illustrations and remarks concerning the 138-kv breaker, even after one of these breakers has been installed and operated, if changes should be made in the system either by increasing the voltage or increasing the interrupting duty, it is a relatively simple matter to add one or two supporting insulators and one or two interrupting sections, thereby increasing the voltage and interrupting capacity of the breaker without discarding any of the parts. For instance, a system might initially operate at 110 kv and in later years be raised to 138 kv or 180 kv by the additions to the breaker as indicated.

The same remarks apply to the 230-kv breaker in regard to a possible increase in voltage from 230 kv to 280 kv for instance, which could be accomplished by adding one or two supporting insulators.

Low-Voltage Air-Blast Breakers

Figures 13, 14 and 15 show installations of 15-kv and 4-kv air-blast breakers in Canada. The first few breakers of this type were imported from the Delle Company in France. The other breakers of the same design were built by the English Electric Company of Canada. The interrupting capacity has been established by the tests made in the testing laboratories in France and by certain tests made in the testing laboratories of the I-T-E Circuit Breaker Company in Philadelphia. Further tests have been made on these breakers at the stations where they are installed. Certain improvements in detail have also been made by the Canadian company to meet Canadian requirements.

The 15-kv breakers illustrated have been operating satisfactorily for about two years on 11 kv in a large generating station which is equipped with air-blast breakers exclusively.

History of A-C Wave Form, Its Determination and Standardization

FREDERICK BEDELL
FELLOW AIEE

Synopsis: With the birth of the transformer and the first distribution of alternating currents, wave form assumed interest, and methods were developed for its determination, chiefly the point-by-point method of instantaneous contact, mechanical oscillograph, cathode-ray oscillograph, and the oscilloscope with stabilized time axis. The point-by-point method, by which were made the first major contributions, is now practically superseded by oscillograph and oscilloscope, each finding increasing use in its field.

With the determination of wave form accomplished, demand arose for its standardization corresponding to expanding applications. No single standard being suited to all applications, different standards have been developed in different fields, as in power, communication, and insulation. While it is desirable that standards, once set up, remain fairly stable, they should be subject to review and occasional change to keep in step with technological advances. Minor revision in communication is in progress. Although standards in other fields do not appear ideal, no immediate revision is recommended. Forty references are appended.

Alternating Current in the Late 80's

THE distribution of alternating current as we now know it began in 1885–86. Previous to that time, alternators were used to operate arc lamps in lighthouses, each machine operating one large arc lamp, but there was no distribution. Late in 1885, William Stanley made his first constant potential transformer, and early in 1886, using six transformers for operation in parallel distributed current at Great Barrington, Mass., to a score of customers at a distance of 4,000 feet. The secondary voltage was 100 volts. Current was supplied from a Siemens alternator, designed for 12 amperes 500 volts, imported for the purpose. At the time of this first installation, it was pointed out by electricians that "if a high potential primary circuit of 500 volts or more were used to distribute electricity throughout a community, there was a grave fire and life danger." A few years later a bill was introduced[1] but not passed in the Virginia legislature to limit a-c pressure to 200 volts, alternating current being considered (by those opposing its use) to be more deadly than direct.

Stanley's installation at Great Barrington was put in regular service in March 1886, and operated until summer, when an attendant dropped a screw driver into the alternator and ruined it. Meanwhile, on April 6, 1886, George Westinghouse, accompanied by W. L. Church, F. L. Pope, W. C. Kerr, and others, had seen the system in operation and determined to actively enter the a-c field. The manufacture of a new type of alternator designed by Stanley, the radial-pole type thereafter generally used, was undertaken in Pittsburgh. The story is well told by Stanley[2] himself with interesting side lights with credit to others.

The following winter the first commercial installation was made at the station of the Buffalo Electric Company. The question of the determination of a-c wave form then arose as an engineering problem. Before considering wave form, we should note the meagerness of knowledge then possessed concerning the behavior of alternating currents.

In the late 80's many misconceptions impeded progress. Series *versus* parallel operation of transformers was much discussed without adequate understanding. In 1886, at the very time that the parallel operation of transformers was successfully accomplished as we have just seen, a distinguished cantor lecturer held such a connection to be impracticable, maintaining that a separate lead to each transformer would be necessary, or each transformer should have a special regulating apparatus.

Referring to constant current operation with transformer primary windings in series, the chief of an electrotechnical testing station explained:[3] "When no secondary current is flowing, the electromotive force in the primary and secondary coils is a maximum. (Quite correct.) We have consequently this disproportion that *the smaller the output of the apparatus the greater the energy consumed.* With the secondary circuit open, and a constant exciting current, the energy used could be as much as ten times as great as under full load." Power factor was overlooked or unknown.

The proponents of the series connection of transformers operated with constant primary current reversed the argument with the same misconception. They held that inasmuch as primary electromotive force decreased with increase of secondary load, power input also decreased (primary current being constant), with the happy result that *as more power was taken out, less power was put in*—surely a condition to be desired. Here again, power factor was neglected or unknown. Yet, without meters for measuring power, power factor or phase, such misconceptions should be expected; they merely reflected the state of the art at the time.

The United States Patent Office had shown a like misconception when in 1883 it refused[4] to grant a patent on a transformer on the ground that it would be impossible to get a larger current out of the secondary winding than was supplied to the primary winding, but in 1886 a patent was allowed for this very thing.

In the Early 90's

Many of the misconceptions of the 80's trailed along into the early 90's. In the field of alternating currents there was a growing collection of isolated facts, some understood and others not, but there was no broad foundation on which to stand. This was the situation, as recalled by the author in 1890 and 1891, when he first became interested in alternating currents and in wave form. The open-magnetic-circuit transformer was still discussed. The merits of the "nonpolar" transformer with its closed magnetic circuit was not yet fully recognized. The capacity "effect" with current before the electromotive force that produced it (the effect before the cause) and the Ferranti "effect," with electromotive force received at the far end of a cable greater than the electromotive force applied, were found baffling.

Two "systems" of a-c distribution were then in use, apparently well-established: the "high-voltage" *constant potential* (Westinghouse) system operating transformers with primary circuits of 1,000 volts and 2,000 volts, with secondary circuits wound for 50 volts and 100 volts for supplying incandescent lamps in parallel;

Paper 42-152, recommended by the AIEE committee on basic sciences for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 17, 1942; made available for printing July 21, 1942.

FREDERICK BEDELL is professor emeritus of physics, Cornell University, Ithaca, N. Y., and consulting physicist, R. C. Burt Laboratory, Pasadena, Calif.

The author is indebted to A. C. Crehore, his first co-worker, and to later co-workers to some of whom reference is made; to L. F. Blume of Pittsfield, O. E. Buckley and H. S. Osborne of New York, L. W. Chubb and R. D. Evans of Pittsburgh, who furnished material and references; and to the staff of the California Institute of Technology.

and the *constant current* system, about 10 or 15 amperes for supplying arc lamps in series. Transformers were limited to small sizes, the dictum from high sources that transformers larger than two kilowatts would not be economical being generally accepted. Higher voltages and the use of a-c motors were in the offing. The attempted use of iron wire for a-c transmission has been reported.

It was in 1890–91 that P. N. and L. L. Nunn installed the first commercial transmission of alternating current for power, to operate a 3,000-volt synchronous motor at the Gold King Mine at an altitude of 11,500 feet near Telluride, Colo., from water power 3,000 feet lower at a distance of three miles. The situation at that time was vividly described by P. N. Nunn in an address (mimeographed) before AIEE Los Angeles section, May 8, 1934, on "Early Experiences in the Power Industry," from which the following is quoted:

> "In spite of its shortcomings, alternating current seemed the most feasible. A pair of conventional alternators were installed, one as generator, the other as motor, identical to assure identical 'wave forms,' *whatever that might be.*
>
> "In 1890 alternating current was just plain *freak;* it did not follow Ohm's law and 'clogged' itself in its circuits. Bedell and Crehore had doped out its laws and demonstrated their concepts in 100 pages of solid calculus.
>
> "Wattmeters had not been developed, nor had the term 'power factor' been adopted into the vernacular."

Evidently wave form, power factor, and the clogging effect of impedance were dimly discernible. The need of a standard wave form, "whatever that might be," was thus early recognized. From this first power transmission it was a far cry to the 287,500-volt transmission with its magnificent equipment at Boulder Dam today. The increase from 3,000 volts came slowly with gradual increases in demand for more and more power from greater distances, with notable jumps to 33,000, 40,000, and 60,000 volts. With high voltages and long distances arose problems of insulation and interference, in which questions of wave form play such important part.

Going back to horse-and-buggy days, with constant-current and constant-potential systems both in use, the question arose as to whether incandescent lamps and arc lamps could be supplied from the same system. Early in 1891 a promoter, an ardent believer in the future of the constant-current system,* sought the aid of A. C. Crehore and the author in the development of a constant-current to constant-potential transformer for operating incandescent lamps from such a system. Easier said than done, but with the enthusiasm of youth, the problem was tackled. In this connection the development of the principles governing the flow of alternating currents was undertaken, while at the same time experiments were started on a high-voltage constant-current arc-light circuit, the only supply available.

From the experimental work much was learned, although it was never completed. As at Great Barrington it was learned that a short circuit by a screw-driver could wreck a constant-potential generator; so the lesson was now learned that an open circuit caused by the slipping of a connector from a mercury cup could wreck a constant-current system and cause a general blackout! A mercury-cup contact is ill-suited for high-voltage experiment. Permission for experiment was withdrawn. The work, thus summarily ended, was never renewed; meanwhile a better solution had been found by Elihu Thomson—the "tub" transformer with floating secondary winding delivering constant current from a constant-potential primary winding. Constant-potential primary distribution had become firmly established.

The theoretical work, on the other hand, the development of the principles governing the flow of alternating current, gave better results, opening a fruitful and ever widening field with direct bearing on a-c wave form. This work, prepared initially without thought of publication, formed the basis for the first paper by Bedell and Crehore[5] presented before the Institute at its annual convention (then general meeting) in Chicago just 50 years ago. In this the principles governing current flow in transient as well as in steady conditions were first fully developed. The sequel published in book[6] form later in the same year defined the limitation to telephony (page 201) due to change in wave form of a complex wave along a line[6a] with distributed capacity and the modification produced therein by self-induction, successfully accomplished later by M. I. Pupin with the use of loading coils. In it were included the development of vector methods for solving a-c problems and the extensive use of circle diagrams, now so common.

The first use was here[5,6] made of $j=\sqrt{-1}$ in a-c analysis. Its use in astronomy and other fields had long been known, the symbol $\sqrt{-1}$ as a sign of perpendicularity appearing in a memoir to the Royal Society of Arts and Letters of Denmark by Caspar Wessel[7] in 1797. It is to A. E. Kennelly,[8] however, that credit[9] should be given for bringing out its full significance in the application of complex quantities to a-c problems, and to C. P. Steinmetz for so ably extending its usefulness.

Vector methods and circle diagrams for solving a-c problems were not infrequently criticized, when they were first developed, as being dependent upon the so-called "sine assumption," whereas in fact electromotive forces produced by a-c generators *are not true sine waves.* To this criticism with its part truth there was no categorical answer. As a circle is defined by three points, a circle diagram permits the determination or predetermination of the performance of a-c machines and systems with a minimum amount of observation and calculation. Experimental diagrams[10] were early found to check** closely with theory. The wide use of the circle diagram today is evidence of its value.

The assumption of equivalent sine waves has likewise proved adequate[11] for many cases. For other cases more elaborate methods,[12] sometimes involving vectors in more than two dimensions, have been developed. These methods, also, have been criticized on the ground that electromotive forces produced by most a-c generators *are practically sine waves;* so that these more elaborate methods are unnecessary. Again a part truth! Both assumptions, sine wave and nonsine wave are open to criticism, but each has its field of usefulness. What allowable limits should be set to the departure from a sine wave remains to be determined.

Wave-Form Determination

H. J. Ryan[13] in 1889 made an extensive study of wave forms of a closed-magnetic-circuit transformer under different operating conditions, using a synchronous contact maker to obtain instantaneous readings point by point. In this way complete wave forms of currents and voltages and their phase relations were obtained, showing definitely the behavior of such a transformer. By this method studies were made of generator wave form by Tobey and Walbridge[14] and the wave

* Well into the present century engineers of eminence believed that constant current would be the ultimate in power transmission.

** It is interesting to note that such a close check, even though not complete, could be made without wattmeter, phase, or power-factor meter and with limited instruments for current and voltage measurements. Primary and secondary voltages were determined by reading, with telescope and scale, the elongation of two fine German-silver wires; primary and secondary currents, similarly, with two coarse wires. Very competent were the three observers named in the reference, with later careers of note.

forms of an open-magnetic-circuit transformer by Bedell, Miller, and Wagner,[15] using a liquid-jet contact maker, with some modifications in methods of measurements and the use of capacitors to improve power factor. The open-magnetic-circuit transformer with its large magnetizing current and low power factor could not survive.

The use of a synchronous commutator[16] in place of a contact maker eliminated error caused by duration of contact and made possible the direct determination of flux. The mechanical plotting of points on a synchronous drum was introduced by E. B. Rosa[17] to eliminate tedious plotting by hand. All methods employing synchronously driven mechanism, however, had their day. Besides being cumbersome and inconvenient, they were limited to commercial frequencies and at best gave only points rather than continuous curves.

Meanwhile, a parallel development, starting with the optical study of the excursions of a telephone diaphragm, had led to the oscillograph,[17a] perfected by Blondel, Duddell, and others, employing a suspended element light enough to follow closely the rapid changes in a quantity under observation. There is no need for expanding on the wide and continued usefulness of the oscillograph in the determination of wave form. Point-by-point methods were thus outmoded. The moving element of an oscillograph, however light it may be, has *some* inertia which, though practically negligible for many purposes, limits its ability to follow very rapid changes in the quantity under observation. A vibrator with no weight at all would be most desirable.

It had long been known that a cathode-ray beam would be deflected by a magnetic or electric field. Ryan[18] grasped at this fact and, with a special cathode-ray tube made for him by Mueller Uri, constructed and used the first cathode-ray oscillograph, an oscillograph in which the moving "part" had no weight and could accurately follow the changes in whatever quantity was under observation. A new field was thus opened.

In the cathode-ray oscillograph the spot of light caused by the cathode ray impinging on a fluorescent screen became a curve, by persistence of vision, when the cathode-ray beam was deflected simultaneously by two fields at right angles, one field being set up by the variable under observation, and the other by a known variable of reference. Various Lissajous figures were thus produced. In studying a-c wave form, Ryan used a known sine wave for reference, the resultant curve being a smooth ellipse in case the wave under observation was also a true sine wave. Departure from an ellipse indicated departure of the unknown a-c wave from a sine wave. The observed curve was then laboriously replotted with time as an axis, as there was then no means for obtaining this directly.

The apparatus used by Ryan was cumbersome. The tube required 5,000–10,000 volts accelerating potential, obtained from a motor-driven Wimshurst machine. Furthermore, it required the maintenance of low vacuum, obtained from elaborate vacuum apparatus with frequent attention. These inconveniences were overcome in the low-voltage hot-cathode tube of Johnson,[19] with an accelerating potential of only 300–500 volts and greater sensitivity. The tube contained a small amount of gas and required no re-evacuation during its life. The general use of the cathode-ray tube for determining wave form thus became possible.

To obtain a linear time axis, as now commonly used, required a saw-toothed wave for the wave of reference, instead of the sine wave used by Ryan. Various means for developing such a wave were advanced, some mechanical, as from a synchronously driven rheostat, and some electrical from various types of circuit. Mechanical means were cumbersome and limited in frequency range and never came into general use. Electrical means for obtaining a saw-toothed wave, properly synchronized and stabilized, led to the oscilloscope[20,21] with linear time axis so widely used today.[22,23] To maintain curves stationary, a stable linear sweep circuit is essential. With the oscilloscope practically no energy is drawn from the circuit under test.

With wave form determined, many methods and machines have been developed for its analysis, when plotted either in rectangular or polar[24] co-ordinates, into its harmonic components. Early attempts were made to determine the separate harmonic components in an a-c wave by direct electrical measurement. Some success was obtained by resonance[25] and by other means, as by passing currents of various harmonic frequency through one coil of a split dynamometer, the current to be analyzed through the other. The results, however, were meager, as the harmonic components without amplification, were too small to give significant measurement. Amplification, however, has made possible the development of many successful analyzers that give the components of an a-c wave directly by electrical measurement.[26–29]

Wave-Form Standardization

With the expanding use of alternating currents, the need for the standardization of wave form arose, and the adoption of some factor or factors that would indicate quantitively the degree of departure from a sine wave. Form factor, the ratio of effective to average value, although useful in connection with transformer loss, had no general significance, widely different wave shapes having the same form factor.[30] Other factors were from time to time proposed for this purpose, including distortion factor, peak factor, harmonic factor, curve factor, and deviation, and in some cases, after discussion, were sanctioned by the standards committee. Each factor had its own[31] significance as the numerical measure of the departure of an irregular wave from a pure sine wave, varying each in its own way with variation of amplitudes, phase, and frequencies of the harmonic components of the wave. Each, therefore, had special usefulness for special purposes. Whether a single factor could be found, sufficiently satisfactory for all purposes, was a question.

It was generally agreed that a sine wave of electromotive force at generator terminals or on a transmission line is best for most purposes, and that methods for prescribing allowable departure therefrom should be determined. In 1915 the standards committee, through a subcommittee* on wave form, undertook a study of the subject to ascertain what standard or standards could be specified that would be most suitable in characteristics and practical in application, avoiding tedious analysis and cut-and-try methods as far as possible.

Admittance Standards

As the troubles caused by a departure from a sine wave depend in many cases upon the frequency of the harmonic or harmonics present, the assignment of penalties to different harmonics according to their frequencies appeared to be an obvious way to make the penalty fit the crime. For doing this, an admittance type of wave-form standard[32] appeared well suited, with the possibility of assigning different allowable weights or penalties to harmonics of different frequencies according to their behavior or misbehavior. The admittance of a circuit is readily measured, being proportional to

* Membership of the subcommittee: F. Bedell, chairman; L. W. Chubb, F. M. Farmer, H. S. Osborne, and L. T. Robinson.

current. The admittance of a circuit with capacitance (C) increases, and in a circuit with inductance (L) decreases, with the frequencies of any harmonics in the applied electromotive force. With L and C both in the circuit, the admittance reaches a resonant peak at a particular frequency, the broadness of resonance being controllable by the resistance (R). Values of L and C can, accordingly, be selected for resonance at a particular resonant frequency, giving maximum penalty to a harmonic of that frequency, the admittance and penalty tapering off on each side, more or less rapidly, according to the value of R.

The shape of the tapering slopes on the two sides can be controlled to a certain extent by employing a composite, instead of a simple circuit, with R, L, and C in the admittance standard. Desirable penalties can thus be assigned to different harmonic frequencies according to the degree of crime. The possibility of better weighting thus obtained led to the development of a composite circuit, instead of a simple circuit as an admittance standard, despite the advantage that the latter could be readily duplicated with common laboratory equipment.

The degree of crime, however, and hence the penalty to be assigned, is different in different fields of application, as in power transmission and machinery, in communication or insulation. It soon developed that penalties could not be uniformly prescribed in all fields, and no one universal wave-form standard, however desirable on account of simplicity, would prove generally acceptable. Special standards thus appeared to be necessary to meet practical conditions in each case.

In Inductive Co-ordination

The admittance type of wave-form standard was found to be particularly suitable in the inductive co-ordination field. After extensive studies of induction problems involving power and telephone systems, a *telephone interference factor*, TIF, was proposed[33] in 1919 and a TIF meter, of the admittance type, for measuring power-system wave shape in terms of its influence on telephone circuit noise. Definite weightings were determined, based on the interfering effects of different frequencies, depending in part on the telephonic equipment in use and in part on the characteristics of the human ear. In 1935 changes in telephonic equipment and new studies led to new weightings,[34] and the name telephone interference factor was changed to telephone influence factor, as more appropriate. In 1941 weightings[35] were again revised, with corresponding changes in the admittance net work of the TIF meter. Wave-form standards as applied to inductive co-ordination problems are thus being well cared for.

In the Power Field

In the power field, deviation and distortion factors are both in use, but not extensively. Deviation is included in some specifications, and acceptance tests are made to see that the specification is met. Distortion factor* is more rarely encountered, being sometimes used by designers for calculating performance of machines. Good wave shape is a matter of evolution, attained by experience. With the increase in size of machines good design for wave form becomes less difficult.

By American Standards Association[36] definition, 1.217–10.95.420:

"The *deviation factor* of a wave is the ratio of the maximum difference between corresponding ordinates of the wave and of the equivalent sine wave to the maximum ordinate of the equivalent sine wave when the waves are superposed in such a way as to make this maximum difference as small as possible."

"The deviation ractor of the open-circuit terminal voltage wave of synchronous machines shall not exceed ten per cent unless otherwise specified." (Rule 3.220)

By ASA definition, 1.218–10.95.430:

"The *distortion factor* of a voltage wave is the ratio of the effective value of the residue after the elimination of the fundamental to the effective value of the original wave."

To determine deviation, as defined, requires a curve of wave form and the use of cut-and-try methods. Deviation is not directly measurable. In contrast with the admittance type of standard, it takes no account of the frequencies of the harmonic components, a characteristic which may be an advantage or a disadvantage according to the use that is made of it. If there were simple means for its determination, deviation would serve well as a general standard, but no such means are available.

Distortion factor, also, takes no recognition of frequencies, although giving total harmonic content. It can, however, be determined by analytical processes, and indirectly from measurement without requiring a curve of wave form, advantages in its favor.

In Dielectric Tests

In dielectric tests, by ASA rule 2.122:

"The wave shape of the test voltage shall be of acceptable commercial standards: that is, it shall come within the deviation specified as allowable in paragraph 3.220. The test shall be made with a voltage having a crest equal to $\sqrt{2}$ times the test voltage specified."

More recent AIEE Standards[37] specify further in paragraph 3 of appendix:

"With the test specimen in circuit, the crest factor (ratio of maximum to mean effective) of the test voltage shall not differ by more than five per cent from that of a sinusoidal wave *over the upper half of the voltage range.*"

Crest voltages and crest factor may be determined by the use of a synchronous commutator[38] or rectifying tube, specification for a crest voltmeter being given in paragraph 4-80, AIEE Standards.[37]

In a Standards subcommittee report,[39] the use of crest deviation factor (the departure of the crest factor from 1.414 calculated in percentage) is suggested, and it is recommended that, as deviation requires a trace of wave form, it be not used for specifying wave form in dielectric power-factor measurements, and that distortion factor be adopted in its stead.

* Distortion factor is frequently used in the communication field in rating high-quality program and broadcasting equipment.

Summary

Since 1890, when alternating current was considered just plain "freak," not obeying Ohm's law and "clogging itself in its circuits," our knowledge (with or without calculus) has become greatly advanced and the importance of wave form, "whatever that may be," so well recognized as to require most careful standardization.

A fuller discussion of wave-form standardization would here be out of place. Standards must always be subject to revision with technological development, such revision being made only after a strong need has developed. This is not the occasion to suggest revision.

The author has outlined the history of wave form, without venturing a prediction as to the future. The paper merely runs a thread through a maze of material with no pretention to completeness, the story being more fully told in the references and their extensive bibliographies.

Design and Operation of High-Voltage Axial Air-Blast Circuit Breakers

ARMIN K. LEUTHOLD
MEMBER AIEE

Synopsis: The air-blast high-voltage circuit breaker has been developed and applied on high-voltage systems of 150 and 240 kv. Both single-phase and three-phase automatic high-speed reclosing can be carried out with this new type of circuit breaker. The principles of design and operation are explained and the construction of two high-voltage air-blast circuit breakers rated at 150 kv and 220 kv, installed in Canadian power-distribution plants, is described and supplemented by a discussion of performance tests and oscillograms. The construction of an air-blast circuit breaker with axial blast, designed for extremely high voltage and high interrupting capacity, is explained, and results of various tests discussed.

THE air-blast type of circuit breaker was developed very rapidly from the indoor low-voltage type to the outdoor high-voltage type of circuit breaker, as extensive test experience clearly showed the many distinct advantages of applying compressed air for arc interruption. Besides the elimination of the oil hazard, the application of compressed air assures a very fast arc-interrupting ability and enables extremely fast tripping and automatic high-speed reclosing, by means of which the ideal protection of high-voltage power-transmission lines can be achieved.

The description of the following high-voltage air-blast circuit-breaker installations will show to what extent this type of breaker has been developed.

Construction and Operation of 150-Kv Air-Blast Circuit Breaker

The construction of the 150-kv air-blast breaker is illustrated in Figure 1. The breaker consists of three individual poles which are pneumatically interconnected or controlled by a common closing and tripping shaft. Each pole comprises a compressed-air tank (1), with a control valve and piston assembly (2, 3, 4), and a porcelain insulator column (5), on which is mounted the arcing chamber (6), which contains two arc breaks (7), and an air-saving piston arrangement (8). A movable isolating contact (9) is connected in series with the arcing contacts and is operated by a rotating insulator (10). The stationary isolating contact (11) is supported on an insulator (12) which can be designed to accommodate, at the same time, the current transformers for the necessary protective relays and instruments.

To obtain a maximum arc-interrupting effect, an optimum distance between the arcing contacts is required and it is, therefore, necessary to connect a movable isolating contact in series with the arcing contacts in order to provide a satisfactory isolating distance between the live breaker parts in the open breaker position. This separation of the arc-interrupting and isolating functions allows the arcing contacts to be designed relatively small and light, and this, in turn, makes it possible to obtain a very fast opening as well as a high-speed reclosing of the breaker by means of operating the arcing contacts only.

In cases where automatic high-speed reclosing operation is required, a separate insulator tube (13) is applied to supply compressed air for the automatic high-speed reclosing of the arcing contacts.

Breaker Operation

In the open position of the breaker, the isolating contact (9) is open while the arcing contacts (7) are held closed by spring pressure.

When the breaker is closing an auxiliary control valve becomes energized and feeds air from the breaker tank to the isolating contact piston (4), which closes the movable isolating contact (9) by means of a bevel gear drive and the rotating insulator (10).

When the breaker is tripped, compressed air is fed through an auxiliary control valve from the breaker tank to an auxiliary piston (3) in order to open the main blast valve (2), by means of which air flows with high velocity through the insulator column (5) into the arcing chamber (6) and opens the arcing contacts (7) pneumatically and extinguishes the arc at an early current zero. After the arc is extinguished, the air-saving piston (8) closes, and full air pressure is maintained between the open arcing contacts to provide a high dielectric medium which prevents reignition of the arc during the time when the movable isolating contact (9) opens. The pneumatic control is so arranged that, as soon as the isolating contact is fully open, the main air-blast valve closes again, and only the arcing contacts move back into closed position because of spring pressure.

In case automatic high-speed reclosure is applied, the arcing contacts open as on a normal tripping operation, but without operating the movable isolating contact (9), and they are held open under air pressure until, by means of an auxiliary air supply through the reclosing insulator tube (13), these contacts reclose again.

In case of a permanent fault, the breaker immediately opens again after the first automatic reclosure, in a similar way as on a normal three-phase tripping, by the opening of the arcing and isolating contacts, and will remain in open position.

150-Kv Air-Blast Circuit-Breaker Installation in Canadian Power Plant

Figure 2 shows the air-blast breaker installation of the Aluminum Company at Arvida. This breaker, designed for a service voltage of 150 kv and an interrupting capacity of 1,800,000 kva, has been in service since 1939. The large insulators in the foreground, upon which the stationary isolating contacts are mounted, also contain the current transformers which are necessary for the protective relays; otherwise the construction is the same as described previously. Automatic reclosing operation was not requested, and, therefore, this breaker was not equipped with reclosing device.

Arcing Chamber

The construction of the arcing chamber of this breaker is illustrated in Figure 3. Two arc breaks are connected in series which operate as follows:

When the main air-blast valve has opened, compressed air flows under high velocity through the hollow breaker insulator column and ducts into the outside space of the lower and upper arcing chambers, by which means the arcing contacts (1) move their full stroke away from the stationary arcing contacts (2), thereby striking the arcs. Compressed air rushes through the hollow movable arcing contacts and through the muffler (3) to the open air and envelopes the arcs by a stream of high-velocity air which extends the arcs while, by forceful cooling due to air expansion, the arc paths become deionized to such an extent that the arcs extinguish at an early current zero.

Paper 42-155, recommended by the AIEE committees on power transmission and distribution and protective devices for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted May 19, 1942; made available for printing July 30, 1942.

Armin K. Leuthold is engineer with the Brown Boveri and Swiss Electric Company of Canada, Ltd., Montreal, Quebec, Canada.

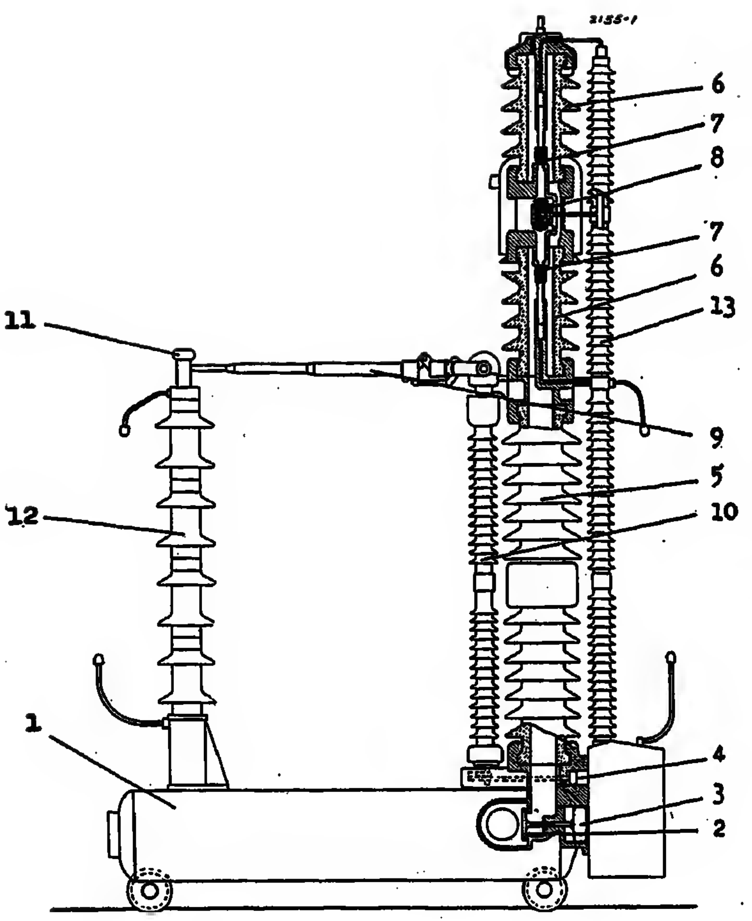

Figure 1 (left). Construction of 150-kv air-blast circuit breaker with double arc break

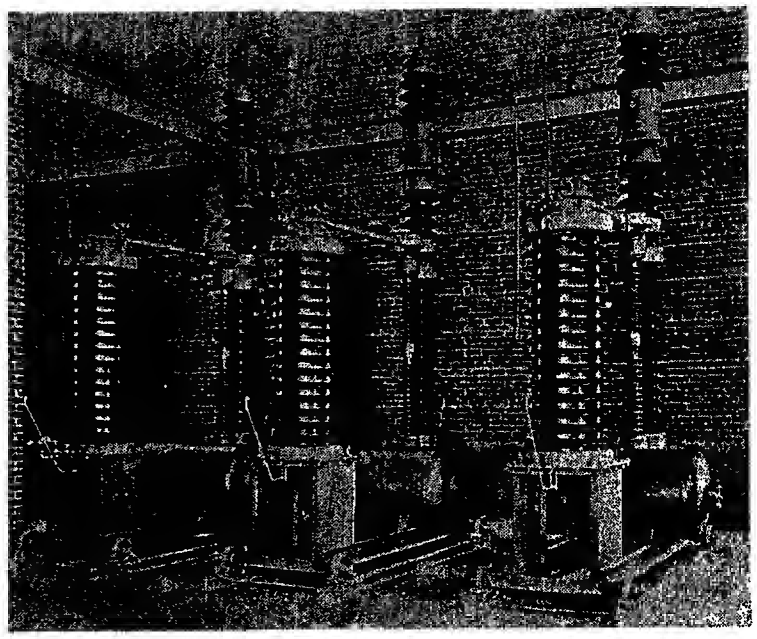

Figure 2 (right). 150-kv air-blast circuit-breaker installation of the Aluminum Company of Canada, Ltd.

When the arcing contacts move into the open position, some ports (4) become uncovered, through which compressed air can flow to the underside of the air-saving pistons (5), and, therefore, these pistons move against the arcing chamber partition, thus preventing a further escape of compressed air from the arcing chamber to atmosphere. A pneumatic time lag retards the closing of the air-saving pistons long enough to ensure positive extinction of the arcs. At the same time, when compressed air is fed into the arcing chamber, it is also admitted to an auxiliary piston which opens, with a time delay of a few cycles, the movable isolating contact. After the latter is fully open the main blast valve closes, and the air-saving piston returns to open position.

Operation

The operation of this type of air-blast circuit breaker is illustrated in oscillogram Figure 4, where a make-break operation is recorded. On a single-phase short-circuit at a voltage of 142 kv, a current equal to a three-phase interrupting capacity of 638 megavolt amperes was interrupted. As indicated on this oscillogram, the short-circuit was initiated at (1), at (2) the breaker tripping coil was energized, at (3) the arcing contacts were separated, and at (4) the arc interruption was completed. Including the arcing time of 0.007 second, the short-circuit interrupting time of the breaker proper (protection relay time excluded) amounted to 0.046 second.

The first high-voltage-type air-blast breaker in Canada was installed at the power distribution plant at Arvida in 1939 and has operated up to the present time very satisfactorily without any failure. A second 150-kv air-blast circuit breaker was installed at the same power distribution plant in 1941. This second breaker has also given excellent service. Experience has shown that no appreciable arcing-contact deterioration is caused even after several short-circuit interruptions. The inspection of the arcing contacts can be carried out in a few minutes, and the maintenance work on these breakers is very little compared to that on an oil circuit breaker.

150-Kv Air-Blast Circuit Breaker With Automatic Reclosing Device

Figure 5 illustrates the same type of air-blast breaker rated 150 kv but equipped with additional devices for automatic reclosing. Several breakers of this type are installed outdoors in European power distribution plants and have given very successful operating results on applying automatic high-speed single and three-phase reclosing.

Oscillogram Figure 6 illustrates a short-circuit interruption with high-speed reclosing which was carried out with this type of breaker on an overhead line of 150 kv. On the upper oscillogram the interruption of an arcing short circuit is shown with automatic reclosing. Experience has shown that restriking of transient system faults could be prevented in most cases if the breaker stayed open approximately 10 to 15 cycles. Therefore, the breaker reclosing time was set in such a way that the breaker was delayed in reclosing approximately 0.19 second. With this time delay in regard to the automatic reclosing, very satisfactory operating results were obtained. At a voltage of 150 kv, a current of 2,200 amperes was interrupted. The total short-circuit interrupting time of the breaker proper (protective relay time excluded) was 0.043 second.

The lower oscillogram of Figure 6 shows the interruption of a metallic permanent short circuit. After the first arc interruption is finished at (2), the breaker recloses automatically only once at (3), and then immediately opens a second time by a final trip and stays open.

Breaker Operation at Low Temperature and Under Heavy Ice Formation

In order to check that the movable breaker parts and piston mechanism operate reliably even under heavy snow and

ice formation, extensive tests under similar conditions as shown in Figure 7 have been carried out with various high-voltage air-blast breakers, and it was found that, even under extremely heavy snow and ice formation, all the movable breaker parts operated very satisfactorily, both as to tripping and closing of the breaker.

In order to prevent condensation and ice formation inside the outdoor air-pipe system and breaker parts, special air-drying equipment was applied through which the compressed air is filtered and dried. Furthermore, an additional outdoor-erected air-storage tank was used in order to refill the breaker air tank, at each breaker operation, with air at approximately the same temperature as the breaker parts.

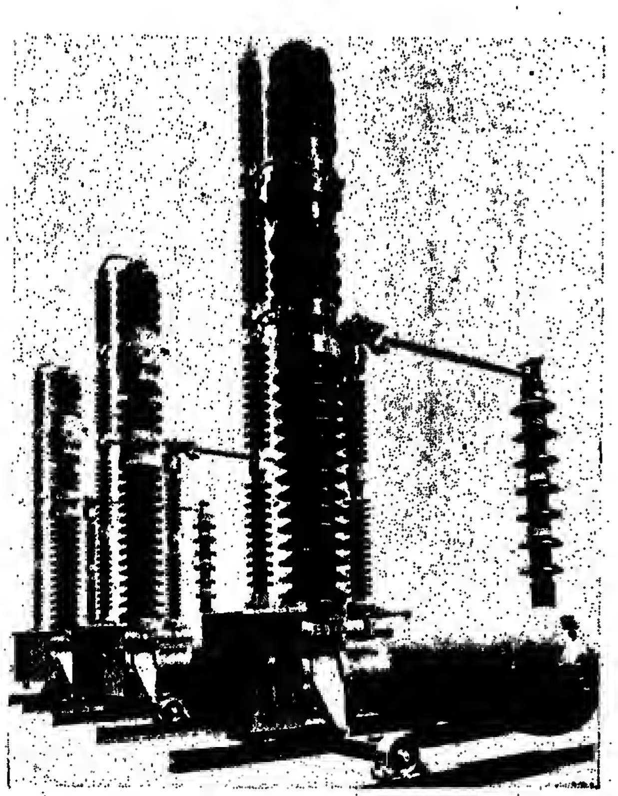

Figure 5. 150-kv outdoor air-blast circuit breaker with automatic high-speed reclosing devices

220-Kv Air-Blast Circuit Breaker Installed Outdoors on a Canadian High-Voltage Power Line

Figure 8 shows a 220-kv air-blast high-speed circuit breaker installed in the outdoor switching station of the La Tuque power plant of the Shawinigan Water and Power Company. This breaker is rated for an arc-interrupting capacity of 2,500,000 kva at 220 kv and is equipped with additional devices for carrying out single-phase or three-phase automatic high-speed reclosing.

Construction

Each breaker phase has a separate undercarriage upon which two large insulator columns are mounted; to each breaker undercarriage are attached four air receivers and a complete control valve and piston assembly as required for the operation of each individual breaker pole. Each insulator column consists of a large foot insulator upon which a double arcing-contact chamber is mounted, thus forming four arc breaks in series for each breaker phase. Inside the foot insulator are located two porcelain pressure tubes for supplying compressed air for the arc interruption and for the high-speed reclosing. Furthermore, to each insulator column is attached a movable isolating arm which is operated by means of rotating insulator and bevel gear drive from a separate piston on closing and normal tripping. Otherwise, the design of each insulator column is similar to that described on the 150-kv air-blast circuit breaker.

Arcing Chamber

The arcing chamber, mounted on top of the foot insulator, is illustrated in Figure 9. Two movable arcing contacts (1) and two stationary contacts (2) are mounted inside two porcelain insulators (3), which are surrounded by capacitance tubes (6) which control the potential

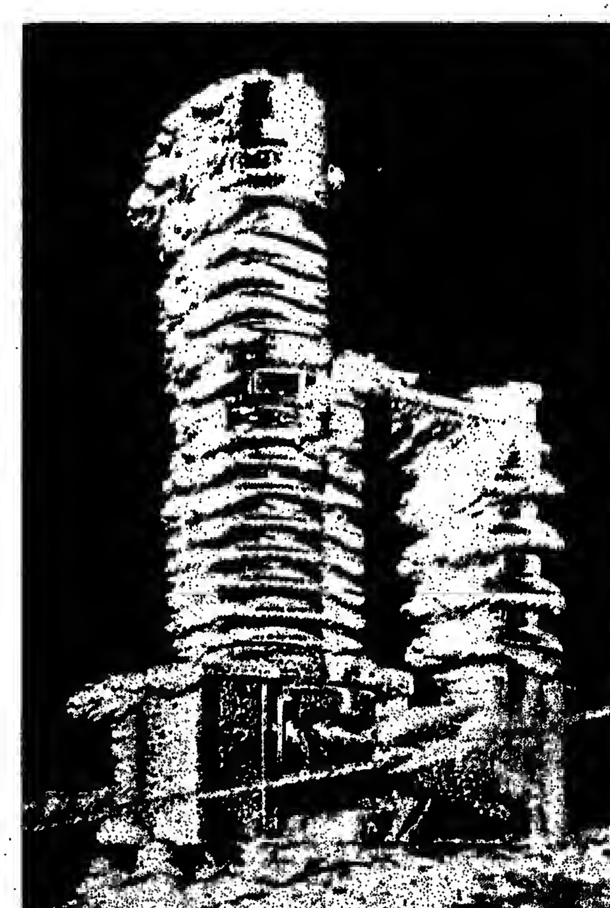

Figure 7. Air-blast circuit-breaker tests under heavy snow and ice formation

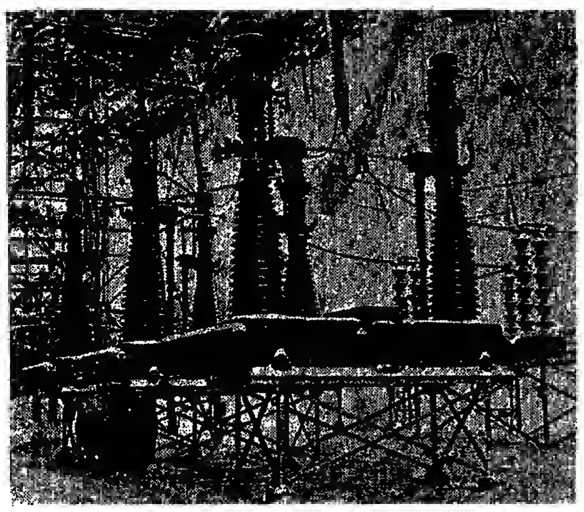

Figure 8. 220-kv air-blast circuit-breaker installation of The Shawinigan Water and Power Company

distribution between the individual arc breaks. The movable arcing contacts (1) are operated by means of a differential piston (7) and a lever arrangement (5); the latter assures simultaneous opening of the arcing contacts in series. In the intermediate piece (4) and also in the cast-iron piece (8) located at the top and at the bottom of the fixed arcing contacts, are the air-saving pistons (9), through which the compressed air in the arcing chamber escapes to atmosphere.

Operation

When the breaker is tripped by the opening of the main blast valve, compressed air is supplied through the large porcelain pressure tube (10) and ducts into the outside space of the lower and the upper arcing chambers and also through a duct into the intermediate piece (4) behind the differential piston (7). As soon as the air pressure is built up, this differential piston opens the arcing contacts by compressing the contact spring (11), and a stream of air flows with high velocity through the hollow arcing contacts and the air-saving pistons to atmosphere, which creates a rapid deionization of the arcing path and extinguishes the arc at next zero passing. At the same time part of the compressed air also flows through a special duct into the air-filling volume (12), which closes the air-saving pistons with a certain time delay, thus preventing a further escape of compressed air to the outside after the arc is extinguished. Closing the air-saving pistons, the compressed air re-establishes a high dielectric strength between the arcing contacts and, therefore, prevents reignition by the recovery voltage. At the same time, when compressed air is supplied to the arcing chambers, air is admitted also to the isolating contact piston which opens, with a short time delay, the movable isolating contact under no-load condition. After the complete opening of the isolating contacts, the main blast valve closes again, the arcing contacts close, and the air-saving pistons open again by spring pressure.

On tripping with automatic high-speed reclosing, only the arcing contacts open as previously described—but without opening the movable isolating contact. The arcing contacts are held open under air pressure until, by means of an auxiliary reclosing piston, air is admitted through the porcelain pressure tubes (13, 14) to the differential piston (7) and air-saving pistons (9), which simultaneously reclose the arcing contacts and open the air-saving pistons.

The following operations are carried out by the breaker protective and control devices:

By means of control relays, the breaker opens at the first tripping impulse, either single or three-phase, by the arcing contacts only, and recloses automatically upon an auxiliary reclosing relay impulse with a definite time-delay which can be adjusted to any value most suitable for the particular network. In case of a single-phase tripping by a permanent single-phase short-circuit, the breaker automatically recloses only once on the faulty phase, and immediately opens again by a final three-phase trip with the arcing and isolating contacts and stays open.

By means of a control and minimum air-pressure valve, it is assured that the breaker operates only if the available pressure of the compressed air, stored in the breaker tanks, is in the range of the admissible operation pressure. If on any reclosing the air pressure drops lower than normal, the reclosing function will not be carried through, and the breaker opens immediately by a three-phase final tripping, which will be initiated by means of a contact pressure gauge.

If while closing the breaker, an urgent trip is required, the air to the closing piston will be shut off immediately by means of an anti-pumping valve, which allows the tripping operation to be carried out without delay. By these various protective and control devices, it is assured that the breaker will always carry out the best suitable breaker function in connection with the particular operating condition.

Test Results

Field tests have been carried out with this installation where the principle functions were recorded simultaneously on all three breaker poles. Furthermore, by high-voltage short-circuit tests, the arc interrupting ability of the breaker was checked.

The upper oscillogram of Figure 10 illustrates the operation of this breaker in case of a permanent single-phase fault. Only the faulted phase opens initially, followed by automatic reclosure after a short time delay. Thereupon, the breaker immediately opens again, this time on all three phases, both arcing and isolating contacts, and remains opened. As shown on the lower oscillogram of Figure 10, a similar sequence is carried out for a permanent three-phase fault, except that in this case all three phases are opened on the first as well as on the second opening. The recorded potential of the travel indicator, which was attached to the rotating insulator of the movable isolating contact, shows that at the first interruption the movable isolating contact did not move, while at the second, final interruption this contact opened a few cycles after the arcing contacts parted.

From these oscillograms, Figure 10, the following breaker speeds were obtained: The breaker opening time until the arcing contacts part is $2^3/_4$ to 3 cycles. The automatic reclosing is delayed 23 cycles on single-phase and 16 cycles on three-phase circuit interruption, but this delay can be set to any desired value by means of a relay with an adjustable time-delay device. The movable isolating contact parts approximately four cycles after the opening of the arcing contacts.

For testing the arc-interrupting ability of this breaker, special short-circuit tests were carried out after the installation of this breaker was completed. At first, sev-

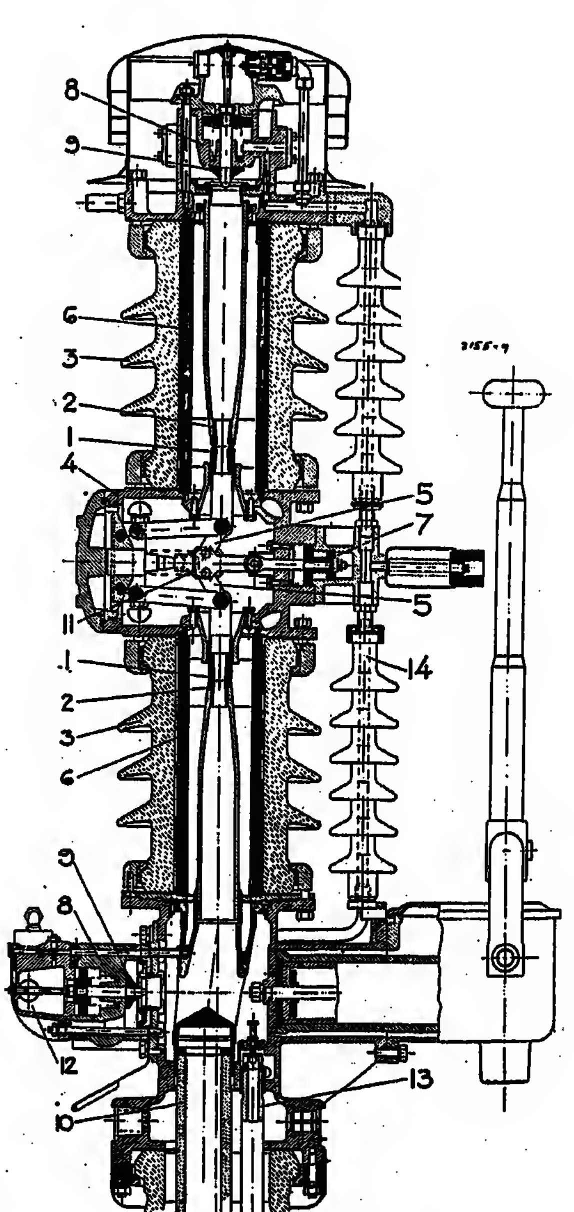

Figure 9. Arcing chamber of 220-kv air-blast circuit breaker

eral short-circuit tests (single-phase-to-ground) were carried out during which the line voltage was gradually raised from 220 kv to 260 kv. A fault current of approximately 280 to 330 amperes was interrupted without any difficulty, with an arcing time of less than one cycle.

In addition, similar short-circuit tests were carried out on the network with the power plants connected in parallel so as to obtain the maximum possible short-circuit capacity. With all these networks in parallel, the breaker interrupted a short circuit which was equal to a three-phase interrupting capacity of approximately 1,000,000 kva as illustrated in oscillogram Figure 11. The time required for the protective relay and the auxiliary contacts of the control circuit of the particular test arrangement was $3^1/_2$ cycles, the breaker opening time proper, including arcing time, was only $4^1/_2$ cycles, and the arcing time was less than one cycle.

Tests also were carried out with all networks in parallel where the breaker was switched twice into a short circuit by automatic high-speed reclosing with a time delay of only 17 cycles between the first and the second arc interruption, and twice a short-circuit current of 2,740/2,330 amperes at approximately 220 kv was interrupted satisfactorily with an arcing time at both interruptions of approximately one-half cycle. At the first interruption (which was equal to a three-phase interrupting capacity of approximately 1,000,000 kva) the arcing contacts opened without opening of the isolating contacts and, therefore, the full recovery voltage of approximately 220 kv had to be held between the small distance of the four arc breaks in series until the breaker automatically reclosed again.

All these tests, including the test with automatic reclosing, had so little influence on the large network system that these short circuits could hardly be noticed at the different power stations. Full stability of the networks was maintained through all these various short-circuit tests.

After several weeks of satisfactory operation with this breaker, a flashover took place inside the small porcelain pressure tube for automatic reclosing, and this put the breaker out of operation until the replacement of the damaged parts. It is assumed that probably condensation on the surface of this porcelain tube led to this flashover.

From the various tests and operating results we may conclude that these high-voltage air-blast breakers of 150 and 220 kv have shown the advantage of interrupting large short-circuit capacities with an air stream of high velocity and the facility of carrying out automatic high-speed single and three-phase reclosing.

Latest Design of an Air-Blast Circuit Breaker for Extremely High Voltage and High Interrupting Capacity

Based on experience from the high-voltage air-blast circuit breakers installed in various power plants and on extensive high-voltage arc-interrupting tests carried out in their large breaker test room,

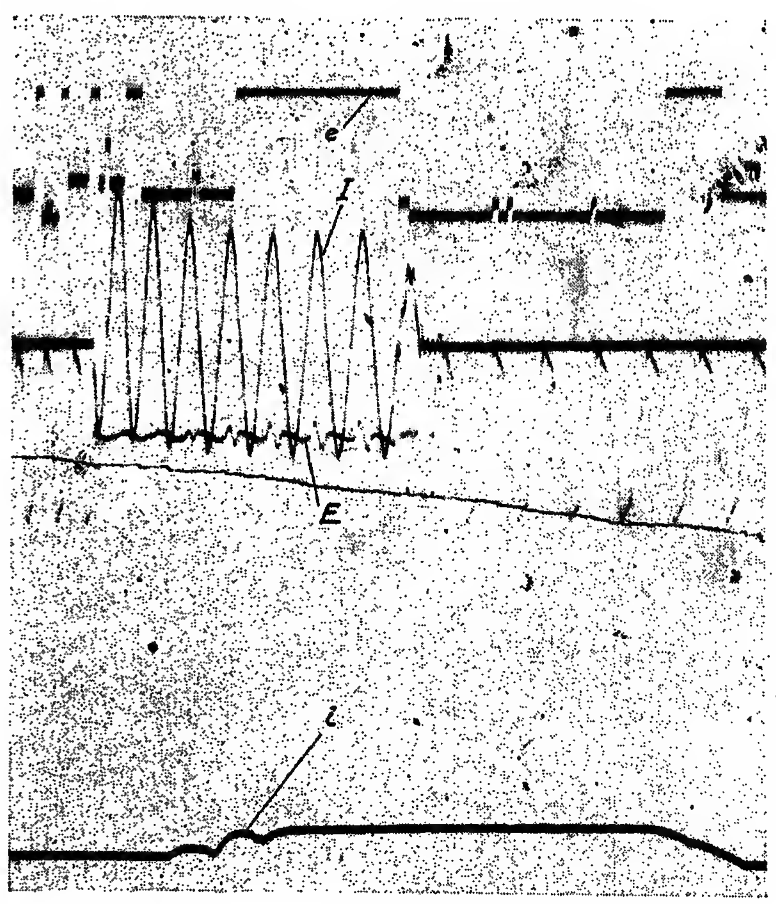

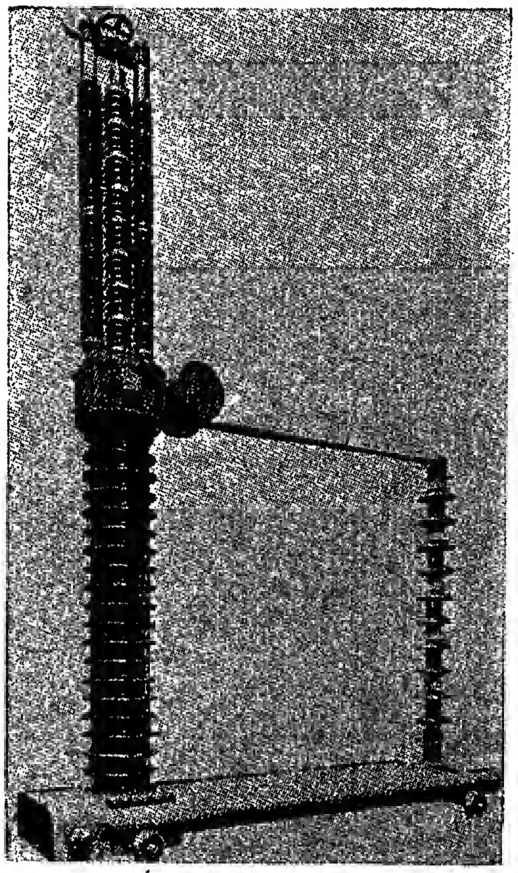

Figure 12. Air-blast circuit breaker for extremely high voltage and high interrupting capacity with eight arc breaks in series

Brown, Boveri and Company have developed, in addition to the previously described air-blast breakers of 150 and 220 kv, an air-blast breaker for extremely high voltage and high interrupting capacity as illustrated in Figure 12.

Construction

On this breaker eight potential-controlled arc breaks are connected in series, which open simultaneously by means of compressed air, and which provide an extremely short arc interruption. In regard to the various pistons and other breaker parts, the design in principle is

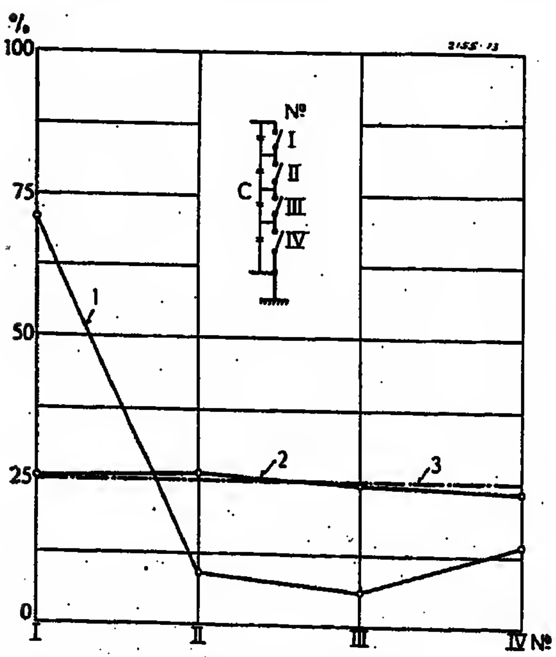

Figure 13. Potential distribution across four arc breaks in series

1. Without potential control
2. With potential control
3. Ideal distribution of potential

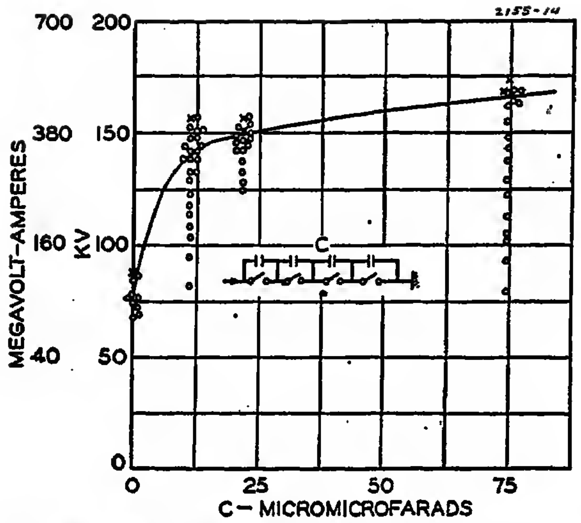

Figure 14. Increase in interrupting capacity and interrupting voltage in function of the control capacitance (C) across the four arc breaks in series

similar to the previously mentioned design but simplified to a large extent. The inspection of the individual arcing contacts can be carried out in a few minutes, since it only requires loosening the spindle of a press clamp for taking off the contacts for inspection.

This breaker is also equipped with high-speed reclosing devices, by means of which single and three-phase high-speed reclosing can be carried out as previously described.

Breaker Tests

The design of this breaker has resulted from the following tests, which give proof of the interrupting ability of this breaker. Extensive investigations have shown that the application of arcing chambers with potential-controlled multiple arc breaks presents the best solution for an air-blast breaker of extremely high voltage and high interrupting capacity, because it allows re-establishment of the dielectric strength across the arcing path at several breaks simultaneously, which extinguishes the arc very effectively. With the rise of the recovery voltage after arc interruption, the distribution of the voltage across the arc breaks is influenced by the charging currents of the capacitances across the breaks and to earth and, therefore, it is of paramount importance to assure an equal distribution of the voltage across the different arc breaks by means of connecting small capacities across the individual breaks.

The test results, as illustrated in Figure 13, show clearly that the highest voltage across one break (with four uncontrolled arc breaks in series) can rise as high as 71 per cent of the total voltage (as shown by curve 1) while, if all four arc breaks are potential-controlled by means of small capacitances, very equal potential distribution between the four arc breaks is attained (as shown by curve 2).

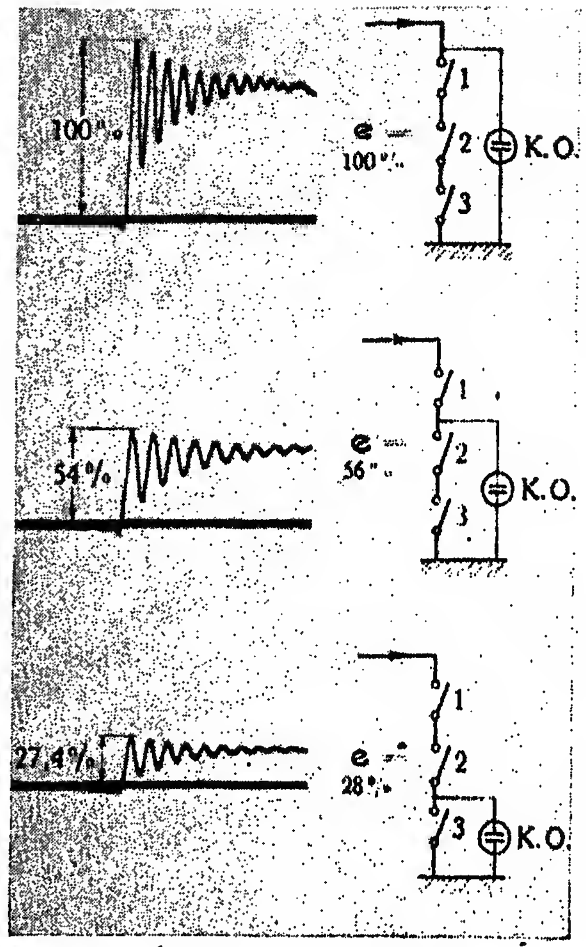

Figure 15. Oscillations of the recovery voltage across potential-controlled arc breaks during the breaker opening, recorded by cathode-ray oscillograph

e—Distribution of the potential during the oscillation
KO—Cathode-ray oscillograph

The test data, illustrated in Figure 14, show that the admissible interrupting capacity can be considerably increased with increasing values of the small capacitances which are connected between the individual arc breaks.

Furthermore, it has been proved by potential measurements carried out with a cathode-ray oscillograph (as illustrated in Figure 15) that during the opening of potential-controlled arcing contacts, the equal distribution of the potential is fully maintained and, therefore, the stresses on

Method for A-C Network Analysis Using Resistance Networks

WALDO E. ENNS
ASSOCIATE AIEE

THE mathematical solution of a-c network problems, of the type known as load distribution and voltage studies, is difficult and tedious for complex networks.

Where available, the a-c network analyzer or calculator affords the means of solving this type of problem, as well as many other problems, with good speed and accuracy.

It is the purpose of this paper to describe a new method of calculating a-c network problems and to illustrate with a practical example how a conventional d-c board, comprised of resistance circuit elements, may be used to solve load distribution and voltage studies. The writer has developed a new type of d-c board which would facilitate the use of the method described in this paper, but for the purpose of the present paper the application is limited to the existing types of d-c boards.

The scope of the present paper is restricted to the analysis of three-phase networks with balanced loading on the three phases. If the application to load distribution studies is understood, it is believed the use of the method for short-circuit studies will be evident. For short-circuit work this method can be used to advantage if the resistance of the network circuits is appreciable, so that a network setup representing reactance does not give sufficiently accurate results, and where a setup representing impedance is inaccurate because of differences in ratio of X to R for the circuits forming the network.

In contrast with the a-c network analyzer, inherently this method is not exact, but by successive approximations an exact solution may be obtained. Fortunately the first approximation is close enough for most practical problems, and rarely is it necessary to go further than the second approximation to obtain the desired accuracy. As the illustration shows, the method is simple and is quicker than other methods in analyzing complex networks with the exception of the a-c analyzer. Therefore the writer believes that the method of this paper as applied to a d-c board can be a useful tool for engineers in system planning work.

Simple computations are involved to obtain the voltage drop in a radial circuit with known line constants and loading, particularly when the circuit may be treated as a lumped impedance.

When a current with inphase component ($+I_p$) and quadrature component ($+I_q$) flows through a circuit of resistance R and reactance X, the inphase component of voltage drop is $V_p=I_pR-I_qX$, and the quadrature component is $V_q=I_qR+I_pX$. The components of current and voltage drop refer to the same reference axis.

If a current equal to I_p is passed through a resistance equal to R, the voltage drop I_pR can be measured. If a current equal to I_q is passed through a resistance equal to X, the voltage drop I_qX can be measured. Likewise passing I_p through X and I_q through R, I_pX and I_qR can be measured, and, by using the equation for V_p and V_q, the values of the components of voltage drop are obtained. These simple equations are the basis for the method of this paper.

When these equations are applied to network analysis, it is necessary to choose a reference voltage at one point in the network to which all voltage and current components refer for phase position. For simplicity, a network with balanced loading, is analyzed on a single-phase-to-neutral basis. To obtain a correct solution, it is necessary to satisfy Kirchhoff's laws for a-c network, which may be expressed as follows:

(*a*). The algebraic sum of the components of current toward any junction point is zero.

(*b*). The algebraic sum of the components of voltage around any closed path in the network is zero.

Paper 42-149, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 1, 1942; made available for printing July 17, 1942.

WALDO E. ENNS is electrical engineer with Portland General Electric Company, Portland, Oreg.

---

each individual arc break are in proportional relation to the total interrupting capacity.

As a result of these tests, a definite conclusion can be drawn regarding the performance of the breaker under its rated interrupting capacity by applying the proportional interrupting capacity on one break only. This contention has been proved by the test data shown in Figure 16 where it is shown that the maximum admissible interrupting capacity increases practically in proportion to the number of potential-controlled arc breaks. For high-voltage circuit breakers, relatively high interrupting capacities are required which far exceed the maximum short-circuit capacity available at the present test plants. It is, therefore, of great importance to note from these tests that a breaker with potential-controlled multiple arc breaks can be tested accurately by interrupting the partial load with one break only, which enables one to judge what the performance of this breaker would be under full rated interrupting capacity.

Therefore, judging from these test results, it should be possible today to design, for example, an air-blast circuit breaker for a voltage as high as 500 kv without requiring a test plant of such a high voltage.

Conclusion

The construction of the various high-voltage air-blast breakers and the operating and test data show that today this type of breaker is developed to such an extent that very valuable operating results can be obtained. In summarizing, we can conclude that, besides lowering the maintenance cost, the stability of the transmission systems can further be increased because of the breaker interrupting speed and the possibility of carrying out high-speed reclosing.

In the practical network problem which follows, the compliance with Kirchhoff's laws is illustrated; however, it should be noted that in this particular problem, the transformers involved have the same ratio, so that there is no boost or buck in the voltage in any closed path in the network. The method of treating boost or buck in a closed path will be discussed later in the paper.

Application of Method to Network Problem

Following is an outline of procedure for making a load distribution and voltage study for a complex network with the aid of a conventional d-c calculating board and illustrated with a practical problem. The network shown on Figure 1 consists of 116 miles of 115-kv and 395 miles of 57-kv three-phase transmission circuits. The actual systems involved have more circuit mileage which is radial with respect to the network shown and so is not included in the problem. The estimated loads and generation for the December 1942 peak are used in the study with a total megawatt input in excess of 200 megawatts; however due to simplification by subtracting local load from generation, the net total input is reduced to 157 megawatts for the purpose of the network problem.

1. One-Line Diagram of Network

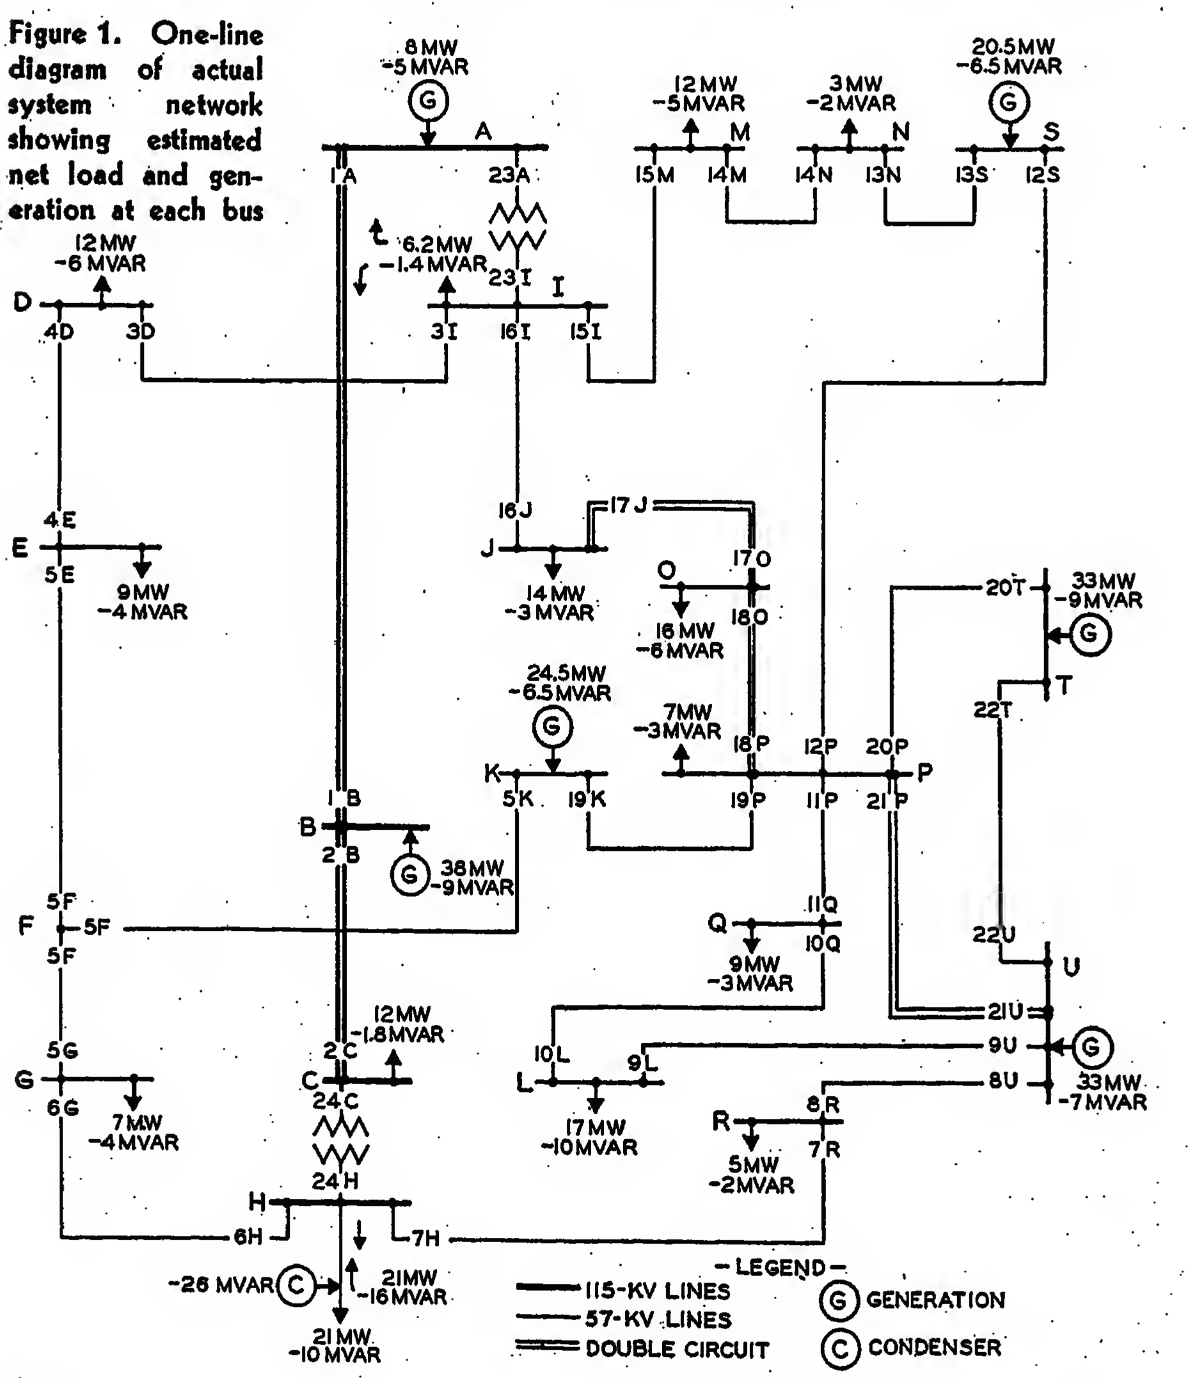
Figure 1 is the one-line diagram of the network simplified somewhat from the actual system to eliminate radial lines which are set up as loads at the network busses.

The method of lettering busses and numbering circuits as shown on Figure 1 is a satisfactory means of simplifying the recording of data and lessening the chance of making errors in the direction of current flow or voltage drop in the network circuits.

2. Circuit Constants

The circuit constants R, X, B, and G are required as shown in Table I. The constants are on a common phase voltage base of 57 kv in the problem but may be on any suitable common voltage or kilovolt-ampere base, if the currents are on the same base. (Where parallel circuits interconnect busses, the constants of the equivalent circuit will simplify the board setup, and if the parallel circuits have ratios of X/R which are substantially different, it is essential that the equivalent circuit be used, otherwise additional successive approximations may be necessary to obtain the desired accuracy in the study.)

Figure 1. One-line diagram of actual system network showing estimated net load and generation at each bus



3. Loads and Estimated Generation

As shown in Table II and on Figure 1, the real and reactive power should be tabulated at all load busses. Wherever generator or synchronous condenser inputs to the network occur at load busses, the input and load real and reactive power should be combined to give the net load or generation at that point. It should be noted that in Table II the leading reactive power at load busses is moved into the generation column, so that all reactive will be at the same algebraic sign, negative.

In the problem the voltage at the electrical load center of the system is 57.7 kv, so that the reference voltage to neutral is chosen as $33.33+j0$ kv. Bus P on Figure 1 is the main receiving station for the generating plants and would be expected to have a voltage phase angle approximately that of the major loads, so that it is chosen as the reference bus. Therefore all voltage and current components for the network will refer to this same reference voltage, $E_n'=33.33+j0$ kv. Since the components of voltage to neutrals E_p and E_q are unknown at the other load busses of the network, E_n' is assumed to exist at all load busses, so that the current components I_p and I_q can be computed as shown in Table II. At generator busses remote from the load center, the values of I_p and I_q are computed on the basis of estimated inputs to the network and estimated voltages, but, as shown in Table II, these input currents in total must equal the sum of the load currents.

4. Setup on D-C Board to Determine Voltage Drops

The resistance units of the d-c board are now set up to simulate the resistance or R network on the basis of the R values of Table I. The positive bus of the board is connected through a rheostat to a common bus from which all I_p input busses are fed through individual rheostats. The negative bus of the board is connected to a common bus to which all output I_p currents flow from their respective load busses of the network through rheostats. The board is then ready for adjustment to set up I_p input and output currents in some convenient proportion to the actual I_p currents shown in Table II. It is important to es-

*Leading or + megavars at loads is shown as − megavars generation.

At loads $I_p = 1{,}000 \times \text{mw}/57.7\sqrt{3} = 10 \times \text{mw}$.

At loads $I_q = 1{,}000 \times \text{mvar}/57.7\sqrt{3} = 10 \times \text{mvar}$.

For input or generation to network, estimated bus voltages are used to compute I_p and I_q from the estimated megawatts and megavars input, but it is essential for the d-c board setup that the totals of I_p and I_q input are equal to the totals supplied to loads.

tablish a small current through the board at the start by adjusting the rheostat between the positive bus and the common input bus to have a high value of resistance as compared to the network resistances, so that it will act as a current limiter or, in effect, help maintain an almost constant total current to the network. Actually it would be better if a constant current supply could be used, but the current limiting rheostat referred to is satisfactory for the purpose. After the I_p currents into the network at generator busses and out of the network at load busses have been adjusted, by means of their respective generator and load rheostats, to be proportional to the desired values of Table II, the resistance of the current-limiting rheostat may be reduced to the point where a substantial current flows through the network. With more current it is then possible to adjust generator and load rheostats slightly to give the values of currents, still proportional to those of Table II, which are to be the basis for the readings of $I_{pr}R$ voltage differences between bus P and all other busses of the network. For example $(I_{pr}R)$ measured from bus A to bus P multiplied by the constant for the d-c board for this set of readings is equal to −635 volts and is recorded in Table III. The board constant depends on the proportionality factors between board resistances and actual network resistances, between board currents and actual network currents, and also on the type of scale calibration on the voltmeter, so that the data for this study are simplified by the elimination of the board constants from the tabulations.

In a similar manner the circuit resistance units are adjusted to simulate the reactance or X network on the basis of the X values of Table I. Again by use of the current-limiting rheostat the board current is reduced, and some minor adjustments in generator I_p and load I_p currents will make them proportional to those of Table II, and the same procedure as described for obtaining $I_{pr}R$ voltage readings is followed to obtain $I_{px}X$ voltage differences between all busses and reference bus P. These readings are in Table III.

In like manner $(-I_{qx}X)$ readings can be obtained. However it will be noted in this problem, and in most problems of

this type, there is some modification of the connections between the network and the input and output busses for the I_q current setup due to the fact that loads with leading or positive reactive power are set up as generators of negative reactive power. In this problem this change is necessary for the connections to busses *H* and *I*. The reason why the voltage differences between all busses and reference bus *P* are designated as $-I_{qx}X$ voltages is that $+I_q$ currents are made to flow in at the input bus and out at the output bus, whereas actually they should be set up as $-I_q$ currents to conform to the signs of Table II.

Similarly by using the *R* network and $+I_q$ currents the $-I_{qr}R$ voltage differences are obtained.

Referring again to Table III, the inphase voltage difference between all busses and the reference bus *P* is $V_p = I_{pr}R - I_{qx}X$ for each case, and the quadrature component of voltage difference is $V_q = I_{px}X + I_{qr}R$.

5. Computation of Components of Current Flowing in Each Circuit of the Network

Referring to Table IV, the voltage differences between the bus terminals of each circuit are derived from the V_p and V_q values of Table III. For example, V_p for circuit 1*BA* is obtained by subtracting V_p for *AP* from V_p for *BP* in Table III which gives $+460-230=+230$ volts. In like manner, V_p and V_q for all circuits of the network are derived.

Next, as shown in Table IV, the equations $I_p = GV_p + BV_q$ and $I_q = GV_q - BV_p$ are used to determine the inphase and quadrature components of current which must flow in each of the circuits of the actual a-c network to give the V_p and V_q voltage differences derived from the d-c board setups. The values of conductance *G* and susceptance *B* are those shown in Table I for each circuit of the network.

6. Computation of Bus Voltages and Real and Reactive Power

As noted at the start of the solution, the reference bus *P* was established as having a voltage to neutral of $33.33+j0$ kv. From Table III the voltage differences to neutral of components V_p and V_q were obtained between all busses and bus *P*. To determine the voltage to neutral at every other bus, these voltage differences are added algebraically to the reference voltage. This is done, and the results are tabulated as E_p and E_q in Table V.

The current components I_p and I_q in Table V are not exactly the same as the current components given in Table II which were the basis of the d-c board setup, but instead are the algebraic sum of the components of current away from each generator bus and toward each load bus, so that Kirchhoff's law will be satisfied. For example at generator bus *A* the actual input current is equal to the sum of currents 1*AB* and 23*AI* expressed in their components. From Table IV, I_p for 1*AB* is −107.0 amperes, and I_p for 23*AI* is +187.6 amperes, and the algebraic sum is +80.6 amperes as shown in Table V. All I_p and I_q current components given in Table V are obtained in this manner.

The computations of real and reactive power in megawatts and megavars are obtained by using equations megawatts = $0.003\,(E_pI_p + E_qI_q)$ and megavars = $0.003\,(E_pI_q - E_qI_p)$ as shown in Table V.

Table VI is added to show the computation of the phase voltages at all busses and to give a direct comparison of the derived values of real and reactive power, which completely satisfy the current distribution of Tables IV and V and the voltages of Tables V and VI, with the problem setup values of Table II.

The comparison shows that for all

* Bus *F* was not set up as a load so that the real and reactive power at *F* may be moved to busses *K*, *E*, and *G* in amounts proportional to the admittance of the circuits between *F* and its adjoining busses. This is done in Table VI.

practical purposes the first solution is adequate for the analysis of this network problem. The greatest difference between derived and setup values of real and reactive power occurs at load buses O and P which are connected by a very low impedance circuit of $(1+j1.5)$ ohms. If the two loads are added together, the derived total is $23.07-j10.93$ megavolt-amperes as compared to a setup total of $23.0-j9.0$ so that the effect of the differences of the two loads would be negligible in the network. However, in case greater accuracy is desired, it is possible to repeat the solution with corrected values of I_p and I_q to obtain derived values of real and reactive power which check almost exactly with the setup values. The method of correcting the I_p and I_q currents is described in the section which follows, but the solution is not repeated, because it would add nothing of value to the paper.

Procedure for Second Solution

Unless a particularly accurate second solution were desired, the values of real and reactive power tabulated in Table VI would be compared, and the difference in the derived and setup values would form the basis for estimating the changes in I_p and I_q which would result in improved accuracy. However, a more exact procedure is given in the following example.

At bus O from Table II the load setup was $16.0-j6.0$ megavolt-amperes instead of the derived value of $13.02-j5.05$ megavolt-amperes, which satisfied the current distribution and voltages of the first solution. The voltage components for bus O from Table V are $E_p=+32.96$ and $E_q=-0.39$, and since these voltage components will not change appreciably in the second solution, the values of I_p and I_q can be computed with the equations:

$$I_p=(E_pP-E_qQ)\ 1{,}000/(E_p^2+E_q^2)3$$

$$I_q=(E_qP+E_pQ)\ 1{,}000/(E_p^2+E_q^2)3$$

In these equations P and Q are in megawatts and megavars and E_p and E_q are in kilovolts to neutral.

Whence $I_p=160.6$ amperes and $I_q=-62.5$ amperes.

In Table II the current components to the load at bus O were set up $I_p=160$ and $I_q=-60$; however in Table V the derived values were $I_p=130.9$ and $I_q=-52.6$. This difference is due to variations in X/R ratios in the circuits of the network, and about the same difference would occur in the second solution. Therefore, a corrected value of $I_p=160.6+(160-130.9)=189.7$ would be used for the second solution. The corrected value of $I_q=-62.5+(-60+52.6)=-69.9$ would also be used for the second solution. This same procedure could be followed at all other busses of the network to obtain corrected values for a second and more accurate solution to the problem.

Application of Superposed Method of Setup to the D-C Board

In cases where the d-c board does not have a sufficient number of rheostats to set up all of the generators and loads, it is possible to set up any proportion of the generators and loads at one time, so long as the total input current of the several generators adds up to the total output current to the several loads. The same voltage measurements from all busses to the reference bus would be required for each such setup, and the sum of the voltages thus obtained would give the same result as though all generators and loads had been included in one setup. This method requires additional readings, but because of the smaller number of generator and load rheostats which must be adjusted to obtain correct input and load currents, the current adjustment is simplified.

Use of Method With D-C Board With Fixed Resistors

If a d-c board is of the fixed resistor type, it may be possible to adapt it for use with this method, provided it has enough rheostats to use for generator and load-current adjustment.

Most networks have many circuits with X/R ratio almost equal. If the board is set up to simulate X only, this network is already available. Assume that 75 per cent of the circuits of a particular network have an X/R ratio of 2/1 or approximately so, and that only 25 per cent vary much from this ratio. If a means is provided for changing this 25 per cent to have the 2/1 ratio for setups requiring the R network, then the method may be used. The board constant for the R network would then be one-half that of the X network.

Use of Method Where Line Capacitance Must Be Considered

In the network problem of this paper, the effect of shunt capacitance of the lines was neglected, because the amount of leading megavars of the circuits would not change the solution appreciably. However, if it is necessary to consider line capacitance, it is suggested that the capacitance + megavars for each line be computed on the basis of estimated voltages at the start of the problem. In the usual manner one half of the megavars of all lines terminating at a bus would be allocated at that bus, and an adjustment in net load or generator megavars at that bus would be made to obtain the corrected megavars from which the I_q component of current would be computed.

Setup of Transformers With Different Ratios in a Loop Circuit

In a paper presented before the Portland section of the AIEE, the writer included an example to show how a series boost or buck may be provided from a separate source of direct current inserted at the point of boost or buck in the loop circuit, but rather than lengthen this paper, the method will be indicated only.

In most networks the quadrature component of voltage with respect to the reference voltage is small as compared to the inphase component, so that the effect of any normal boost or buck on the E_q component is negligible. However, if one transformer has a ten per cent boost or buck with respect to other transformers operating in closed paths with this transformer of different ratio, then a separate d-c source should be inserted at the point of boost or buck in the X network setup with I_q current flowing. This gives the desired effect to the inphase voltage readings for V_p. In the problem of this paper the voltage to neutral is approximately 33 kv at bus I, so if a boost of ten per cent were required in transformers $23AI$, the series potential required would be 3,300 divided by the board constant. It would be inserted between bus A and the resistance unit representing X of the transformers $23AI$. If the potential source had appreciable internal resistance, the $23AI$ unit setting would be reduced by this amount. As noted before, it would be used only in the setup for reading $I_{qx}X$ voltage differences.

Setup Using Ammeter Instead of Voltmeter on D-C Board

Although the measurement of the $I_{pr}R$, $I_{px}X$, $I_{qr}R$, and $I_{qx}X$ voltages between all busses and the reference bus is recommended, it is possible to read current distribution in each of the four network setups on the d-c board and compute the voltage differences for all circuits in each setup, and obtain the same results.

Conclusions

The scope of this paper has been quite limited with respect to the broad field of a-c network analysis, but it is believed that the network problem and the discussion show how this new method can be applied with the aid of a conventional d-c board to solve complex problems of load distribution and voltage conditions for a-c networks in a relatively simple manner and with good speed.

In the application of the method to the conventional d-c board, it probably will become apparent that various combinations of resistance networks could be set up simultaneously, which, together with proper metering arrangements could be used to reduce the analysis from four board setups to one—thus eliminating the greater part of the computation work. Patent application has been made for the method as applied to such simplifying resistance network combinations.

As an indication of the time required for a study of this type, the writer unaided set up the board and took the four sets of readings required in eight hours. An additional six hours was required to make all of the computations and tabulate the results. If the outline of procedure given in the paper is followed, it is believed that other engineers will find the method to be a useful tool in their system planning work.

Design, Manufacture, and Installation of 120-Kv Oil-Filled Cables in Canada

D. M. FARNHAM
MEMBER AIEE

O. W. TITUS
MEMBER AIEE

Synopsis: This paper describes the 120-kv oil-filled cable system of the Montreal Light, Heat, and Power Consolidated, installed during 1941 and in present operation as a link in a large interconnection scheme.

The paper describes the functions of the various sections of the system and the reasons for the choice of this method of effecting the interconnection. The steps required in designing the cable system are outlined and the general principles governing each such step discussed.

A short section deals with manufacture followed by a section covering the organization required for installation and the methods followed. The final section deals with operating practice, especially the basis of loading.

System

THE 120-kv oil-filled cable system of the Montreal Light, Heat, and Power Consolidated as at present installed may properly be divided into the following sections: (Figure 1):

1. Station *A* to station *B*—two circuits
2. Station *B* transformer cables—two circuits
3. Station *B* to station C—one circuit

The first and third parts are much the most important in size, but the second part, while relatively small, presents a use of high-voltage cable of particular interest to transformer station engineers.

In sequence of installation one circuit plus a spare phase of section 1 were purchased and installed initially on one contract, the remaining two phases of that section and all of sections 3 on a second contract. Section 2 was on a third contract but was installed during the same period as section 3.

Section 1 (known as circuits *A* and *B*), takes power from the 110-kv bus of station *A* directly to the new station *B* for service to an important business and industrial section of the city. Station *B* departs from the general substation scheme of the utility, in that it is not part of their 60-kv ring system, but is fed practically direct from the generating source, station *A* acting as a switching station. The present availability of underground cable suitable for 110-kv operation permitted locating the new station at its proper load center without double transformation or further loading or reinforcement of the already busy 60-kv ring. It relieves the ring as well and permits further load growth with existing facilities.

Section 2 takes power from the 110-kv bus of station *B* to the transformers, at present two, with provision for an ultimate of four. Underground feed was chosen as providing a substantial saving in steel structure, greater compactness and better appearance and much less exposed high-voltage circuit. Also when combined with underground cable on the low-voltage side, it permits a virtually "dead-front" station, excepting under the easily isolated and relatively small high-voltage bus section which lies in one 25-foot-wide strip along the south side of the station property.

Section 3 (known as circuit *C*), takes power from the 110-kv bus of station *B* to station *C* and acts in combination with circuits *A* and *B* as a direct tie between the Beauharnois system of the Montreal Light, Heat, and Power Consolidated supplying station *A* and the system of the Shawinigan Water and Power Company, and through it to the Saguenay Power Company system. It also will serve as an additional circuit to station *B*.

This direct tie between the first two systems was made in order to place the entire generating capacities of these three large companies on one interconnection, from which power for wartime industrial requirements could be drawn by the industry most vitally needing it.

The Shawinigan and Saguenay systems were already connected together by high-voltage transmission lines with ample capacity to carry any loads expected. Between the Beauharnois and Shawinigan systems the connection consisted of a 60-kv double ring tied through transformers to the 110-kv system of the Shawinigan Company and through other transformers to the 110-kv Beauharnois system (Figure 2). Thus the power that could be transferred from the Beauharnois system to the interconnection of the Shawinigan and Saguenay systems was limited by the Montreal Light, Heat, and Power Consolidated 60-kv ring and transformer capacity which was partially used by the primary power requirements of the Montreal Light, Heat, and Power Consolidated system.

The original suggestion was to construct an overhead 110-kv tie around the metropolitan area of Montreal between the Beauharnois system and the Shawinigan system. This would have involved the building of about 15 miles of steel tower transmission line over territory where the right-of-way problems were difficult and uncertain, especially as to the cost and time required to negotiate.

The second suggestion was to extend the 120-kv oil-filled cable system then nearing completion under the first contract mentioned above (circuit *A* of section 1) to tie with the 110-kv transmission system of the Shawinigan Company. This required the adding of two phases between stations *A* and *B*, which combined with the spare phase already installed for circuit *A* to become circuit *B* plus about five miles of additional cable circuit across the metropolitan area.

The cable tie was selected on the basis of several factors, most important among which were:

Initial cost
Time required
Stability
Freedom from lightning troubles
Present and future public reaction

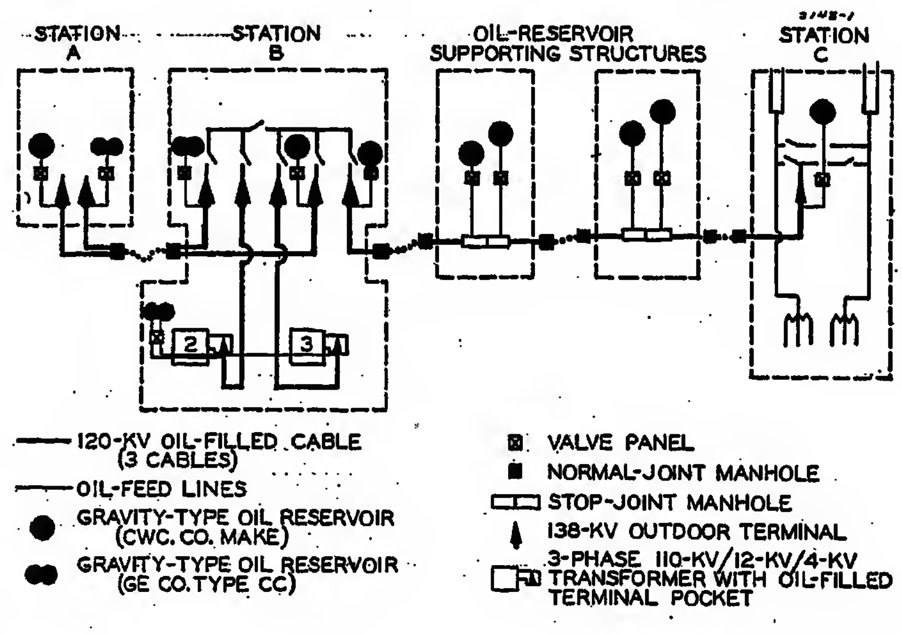

Figure 1. Single-line diagram of system

Paper 42-148, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9-11, 1942. Manuscript submitted June 1, 1942; made available for printing July 8, 1942.

D. M. FARNHAM is assistant distribution engineer, Montreal Light, Heat, and Power Consolidated, Montreal, Quebec, Canada. O. W. TITUS is chief engineer, Canada Wire and Cable Company, Ltd., Leaside, Ontario, Canada.

6. Thickness of Sheath

After consultation with several authorities on stresses permissible in lead cable sheaths (a lead sheath containing approximately 0.06 per cent of copper was used), it was decided not to exceed a fiber stress in the sheath under static conditions of 125 pound per square inch.

The elevation of the oil reservoirs having been determined by considerations dealt with in the next part of this paper, the actual cable profile showed that internal oil pressures would be such that in some sections the cable sheaths would require to be increased. Sheath thicknesses for the 300,000-circular-mil cable varied from 0.125 inch to 0.156 inch and for the 650,000-circular-mil cable from 0.133 inch to 0.164 inch.

Figure 3 illustrates the cable construction.

7. Spacing Between Oil-Feed Points

The making of this decision involved some of the most extensive and interesting calculations of the entire design. The governing consideration is that on dropping load the cable cools and demands oil. During this cooling period a "transient" drop in oil pressure occurs at all points away from the oil supply and is greatest at the point most remote from supply, that is, halfway between feed points.

It is a standard of oil-filled cable system design that no point in the system shall fall below one pound per square inch above atmospheric pressure (in order to prevent ingress of air or moisture if the cable sheath be punctured). When the "transient" drop for unit distance under worst conditions is known and correlated with the pressure head permissible without overstressing the sheath (which sets the reservoir elevation or pressure), the maximum feeding distance is determined.

Steps in determining the "transient" are, in brief:[5]

(*a*). Determination of the thermal capacitances of the cable elements.

(*b*). Determination of the thermal resistances of the cable elements.

(*c*). Determination of the rate of cooling of each element from representative initial conditions such as full load, 75 per cent, 50 per cent, and 25 per cent loads at minimum earth ambients (assumed 0 degrees centigrade).

(*d*). Determination of oil-volume demand (proportional to first power of *c* above).

(*e*). Determination of oil temperatures at each instant and the viscosities of the oil at these temperatures.

(*f*). Determination from *d*, *e*, and fluid friction coefficient of oil channel, of the transient drop for a unit length at successive intervals for each initial loading condition.

Curves of pressure drop against time for dropping from various loads are shown in Figure 4. It will be observed that maximum drop occurs as late as three minutes after zero time.

Figure 5 of maximum pressure drop versus initial loads is then drawn from the maximum values obtained from the curves of Figure 4. It will be seen that worst conditions obtain in dropping about one-half to two-thirds full load during winter conditions.

As pressure heads in the order of 15 pounds per square inch are quite safe for normal lead sheaths of these diameters, it was felt that there were ample margins of safety in using feeding distance of up to 5,000 feet, that is, spacing between feed points of 10,000 feet. This proved suitable for conditions in the field, as station *B* is 8,800 circuit feet from section *A*, and there were suitable locations for oil-reservoir structures at approximately 9,000 feet and 18,000 feet from station *B*, and station *C* lies about 27,000 feet from station *B*.

8. Type of Oil Feed

Two general types of oil reservoirs are available to the design engineer.

(*a*). *Gravity type* in which the requisite pressure to reach all the system is obtained by locating the reservoir at an elevation determined by the cable profile and the feeding distance, as the oil in the reservoir is at atmospheric pressure (plus the slight back pressure of the cell walls). In practically all cases, excepting for unusual profiles, gravity reservoirs must be mounted above the ground surface and cannot be used unless above-surface space is available at the feed points.

(*b*). *Balanced Pressure type* in which the requisite pressure is obtained by gas confined within the reservoir shell (plus auxiliary gas tanks if necessary) and external to the oil cells. The use of such reservoirs requires careful gas volume calculations and adjustments and introduces certain extra operating and maintenance items. However, they can be mounted in manholes and must be used when above-surface reservoir space is not available.

In the systems covered by this paper above-surface space fortunately was available adjacent to desired feeding points. The gravity type of oil feed was chosen.

Figure 6 illustrates one type of gravity-type reservoir employed. This reservoir is a new development not previously used. It was designed and manufactured in Canada and has particularly low dead oil volume and cell back pressure. It is of 36 gallons (U. S.) capacity between plus 0.5 pound per square inch and minus 0.1

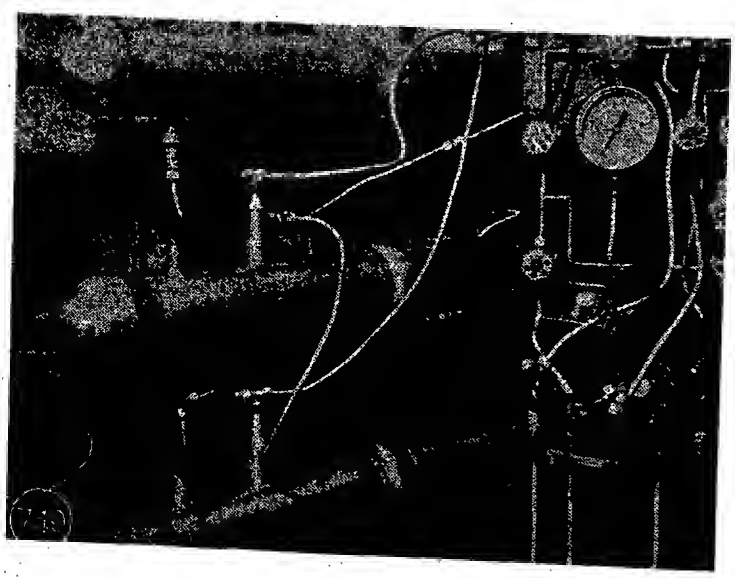

Figure 7 (left). Gang-treating normal joints

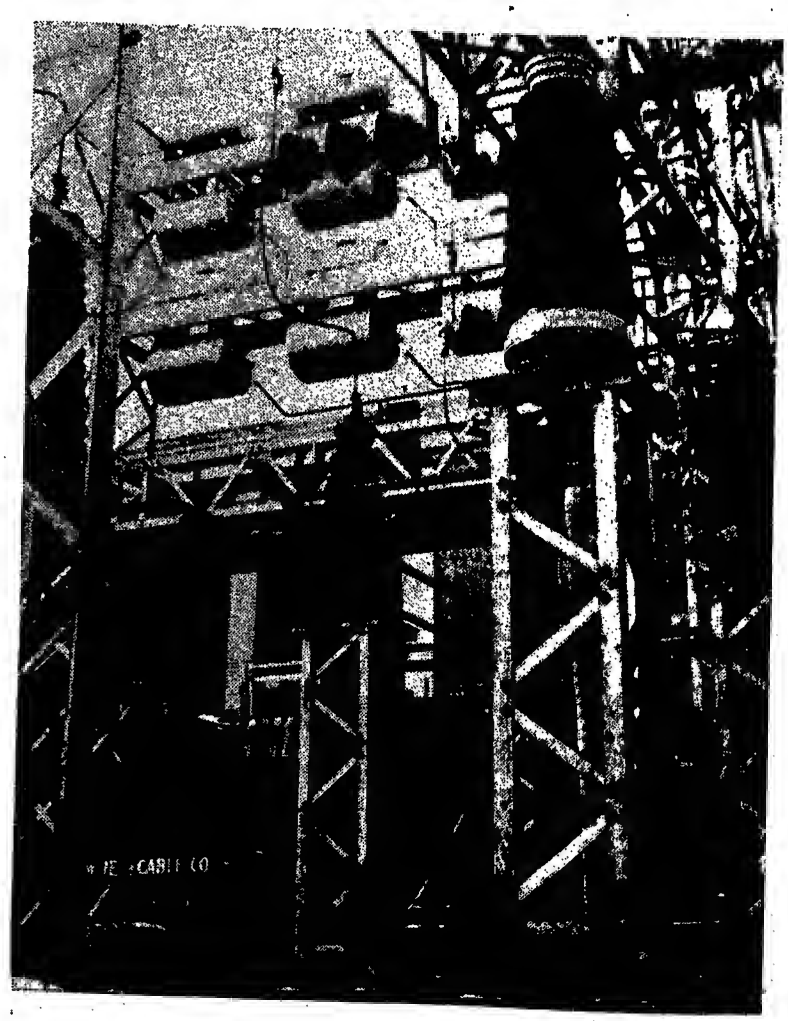

Figure 8 (right). Station *B* potheads, oil reservoirs, and oil pipe lines

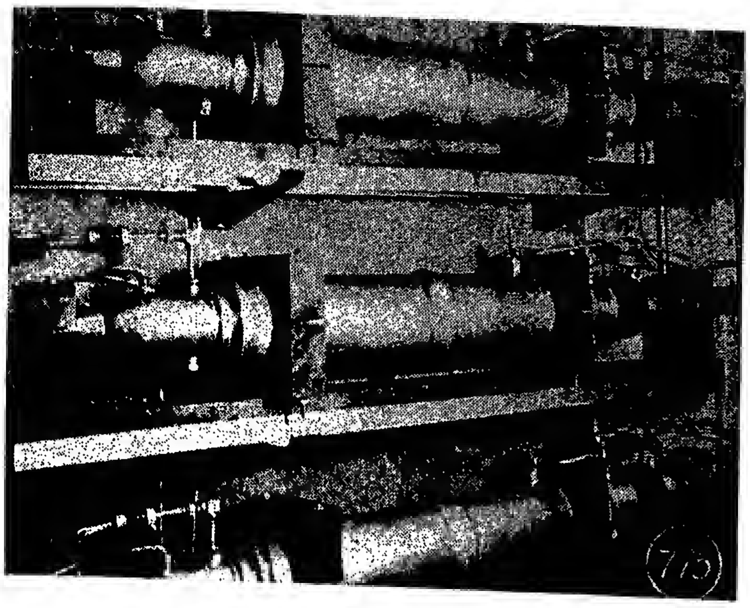

Figure 9 (left). Stop joints, cradles, and piping (manhole 1040)

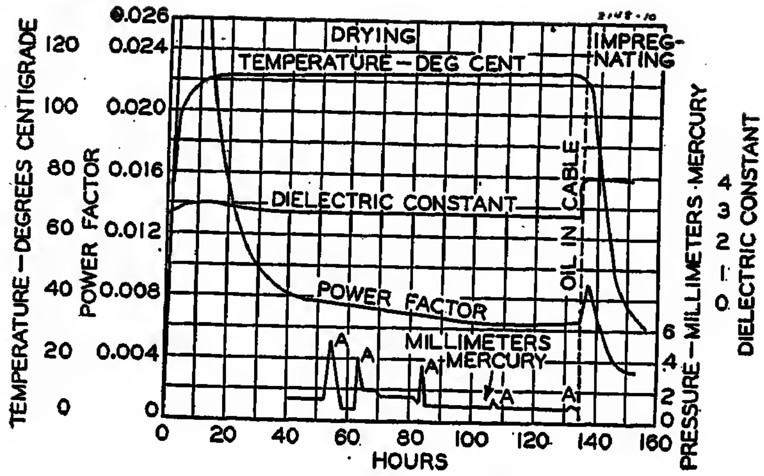

Figure 10 (right). Evacuation and impregnation curves

pound per square inch cell pressures. The smaller tank acts as a riser for the gauge oil to permit keeping the oil cells of the main reservoir completely immersed at all times and out of contact with the air.

The low dead oil capacity is due to both sides of each cell nesting together. Tests of numerous individual cells gave a life of 1,500 cycles not to failure. Each cycle was the full yearly travel of the cell. The daily working would not be 25 per cent of this amount.

9. Normal Joint

Normal joint design is similar to that for high-voltage solid-type cable with provision by means of hollow cores, three way valves, and oil ports for flushing out of any cable oil overheated during the soldering operations and establishing a permanent oil channel through the connector for servicing cable sections lying beyond the joint. Sharp depressions in the connector body which might set up high electric stresses were filled in by lead discs cast on the job and dressed carefully to the contour of the adjacent surface.

The initial joints were imported from the United States. The later ones were made in Canada (see Figure 7). Both were of designs in common use in the United States.

10. Pothead Design

Pothead design requires provision for relieving end stresses such as by combination of stress cones and barrier tubes, access to the cable core for oil to enter and leave the cable, and means of shutting off the core of the cable from the pothead body while erecting, evacuating, and filling the pothead. Two designs in common use in the United States were employed. On account of the low temperatures to be anticipated in the district, extra large oil ports were provided in the connector fittings. Here again part were manufactured in United States, but the later and larger quantities were made in Canada (see Figure 8).

11. Stop Joints

Stop joints serve two purposes. One is to segregate the oil systems where contours require that one section, having for example a higher elevation than an adjoining section, needs its reservoirs mounted at a higher elevation. At the same time troubles in one section are not communicated to adjacent sections. The second main function is that these joints act as a feed point and provide means of ingress and egress for the oil in the cable core. In the design utilized the stop joint essentially is a pair of cable terminals placed end to end, joined by a suitable connector block, and enclosed within a copper sleeve. Reinforcement insulation and enclosure within oil permits these terminals to be quite compact and readily mounted within a manhole. These were imported from United States.

Oil entry fittings are provided at each end of the joint to provide independent oil feeds to the cable sections on both sides of the joint. Impregnated wooden cradles support these long joints (see Figure 9).

12. Size of Oil-Feed Pipe Lines

Due to the very low temperatures likely to be encountered in the locality, and acting on the recommendation of Herman Halperin, it was decided to make exposed oil-feed lines from the reservoirs 1.5-inch copper pipe (Figure 8). Those parts of the oil-feed lines to the stop joints between the valve panel (where it is close to the foot of the structure) (Figure 9) and the stop joints were of one-inch soft copper pipe pulled into fiber ducts.

Manufacture

The manufacture of these oil-filled cables, although only slightly more complex, was different from the manufacture of solid-type cables, chiefly in that drying and impregnating of the paper insulation was done after the core was lead-sheathed. This is possible because of the presence of the oil channel within the conductor.

As may be seen from Figure 3 the conductor is of a novel make-up. Instead of the usual round wires, in single or multiple layers, 12 segments, carefully designed to fit snugly around the steel channel and present a smooth outer periphery, were stranded with a ten-inch right-hand lay.

An advantage for this conductor is that it inherently reduces the electrostatic stresses formed unless remedial measures are used at the crests of wires in conventional stranding.

After insulating, the core was heated at atmospheric pressure for five to six hours, sufficiently long to dry the insulation slightly and loosen the paper tapes so that the possibility of tearing the tapes during leading would be reduced. Leading followed immediately after the preliminary heating. The cable dimensions were as listed in Table II.

Evacuation and impregnation is effected through pipes wiped by fittings to the ends of the cable length, the sheath acting as the vacuum container. A typical impregnation curve with electrical and absolute pressure values is given in Figure 10.

Ionization	0.0008	0.0008
Power factor of insulation at working pressure:		
22 degrees centigrade	0.0045	0.0040
80 degrees centigrade	0.0055	0.0048
60 degrees centigrade	0.0040	0.0043
40 degrees centigrade	0.0043	0.0038
Room temperature	0.0044	0.0040
Dielectric watts loss per foot, three-phase, 20 degrees centigrade	0.70	0.70
Dielectric constant at 85 degrees centigrade	3.94	3.94

After cooling, the cables were tested based on Association of Edison Illuminating Companies specifications.[4] Typical results are given in Table III.

Following the tests, the inside end of the cable length was connected through a flexible pipe to degassed oil storage reservoirs housed in the cable drum (Figure 13); then a pulling eye was fitted to the outside end of the length. The pulling eyes were provided with a threaded opening through which oil connections can be made.

With the pulling eye wiped on, the cable was ready for its final washing. A sufficient quantity of oil was washed through the cable core to remove any trace of burnt oil present in the cable because of the wiping operations incidental to fitting the pulling eye. When the power factor of the oil reached a value similar to that of the degasser storage tank oil, and the volume of oil the cable would expel from ten pounds pressure was under the specified limit showing the almost total absence of dissolved gas, the cable was made ready for shipment.

Installation

As this system was sold on an installed basis, the manufacturer was responsible for the cable and accessories until the cable went into operation. Under the manufacturer's engineer in charge, an organization was set up in which a cable-installation company contracted to do the handling, trucking, pulling, and such similar items, to supply top-grade skilled splicers, helpers, and laborers, and to supervise that phase of operation. Great credit is due to this company, as the success and speed with which the work

was done was in no small measure due to their lengthy experience and to the high quality of workmanship of their skilled staff.

Again under the engineer in charge was a staff of inspectors and engineers. The former checked each operation and dimension as performed. The latter were responsible for "treating" that is, evacuating and filling) all accessories, checking accessories as received, keeping reservoirs filled, and operation of the degasser. They were assisted by truck drivers who became skilled in handling the degasser and in many other duties. In addition, the utility maintained their own staff of inspectors checking and co-operating with the foregoing.

The installation of an oil-filled system involves planning for, training for, or executing the following:

1. Provision of suitable stock room, field office, tools, supplies and equipment, especially portable degassing equipment.
2. Provision for temporary source of degassed oil for feeding cable after pulling into ducts and before jointing.
3. Training of personnel, technical, semitechnical, and skilled tradesmen, in handling of cable and accessories, joint making and accessory installation.
4. Transport of cable and accessories from delivery point to point of installation.
5. Test check of cable or accessory for any leaks or imperfections before starting installation.
6. Actually installing, jointing, and so forth.
7. Continuous inspection and supervision of all operations.
8. Keeping of detail records of each individual operation, progress records, charts, and a daily log.
9. Making field check tests.

The basic considerations are that no air or other gas shall remain in, or in contact with, the cable oil, nor shall any overheated oil remain in the system. All training and inspection keep these prime necessities in view at all times. As detail procedure and instruction sheets are quite lengthy, this article can give only the general principles and procedure followed.

1. Tools and Equipment

(*a*). A portable degasser, a vital piece of equipment, (Figure 11) serves as a source of high vacuum (less than one-millimeter absolute pressure) and as a source of warm degassed oil. The same special oil used in impregnating the cable is taken to the field in 50-gallon sealed drums. Here it is tested for breakdown strength and color, drawn into the portable degasser, filtered, and sprayed under high vacuum into the main tank of the degasser. It is then recirculated, through a rigidly controlled heat exchanger, and again sprayed into the high vacuum until it reaches approximately 60 to 65 degrees centigrade and is thoroughly degassed. A viewing window in the dome of the degasser permits ready inspection of the oil condition. Vacuum and pressure

gauges, thermometers and thermostatic controls, automatic cutoffs, and similar safety devices make this degasser a highly reliable and efficient instrument. During the larger contract two degassers were employed, one mounted in a trailer, the second in a truck.

(*b*). A "treating bottle" and its associated valve panel (Figure 12) are employed at the joint or accessory being treated. These embody a system of valves and vacuum and pressure gauges by which the oil or vacuum from the degasser can be applied to the accessory being treated, the degree of treatment checked, and oil from the degasser checked for quality before being admitted to the cable system.

(*c*). Extra-heavy-walled one-half-inch (inside diameter) special rubber hose is used as vacuum line from the degasser to the work. Soft copper tubing three-eighths inch (outside diameter) is used as the oil line.

(*d*). A plentiful supply of three-eighths inch (outside diameter) soft copper tubing and flare fittings such as nuts, tees, crosses, unions, and so forth was maintained in the field stock room with the degasser and with the inspection crews.

Spare manometers, both atmospheric and absolute types, pressure-vacuum gauges, mercury, a small hand-operated high grade vacuum pump, appropriate wrenches, spanners, and miscellaneous tools were found essential.

(*e*). Report forms were set up in great detail, individual forms covering the following:

Pulling.
Manhole and reservoir inspection.
Normal joints.
Stop joints.
Terminals.
Degasser log.
Truck log.
Progress charts.

2. Temporary Source of Degassed Oil

As the permanent reservoirs were available at the time cable started arriving at the site, these reservoirs were mounted at or close to their permanent locations. Cable deliveries were scheduled so that lengths adjacent to the reservoirs were first pulled in and connected to the reservoirs, the next lengths connected to the first by temporary oil lines, and so on. This eliminated the use of numerous temporary reservoirs and introduced many economies such as less frequent recharging, handling of reservoirs into and out of manholes, besides the investment cost in such temporary reservoirs. No troubles were encountered, nor was it felt that there was added risk with this technique as compared with practice common in United States.

3. Training of Personnel

Before jointing started, a school was instituted in which actual joints were made under simulated manhole conditions. Jointers and inspectors were required to do each operation of their respective duties in this school. All personnel handling the degasser were required to practice its operation until thoroughly conversant with it.

4. Test Checks

Each cable length at the site was checked by means of an "expulsion"

Figure 13. Expulsion test on reel length.

test (Figure 13) to ensure that it was properly impregnated in the factory and that no gas had entered the cable thereafter.

Each reservoir, pothead, feed pipe, and valve panel, before installing and after installing but before filling with oil, was checked for leaks by evacuating and watching carefully for loss of vacuum when blanked off from the source of vacuum.

5. Installation

(*a*) *Cable.* Cable pulling was done by standard methods with careful records of pulling tensions and atmospheric conditions (some of this was done at temperature in the order of 0 degrees Fahrenheit). As the pulling eye enters the manhole toward which the cable length was being pulled, it was connected through a fitting screwed into the pulling eye to a source of degassed oil. The other end of the cable was then disconnected from the reel oil reservoir and pulling completed.

Table A. Coefficients of Pulling Friction

	At Average Temperatures of	
	Cold Weather Minus 7 C	Warm Weather 23 C
Maximum	0.520	0.370
Minimum	0.190	0.120
Average	0.312	0.258

Coefficients of friction computed from recorded pulling tensions are shown in Table A.

(*b*) *Reservoirs.* After erection and with valves installed, reservoirs were checked again by blank off. In the case of the Canadian-built reservoir of new design, calibration was effected as follows:

The cells were completely collapsed and degassed by being placed under vacuum. Gauge oil was then poured in through the riser tank until at the normal zero on the gauge glass. The volume of oil contained by the cells, when at operating zero, (minus 0.1 pound per square inch) is five gallons for these 36-gallon reservoirs. Accordingly, five gallons plus or minus an amount to allow for the contraction or expansion of the gauge oil between ten degrees centigrade (assumed normal temperature) and its temperature at the time of charging were drained from the gauge oil. The reservoir thus calibrated was then charged with degassed oil to whatever volume was required for the system at the time.

(*c*) *Oil Lines.* The permanent oil lines were of copper pipe with joints of the soldered capillary type. Each oil line was heated to remove moisture, tested by blank off for vacuum tightness, flushed with clean oil at 110 degrees centigrade and, if not for immediate use, was backfilled with dry carbon dioxide gas. When about to be placed in service the pipe was flushed with degassed oil, reevacuated, filled with degassed oil, and connected to a source of degassed oil fed from a reservoir.

(*d*) *Joints and Potheads.* As these were points at which the cable insulation and newly applied insulation were necessarily exposed to the atmosphere, special means were employed to remove such contamination. This paper, because of lack of space, does not go into details of splicing and erection, but outlines the added requirements above ordinary solid-type cable joints consequent on the type of cable and the principles followed in ensuring that the quality of the cable was not impaired.

1. All oil overheated by soldering operations must be flushed out.
2. There must not be a stoppage of oil channels when work is completed.
3. No sharp stress points may be left.
4. Proper contours must be maintained.

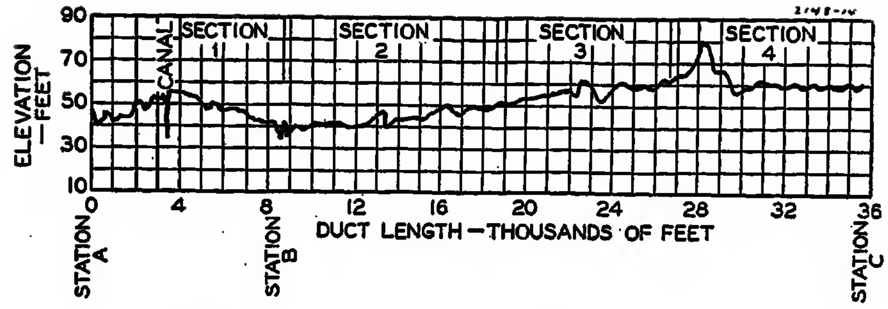

Figure 14. System profile of 120-kv duct line

5. There must be no leaks, even the most minute.

6. Dissolved and occluded gas must be removed.

7. The accessory must be left filled with good degassed oil.

These last two requirements are accomplished by the so-called "treatment." The joint or pothead was connected through the treating bottle to the portable degasser. Vacuum was applied until the accessory had reached a high degree of vacuum and so maintained until, on being blanked off, the completeness of the treating process was indicated by the lack of rise in absolute pressure. Drainage of oil coming out of the insulation during this operation was effected through a drain connection at the lowest point in the accessory. Such drainage, of course, must be into a vacuum.

The accessory was then filled with degassed oil from the portable degasser and connected to the system excepting in the instance of joints when this first filling was drained out, the bottom joint fitting permanently sealed, and the joint retreated and refilled with degassed oil. The top fittings of normal joints were then permanently sealed, as they have no source of oil other than from the cable itself.

In the 300,000-circular-mil section joints were treated immediately after the splicer finished. In the 650,000-circular mil section the splicers completed the three joints in each manhole. The three joints were then "gang" treated (that is, all treated at the same time). (See Figure 7.) This routine permits most effective use of all personnel and equipment and results in substantial time saving provided the skilled mechanics do first-class work. During this phase of operations the gangs were organized for continuous work from 8 a.m. Monday to 8 a.m. Saturday, using three eight-hour shifts.

On account of the small number of stop joints and of other limiting circumstances in the case of potheads this routine was not followed in these cases. Each such accessory was treated as soon as the splicers were finished.

7. Inspection and Supervision

The keeping of detailed and continuous inspection of all operations and constant backchecking was a highly important element in the success of the work. It was found that the skilled mechanics welcomed this inspection and co-operated thoroughly with the inspectors. Besides entering it in the proper report, all unusual results or circumstances were required to be reported directly to the engineer in charge.

8. Keeping of Records and Log

Detail reports of personnel doing the work, time in and out, time each subdivision of the operation was completed, values of pulling tension, vacua, weather conditions, and so forth were turned in by the inspectors or engineers at the completion of the operation. These reports were then typed by the office man, and from them and other data, the "daily log" and progress charts were entered. From these data it can be determined what man did any one operation and under what conditions. Progress charts and records served their usual function of assisting in seeing that no operation was neglected and in correlating progress on all parts of the work and on preparation of progress invoices.

9. Field Check Tests

As work progressed, expulsion, impregnation, and oil-flow tests were made frequently. The former two tests checked that no air or other gas had become dissolved or locked in the system. The last named ensured that there was no stoppage or constriction in the oil channels, such as from a wrongly positioned connector valve in a joint, or from solder working into an oil channel.

Operation

Contracts for the first and second sections of this work were placed in May 1940. As they were approaching completion in May 1941, the contract for the third and much larger section was placed. The whole system received voltage tests and was placed in initial service on December 14, 1941, two weeks ahead of the original schedule.

In order to transmit as much power as possible when available, that is, during the off-peak hours, it was decided to rate the cables as follows: Since the original calculations were based on a $62^1/_2$ per cent daily loss factor, it seemed satisfactory to allow a total daily watts loss from all sources equal to that established by using the standard formula for current-carrying capacity and to use as maximum current that established by using the factory measured resistance of the conductor as indicating the copper area rather than the circular-mil area. Since more power was available between midnight and 8 a.m., curves were made to show the maximum current that could be carried during these hours, depending on the current carried during the previous 16 hours, and to give a loss factor of $62^1/_2$ per cent with no current higher than the maximum allowable by calculation.

Records of ground temperature, idle duct temperatures, sheath temperatures in manholes, duct-mouth movements, and oil demands are being taken, and it is hoped that in the future these will provide some valuable information.

Sheath-bonding transformers of the Halperin and Miller design are being installed on circuit *C* which will increase the present load-carrying ability of the cables a considerable amount and at the same time allow for the saving and transmission of the load that is presently taken by the sheath losses. Because of the time element these were not in the main contracts, but provision was made for these transformers by including solder-seal sheath insulators in the joint casings.

The oil level in reservoirs is supervised by a simple alarm system operated by high- and low-level switches at each reservoir. The high or low oil level, as soon as it exists, is known by a station operator who is able to report the section in trouble to the proper persons.

A further precaution is being taken with reservoirs in the form of a dehydrator attached to the reservoir breather. This consists of a cylinder filled with activated alumina through which the air in contact

with the gauge oil (that is, the oil outside the reservoir cells) must pass before entering the reservoir. It is felt that by removing the moisture in the air, less sludging will take place around the reservoir cells. The size of these cylinders is such that, with expected load cycles, the alumina should not have to be reactivated more often than once a year.

Load has been carried continuously since January 2, 1942. Operating data are being collected, such as duct temperatures, oil demands, cable movement at duct mouths, shifting of joints, and so forth. Sufficient information of this nature to draw conclusions will require considerable time to collect.

A New Single-Pole Service Restorer

E. E TUGBY
ASSOCIATE AIEE

Synopsis: The widespread and general use of three-phase automatic service-restoring equipment on low-cost low-revenue distribution lines has created a field for a single-pole service-restoring device having continuously adjustable characteristics for trip current and time delay, and powered by a prestored source of energy. The device described in this paper utilizes a new and unique application for the prestoring of the operating energy and the restoration of the utilized operating energy after transient fault conditions.

A STUDY of the requirements for a source of operating energy for this new single-pole service-restoring device indicated a need for a source that would be independent of fault current and have available a dependable source of prestored energy when a fault occurs.

The successful operation of a very large number of service restorers powered by manually wound or motor-wound torsional springs logically led to the investigation of a similar source.

From this investigation was developed a new and unique application of previously tried and proved principals. In a paper presented by A. E. Brock at the Pacific Coast convention in August 1941, an improved service restorer using a motor of an entirely new type for rewinding the operating spring was described.

Paper 42-147, recommended by the AIEE committee on protective devices for presentation at the AIEE Pacific Coast convention, Vancouver, British Columbia, Canada, September 9–11, 1942. Manuscript submitted June 1, 1942; made available for printing July 3, 1942.

E. E. Tugby is sales engineer, Pacific Electric Manufacturing Corporation, San Francisco, Calif.

This Vibratorque motor is adapted to this new application, but, instead of the customary secondary source of energy being provided, the motor is arranged to be directly in series with the primary line, thus making the new unit a completely self-contained device.

The operating energy of the service restorer is contained in a motor-rewound flat spiral spring where enough energy is stored to provide four opening operations and three reclosing operations on a sustained fault without rewinding, and an infinite number of operations on transient faults, as the Vibratorque motor restores the expended energy upon reclosing the circuit after each transient fault.

Figure 3 shows a schematic diagram of the entire mechanism.

Rating

This single-pole service restorer is rated at 15 kv 50 amperes continuous current-carrying capacity, with a maximum interrupting rating of 1,000 amperes when using the 25–50-ampere trip coils. When the lower current-rating trip coils are used, the interrupting rating is reduced to 40 times the rating of the trip coils installed.

The interrupting ability of this new service restorer has been amply proven by a comprehensive test program where currents of 1,490 amperes at 15 kv were interrupted on a full cycle of three reclosures and four openings.

A complete oscillographic record was made of the tests for record and study.

Two thousand operations were performed at moderate short-circuit currents considerably in excess of continuous current rating, on a 15-kv system, and, on being inspected, the service restorer was found in condition to perform many more operations.

A complete series of impulse tests was performed, and the results recorded on a cathode-ray oscillograph, to verify operation under lightning conditions, and in every case the restorer flashed over from bushing to ground outside the case.

Arc-Extinguishing Devices

The successful and co-ordinated performance of rural lightly loaded low-cost distribution lines under fault conditions depends primarily upon the rapid extinguishment of the arc and the high speed of the interrupting device protecting the circuit.

As the prestored spring operating energy is restrained by a roller-type latch,

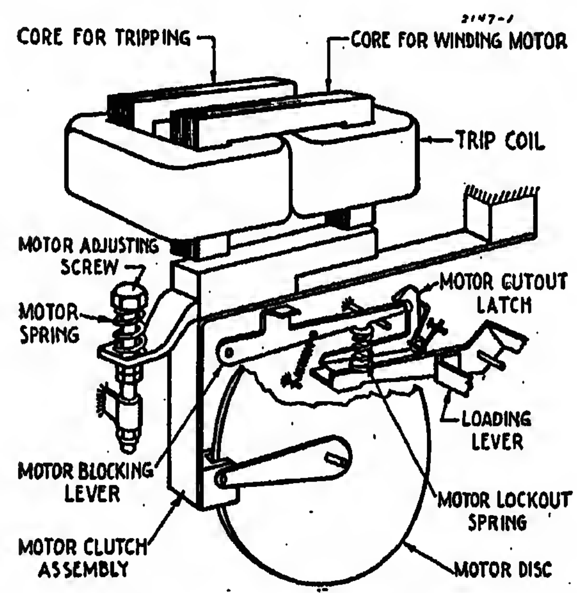

Figure 1. Diagram of Vibratorque motor

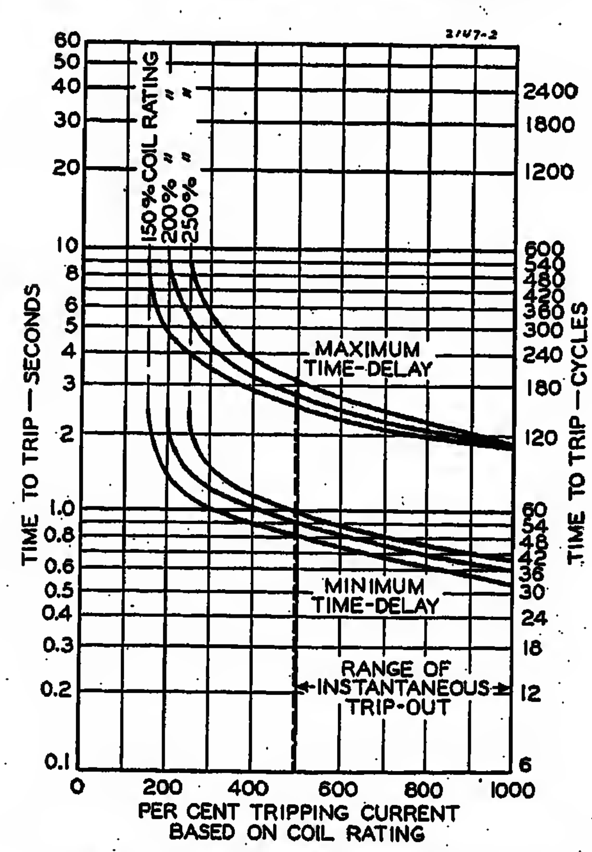

Figure 2. Time-current characteristic curves

Table I. Typical Interrupting-Capacity Tests

Test Item	Number of Tests	Amperes	Average Arcing Time (Cycles)	Duty
1	10	104	1.0	O—5 sec—*OCO—5 sec—OCO—9 sec—OCO
2	6	640	1.1	O—7 sec—OCO—7 sec—OCO—7 sec—OCO
3	6	1,459	0.99	O—7 sec—OCO—7 sec—OCO—7 sec—OCO

* OCO—Open, close, open.

and the fault current affects only the latching mechanism, the operating speed of the arc-interrupting device is independent of fault current. The moving blade travels with a high rate of speed to assure quick extinguishing of the arc in the expulsion chamber, and an actual test performed has shown arc time from 0.65 to 1.2 cycles of arc while interrupting approximately 1,500 amperes at 12.5 kv to ground. The blade tips of arc-resisting Elkonite also assure a minimum of material vaporization, thereby minimizing oil carbonization and consequently reducing maintenance and inspection.

A test run of in excess of 2,000 operations at a moderate short-circuit current and full voltage failed to reveal serious burning of contacts which gave complete proof of the adequacy of the design.

Rewinding Motor

The rewinding motor is of a unique design and has a number of novel features not available heretofore.

A cross section of this Vibratorque motor (shown in Figure 1) illustrates the principle involved.

In referring to this drawing, it will be seen that an armature is mounted on a spring that is rigidly supported at one end and has an adjustment to limit the travel of the spring at the other end. At right angles to the armature is an extension carrying a clutch that engages both faces of a flat hard steel disc. The clutch consists of two hardened steel-bearing rollers engaging in a tapered slot, so co-ordinated as to provide the most efficient transfer of energy from the vibrator to the steel disc, with the least friction on the return stroke. The armature is alternately attracted by an a-c magnet coil assembly consisting of two identical coils mounted on a laminated solenoid core, and returned by a spring. The reciprocal motion of the vibrator alternately causes the clutch to engage on the disc which travels forward a small increment, then to disengage and move back to its original position. The disc rotates in a rapid series of small increments which are transmitted through gears to the main spiral operating spring, where the energy is stored for use in operating the service restorer.

The speed of the output shaft is a function of the weight and size of the armature, ampere turns of the coil, and characteristics of the spring which supports the armature.

The Vibratorque motor develops compound characteristics and with a change in load assumes a moderate output speed change. The magnet coils which also act as trip coils are, as previously stated, connected in series with the line and arranged in two halves to give flexibility. Since they are in series with the line, no external source of operating energy is necessary, and, as the rewinding energy is provided during normal operating conditions, the stored energy is instantly available to operate the device during fault conditions.

The motor will operate successfully with the smallest coils when a current as low as one-half ampere flows through the line.

The magnet coils also perform a dual duty as trip coils and are available in ratings from 3–6 amperes to 25–50 amperes. It is to be noted that pairs of coils have a dual value; as, when the coils are connected in series, they have their lowest rating, that is, 3–6 ampere coils would carry three amperes, but if they were connected in parallel, they would have their higher rating of six amperes as a unit, with each coil carrying three amperes only.

When the Vibratorque motor has fully wound the operating spring to its required tension, the vibrator spring is automatically locked up against the pole pieces. This is controlled through a differential arrangement on the outer case surrounding the operating spring. A scroll is cut in this outer case, in which rides a stud projecting from a bar which thus travels across the face of the case and assumes a position with direct relation to the amount of spring operating energy available. With the spring fully wound, the projection is in a position near the outer periphery of the spring house, and the bar projects beyond the case. When this point is reached, a catch that is normally held under tension is released, and sufficient pressure is applied to the armature support spring to force it up against magnet coils and prevent further vibration. When the spring energy is expended, the differential bar moves down, under the action of the projection in scroll and re-engages the catch, which

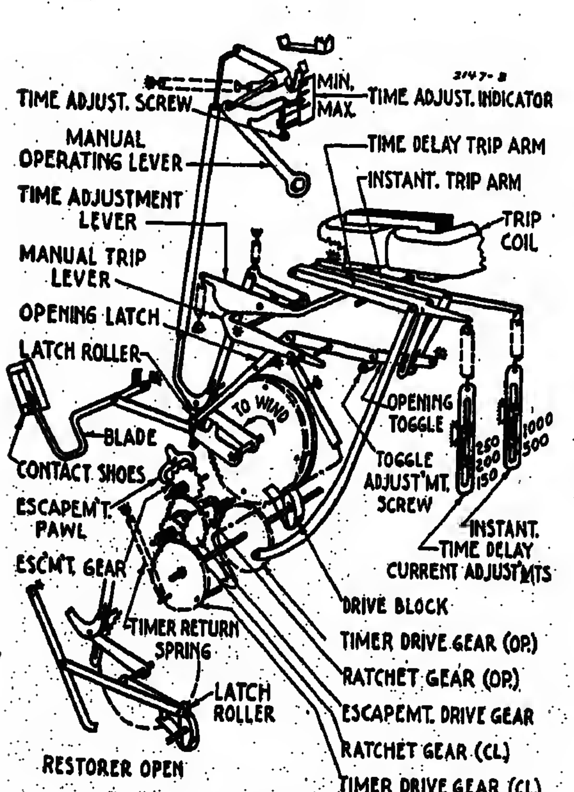

Figure 3. Diagram of mechanism

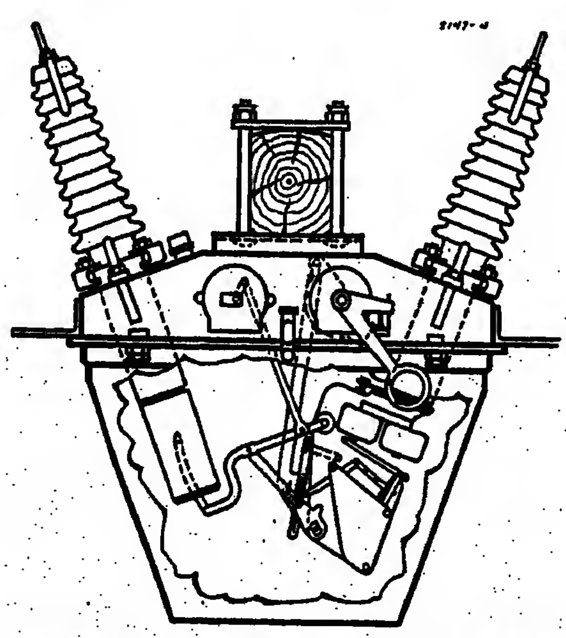

Figure 4. Cutaway section of complete unit

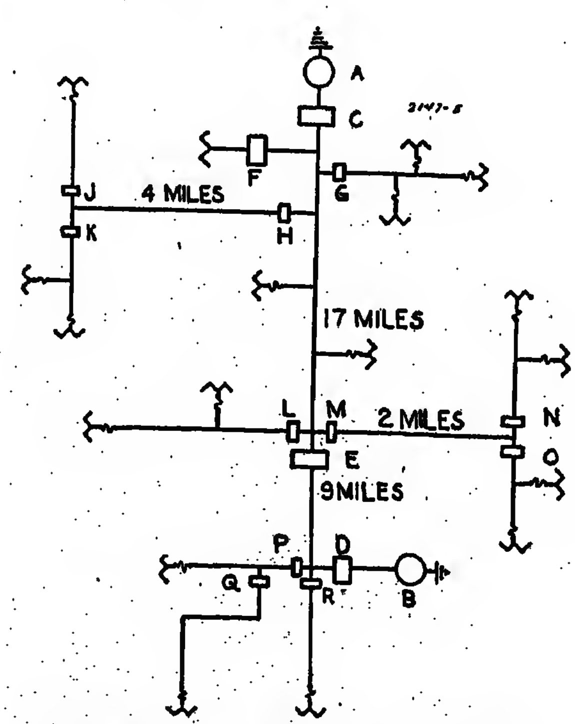

Figure 5. Typical sectionalized system

releases the spring to vibrate and again supply power to the operating spring.

The center of the coil spring is connected to a shaft which carries on its outer end an operating lever, which in turn is connected to the moving contact blade through a connecting rod.

This blade is normally held in the closed position by the operating spring, restrained by a roller latch mechanism. This type of latch mechanism has been found to give positive latching while requiring a minimum of current for tripping without any diminution of the tripping speed.

The latch may be released by one of the three following methods:

1. By the trip coils actuating the time-delay mechanism.
2. By the trip coils actuating the instantaneous high-current trip mechanism.
3. By the operation of the manual trip mechanism.

All three of these schemes act upon a single common toggle independently and, in the case of the first two, are independently adjustable over a wide range.

Escapement-Type Delay Mechanism

As the complete service restorer was designed for low-cost protection, it was imperative that all working parts be utilized to the fullest degree. Since both tripping and reclosing involved time delay, it was decided that one unit serving both operations could perform these duties admirably, and a mechanism was accordingly built with a rugged design that would handle both duties successfully and reliably.

This time-delay mechanism consists essentially of a gear train with an escapement pawl, which provides a time delay that is independent of temperature conditions.

The time-delay driving gear has a ratchet on either side, and each ratchet is connected to a smaller gear on a shaft. On one side this ratchet gear is driven by the opening gear which is connected to the opening toggle, and the other ratchet gear is actuated by the main blade through a suitable mechanism to control the reclosing time delay.

The correct initial starting position is always assured by a cam return spring that brings the gear train back to normal starting position. If the fault clears before the restorer opens, the time delay will immediately return to its initial position ready for a second fault, thus providing a high degree of accuracy of protection. The reclosing time delay is actuated by a projection on the main-blade operating lever. This projection initially engages the flat spring mounted on a cam which initiates the movement of the gear train. After a short travel, the main-blade operating lever engages the cam, and the driving effort of the main operating spring, transmitted through the main-blade operating lever, tends to rotate the cam, but rotation is restrained by the time-delay escapement.

The reclosing time schedule is fixed at seven seconds, but the tripping time delay may be varied. The tripping time is dependent upon the amount of travel of the escapement, which in turn may be limited by a time-adjustment lever. This lever adjusts the position of the trip arms relative to the trip-coil pole faces and is in its turn controlled through a linkage to the manual rewinding lever. This lever is adjustable to its final position by a set screw mounted external to the housing. Calibration points are provided to indicate the maximum and minimum adjustments, which may be easily adjusted in the field with a screw driver.

Manual Rewinding Mechanism

A manual rewinding mechanism is provided and so arranged that the restorer will not reclose until sufficient spring energy is stored for one closing and one opening operation, thus providing a valuable safety factor when closing in against a fault.

If there is no fault on the line, the rewinding motor then takes up its duties and completes the rewinding of the spring to its proper operating tension.

Time-Current Characteristics

Typical time-current characteristics are shown on Figure 2 where it may be noted that minimum trip is arranged for 150 per cent of rated coil current. That is, in the dual ratings with the coils of a 3–6-ampere combination connected in series for a three-ampere maximum current, the restorer would trip at 4.5 amperes, or if the trip coils were connected in parallel for six amperes continuous current, then the restorer would trip at nine amperes. The two sets of curves for minimum and maximum time delay represent the limits of the lever setting previously described, and each family of curves represents the current adjustment obtainable.

It should also be noted that at 500 per cent of rated coil current, an instantaneous trip mechanism comes into play, and the restorer may be tripped instantaneously. This minimum trip may be easily adjusted from 500 per cent to 1,000 per cent if a higher instantaneous trip value is desired. The current adjustments are both internal to the restorer and may be made with a screw driver as calibration marks are provided, and an indicator may be set for each adjustment.

Mounting

This new restorer is designed for either single-arm or direct-pole mounting and may be readily arranged for either type mounting as required.

Construction

Referring to Figure 4, it will be seen that this new single-pole service restorer consists essentially of a pivoted blade actuated by a small coil spring, mounted on the lower end of the one bushing and an expulsion contact mounted on the lower end of the other bushing. Both bushings are mounted, diverging outwardly in the cover, and are of the standard stud type. A slow-speed motor rewinds the operating spring after each reclosure, and this makes available an infinite number of reclosures on transient faults. On a sustained fault, the prestored spring energy is dissipated at such a rate that, after the fourth spring operation following three reclosures, the restorer will not reclose and is "locked out." To reclose the restorer after lockout, it is necessary to manually rewind with the manual rewinding handle for four or five strokes, to store enough energy for one closing and one opening operation before the restorer closes and the motor begins its rewinding cycle.

Application

The problem of providing high-quality protection against faults, and the maintenance of a reasonable continuity of service at a cost comparable with the revenue obtainable with long lightly loaded low-revenue lines have been brought to the fore more rapidly and forcefully with the shift of population from the cities to the country.

The availability of modern low-cost electric appliances in these rural areas has further heightened the pressure to maintain high-quality service, and, inasmuch as the average rural circuit is of the radial feeder type, it is of utmost importance that faults be localized as much as possible and confined to the least number of customers.

Due to the nature of the territory in which these rural lines are located and the types of low-cost construction used, the prevalence of faults due to lightning disturbances and to trees swinging lines together in wind storms and whipping under sleet conditions is very high.

Studies made in many parts of the country show that an average of 80 per cent of faults may be cleared, and service restored on a first reclosure, which thus justifies the use of reclosing devices on a rural system.

The development of the three-pole service restorer described at the AIEE 1941 Pacific Coast convention was one answer to the problem of high-quality protection for the main feeder, and the development of the single-pole unit described in this paper complements the three-pole unit to relieve the three-phase service restorers of a large number of operations, and to localize a sustained fault to any one particular feeder.

An interesting application is illustrated in Figure 5 based on a co-operative system with widely scattered individual customers and on a moderately heavy load. *A* and *B* are two interconnected generating stations with three-pole motor-rewound service restorers at *C*, *D*, and *E* in the three-phase interconnecting power lines, and at *F* to protect a large load. At restorer *E* potential and current transformers were installed in the main line, and power directional relays were provided to prevent generating station *B* from carrying the entire load if generating station *A* were out of service. Single-pole restorer *G* protects one branch line that is in a reasonably clear area and would not be subject to serious faults. Single-pole restorers *J* and *K* protect long lines radiating through heavily wooded area and are in cascade with a single-pole restorer at *H*. Similarly, single-pole restorer *M* also is in cascade with restorers *N* and *O* to protect another area in trees. Restorers *P*, *Q*, and *R* protect feeders in the vicinity of generating station *B*. As no fuses are to be used for sectionalizing protection on this system, the problem of co-ordination was simply one of superimposing the time-current characteristic curves of single-pole service restorers on those of the three-pole service restorer and arranging tripping time and current settings so as to provide a high degree of selectivity.

At each distribution transformer installation, individual fuse protection was provided; therefore, the problem resolved itself into a group of individual circuit calculations to balance all factors to obtain the greatest flexibility, at the same time restricting outages to the smallest area.

A check was made of the connected capacity on each branch feeder, and it was found that, in any individual leg to be protected, the connected transformer capacity did not exceed 20 kva. On the basis of a load factor of 50 per cent the load current would not exceed 1.5 amperes per circuit, which was well under the continuous current-carrying capacity of the smallest trip coil available.

Therefore all single-pole service restorers used were to be equipped with the same size trip coil, namely 3–6 amperes, and were arranged where there were two in cascade so that the unit nearest the source had the trip coils connected in multiple, for six amperes continuous current-carrying capacity, and those furthest out were arranged with the coils in series for three amperes continuous current-carrying capacity. It was then necessary to make field adjustments as to the time delay and instantaneous trip at various points to properly co-ordinate the entire system.

The three-pole service restorers *C* and *D* at the generating station were each equipped with a first instantaneous tripping action, followed by time-delay tripping on subsequent tripping operations.

It is thus to be seen that each branch line is fully protected by a single-pole restorer which will trip after a time delay. The main-line protective restorer at the generating stations, being equipped with instantaneous initial trip and instantaneous first reclosure, will operate to protect the entire system against heavy transient faults in the main feeders.

The single-pole restorers would be arranged so that the tripping time delay is less than that of the main-line restorer on the second trip out; thus under sustained fault conditions the single-pole restorer will take over the duty of isolating the fault, and the remainder of the system continues with uninterrupted service. Under transient fault conditions the single-phase restorers will clear a fault on the branch lines, of lesser magnitude than that required to operate the main-line restorer at either *C* or *D* and will automatically restore the expended operating energy upon the line circuit being re-energized.

In the case of the system under discussion, after three transient faults had been cleared, each subsequent operation of the single-pole service restorer may be considered as saving the expense of a service man with his transportation to and from the maintenance base to patrol the line and restore service. This saving of labor and transportation offers a considerable reduction in maintenance expense and at the same time provides a very high quality of service in rural areas, comparable to that obtainable in suburban areas, at a very low initial cost.

Stability Study of A-C Power-Transmission Systems

JOHN GRZYBOWSKI HOLM
MEMBER AIEE

Part I

FOR the operation of power-transmission systems of medium and long length, the problem of stability is becoming increasingly important. This is true in the steady state of the system as well as in the transient state, during and after the occurrence of a fault on the system. Since the design of the transmission system is primarily responsible for its proper operation, and since the a-c network analyzer offers the best means for system analysis, the present study was undertaken for the purpose of correlating the design and operational data by means of the a-c network analyzer. For this purpose several power-transmission systems were selected, and their steady-state- and transient-stability characteristics studied. Thus the steady-state- and transient-stability limits of the system were obtained on the analyzer.

As a result of the study, curves were constructed from which it is possible to determine, at various voltages, the stability limits of transmission systems of various lengths, to select the proper voltage for a certain transmission project, and to determine the kilovolt-ampere capacity of generators to be installed, in order that certain steady-state- or transient-stability limits might be attained. Curves were suggested for rapid estimating of system steady-state- and transient-stability limits. Certain means for increasing the stability limits were studied, such as the intermediate synchronous condenser, the resistance in the neutral of the sending transformer, and the reactor on the generator bus. The necessity of the application of these means to the various systems, and the need for generators of special design with lower-than-normal transient reactance and higher inertia constant are shown.

General Principles of System Design

Thirty-one power-transmission systems were designed for the purpose of purely academic study. The systems transmit blocks of power of 50,000, 100,000, 250,000, 500,000, and 800,000 kw (at the receiving end) over distances of 50, 75, 150, 250, and 500 miles, at sending-end voltages of 69, 138, 230, and 345 kv, at 60-cycle frequency. The power is transmitted from hydroelectric power plants to distant metropolitan load centers, and the transmission lines were designed so as to transmit the predetermined block of power. In line with the trend toward high standards of reliability and security of operation, the systems were required to deliver a 100 per cent block of power under a double line-to-ground fault at the sending-end bus, cleared in 10.5 cycles with a consequent loss of a circuit, or a section of it if the circuits are sectionalized. Each system thus has a minimum of two circuits. The block of power transmitted under these conditions and delivered at a corona power loss as small as is economically justified, is taken as the rating of the system.

The long-line theory of line design was used throughout, and the general circuit constants were calculated for the line alone, for a circuit, or for a section of it. In several cases the transmission of a certain block of power over a certain distance was made at two different voltages in order that the effect of the voltage on system stability could be shown.

Transmission-Line Data

All systems were designed to operate at standard voltages at both ends of the system. The voltage drop of approximately five per cent in the line was maintained by means of synchronous condensers at the receiving end of the system.

On all systems under study, only copper conductors were used—both the standard concentric stranded conductor and the hollow copper conductor of the *HH* type manufactured by the General Cable Corporation. The corona power loss was calculated by the Carroll-Rockwell method.[1–3] In view of the great difference in the corona power loss of the two types of conductors, it became necessary to establish conditions for the use of either of the two conductors. A rather conservative criterion was established by which the hollow-type conductor was used whenever the cross section of the concentric stranded copper conductor, of the diameter necessary to secure the desired corona power loss, was about 50 per cent greater than the cross section required of this type of conductor to carry the emergency current of the line.

In every other respect the lines are of conventional design.[4–6] In view, however, of the effect that certain design factors have on system stability limits, it is pointed out that all systems have high-voltage busses at both ends, and all are equipped with a single continuous-type tower-to-tower counterpoise. The list of the systems designed, the types and sizes of conductors, and the corona power losses are given in Table I. Normal and emergency circuit conditions of the transmission lines are represented in Figure 1.

System Characteristics and Representation on the A-C Network Analyzer

The basic study of systems on the network analyzer was made for those with generators of standard design, and not equipped with devices for stability improvement, in order that the stability limits might be obtained for systems with standard equipment. Subsequently the various means for improvement of stability were investigated (see part II) and applied where needed.

The generators were not equipped with damper windings for this study, and their saturated synchronous reactance was taken at 80 per cent of the unsaturated direct-axis synchronous reactance assumed to be 100 per cent. The transient and negative-sequence reactances were taken at 35 and 45 per cent, respectively. The transformer reactances were taken at standard values, with 12.5 per cent for the 345-kv units. For the basic study, the high-voltage neutral of transformers was solidly grounded in all systems. The saturated synchronous reactance of the receiving-end synchronous condensers was taken at 128 per cent, and the transient and negative-sequence reactances were taken at 40 and 24 per cent, respectively.

The transmission systems feed into a metropolitan-system load. The magnitude of this load is assumed to vary in-

Paper 42-117, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted November 21, 1942; made available for printing May 19, 1942.

JOHN GRZYBOWSKI HOLM is with the Stone and Webster Engineering Corporation, Boston, Mass.

To the engineers of the General Electric Company, the Westinghouse Electric and Manufacturing Company, the General Cable Corporation, and The Okonite Company, and to several electric-public-utility and consulting engineers, the author expresses appreciation for valuable advice and data.

versely with the block of power transmitted, ranging from 400,000 kw for the 50,000-kw systems to 1,600,000 kw for the 800,000-kw systems. The power factor of the load is 0.85 lagging. In the circuit representation for the network-analyzer study, the metropolitan load was represented by an equivalent synchronous motor with proper constants and excitation voltage. Such a representation follows from the study of the input characteristics to the metropolitan-load system which, when plotted in the form of synchronous motor charts, resemble the characteristics of the synchronous-motor charts.[7] The reactance of the equivalent synchronous-motor load was taken at the same value for both the steady-state- and the transient-stability studies. Similarly the positive- and the negative-sequence reactances of the load were taken equal.

The inertia constant of generators and synchronous condensers was taken at standard values for the sizes of machines assumed.[8] The inertia constant of the load was calculated for the proportion of turbogenerators and synchronous motors known to be representative of large metropolitan-load centers, and ranged from about 5.15 to 5.60 kw-sec per kva.

System reactances, as represented on the a-c network analyzer, are given in Table II.

Synchronous Condensers at the Receiving End of Systems

Synchronous condensers were placed at the receiving end of every system, of sufficient capacity to maintain rated voltage under all conditions from full load to no load, at an approximate ratio of 1.05 of the voltages at the system ends. The leading kilovolt-amperes were determined for the 100 per cent load under emergency conditions. At the 1.0 to 0.5 lead-to-lag ratio of this condenser, the lagging kilovolt-amperes measured at no load and under normal circuit conditions, were always below the maximum allowed by this ratio.

Table I. List of Systems Designed—Type and Size of Conductors—Corona Power Loss

Corona power loss calculated for an elevation of 3,300 feet above sea level and a temperature of 50 degrees Fahrenheit. The equivalent-delta spacings are 10.28 feet for 69-kv lines, 16.67 feet for 138-kv lines, 32.13 feet for 230-kv lines, and 47.88 feet for 345-kv lines.

The kilovolt-amperes of the receiving-end condensers, as obtained from measurements on the a-c network analyzer, are given in Table III. The average leading kilovolt-amperes per kilowatt of the line rating is 1.05 kva in the 50- to 150-mile lines. In the 250- and 500-mile systems, equipped with intermediate synchronous condensers, the average is 0.85 kva per kilowatt of system rating.

The analysis of the figures obtained substantiates the common experience, to the effect that the receiving-end condenser kilovolt-amperes required per transmitted kilowatt increase as the transmission distance or the block of transmitted power increases, and decrease with an increase of the transmission voltage, the other parameters remaining unchanged. The data which have been obtained for a large variety of systems make it possible to estimate the required kilovolt-amperes of receiving-end synchronous condensers for numerous systems, either by direct use of the figures given or by their judicious interpolation.

It should be borne in mind, however, that the systems designed do not make use of the rotating equipment within the metropolitan-load area into which they feed, and are thus made independent of it. Should such use be made, the condenser kilovolt-amperes may be reduced.

The receiving-end condenser unquestionably contributes somewhat toward the steady-state- and transient-stability limits of the system, and hence toward the system rating. The degree of this contribution, however, is difficult to determine rigorously (if, indeed, it can be determined at all), in view of the difficulty in maintaining the same voltages at the ends of the system in the two cases where the system has, and where it does not have, a condenser at its receiving end.

Procedure and Approximations in the Stability Study

The determination of the steady-state- and transient-stability limits was made according to the standard accepted procedure.[9] The steady-state-stability study was made for normal circuit conditions of the system. From the stability limit obtained on the network analyzer, the steady-state-stability limit is calculated for emergency circuit conditions. This calculation is made on the basis that the steady-state limit changes inversely with the total system reactance. The transient-stability limit was determined by the point-by-point method for the condition of a double line-to-ground fault near the sending-end bus. The negative-sequence-

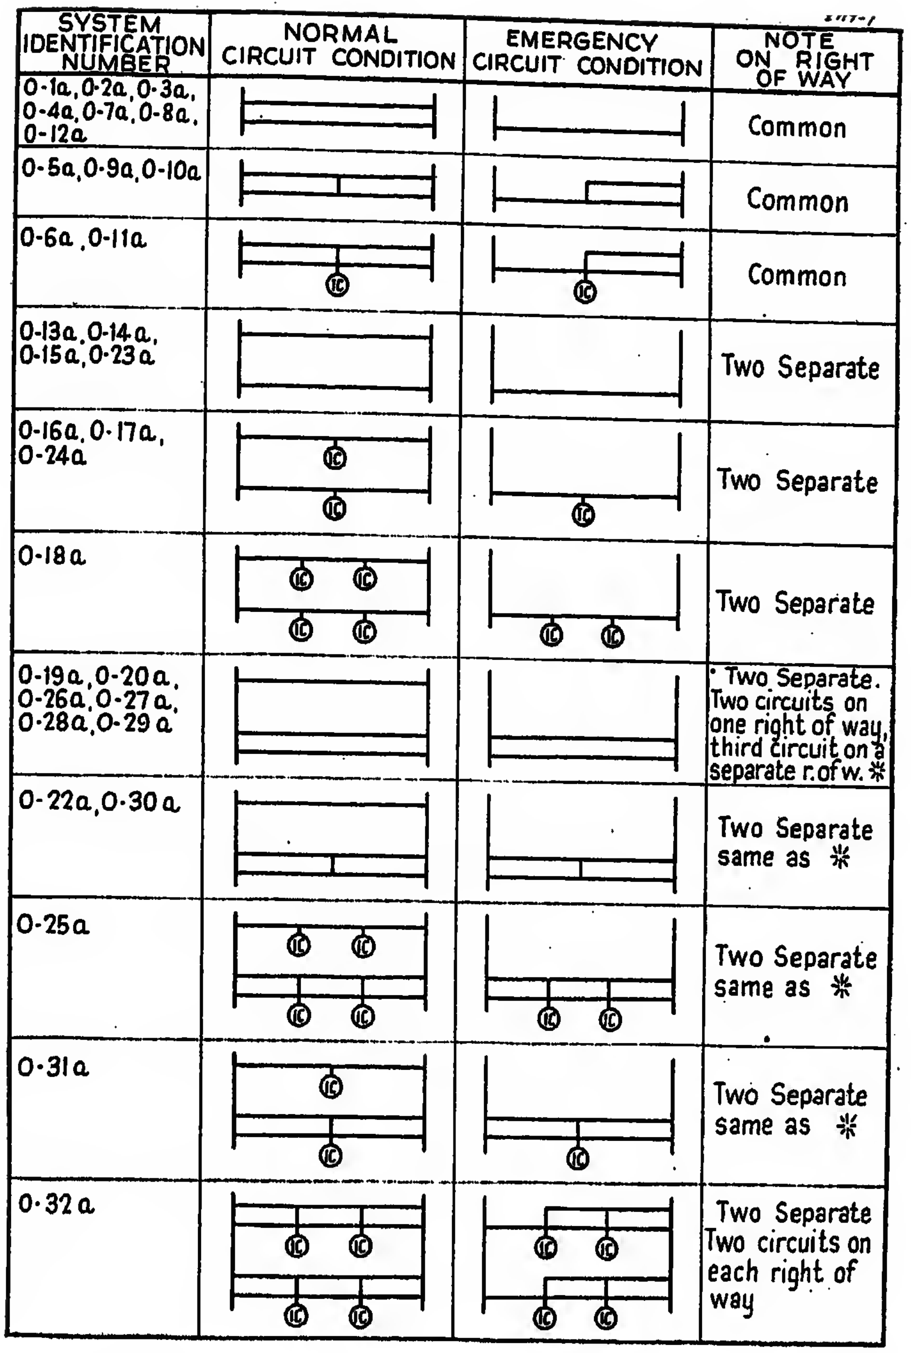

Figure 1. Normal and emergency circuit conditions of transmission lines (single-line diagrams)

IC indicates an intermediate synchronous condenser. Receiving-end synchronous condensers not shown. For commentary of identification numbers of systems, see Table I

and zero-sequence-impedance networks of the system were formed as seen from the place of fault.

Regular simplifications were introduced for the system study on the network analyzer. Of these the following are the most important: The saliency of machines was not accounted for, exciter action was not introduced, and only the first swing of machines was considered. In this part of the paper the stability limits of the 50- to 150-mile systems are reported as obtained in the basic study on the network analyzer, that is, for systems of standard equipment with no devices for stability improvement. The basic study of the 250-mile and 500-mile systems shows that it is absolutely impractical to operate lines of this length with standard equipment, when no devices of any kind are employed for the increase of stability limits. In the present study the intermediate synchronous condenser (see part II) was adopted as the basic device necessary for the satisfactory operation of the 250-mile and 500-mile systems. Therefore, the stability limits of these systems are reported in this part of the paper as obtained for systems equipped with intermediate synchronous condensers, with machines of standard design, and otherwise with standard equipment. The additional means which might be necessary to bring the transient-stability limit of the system to the desired level are discussed in part II.

Discussion of the Steady-State-Stability Limit

The steady-state-stability limit under both normal and emergency circuit conditions is given in Table IV and for normal circuit conditions is represented in Figure 2 as a function of the length of the transmission line. Similarly the stability limit may be represented as a function of the sending-end voltage or of the kilovolt-ampere capacity of installed generators.

The family of curves obtained is susceptible to interpolation and may be used for the following purposes:

1. To determine the steady-state-stability limit of the system when the line length, the system voltage, and the installed generator capacity are known.

2. To select an appropriate transmission voltage for a certain project when the design is to be based on the magnitude of the steady-state-stability limit.

3. To determine the kilovolt-ampere generator capacity which must be installed in a system of a certain length operating at a certain voltage, if a certain steady-state-stability limit is desired. Also to determine the maximum transmission distance when the generator kilovolt-ampere capacity and the system voltage are known.

4. To give an indication of conditions where the steady-state-stability limit may be within the economical region, and hence an indication of the order of magnitude of the kilovolt-ampere generator capacity which can be economically installed.

Figures on the steady-state stability obtained on the network analyzer on a wide variety of systems clearly demonstrate the relative effect on the stability limit of the system reactance and the transmission voltage. In the heavy lines the large kilovolt-ampere generator capacity has an effect on the steady-state-stability limit which is greater than that exerted by the transmission voltage. Since the systems designed represent fairly economical combinations of the block of power transmitted and the transmission distance, it can be seen that in the longest systems the steady-state-stability limit is more affected by changes in the mileage than by changes in the system voltage. This again has a bearing on the economics of the system.

Curves for Estimating the Steady-State-Stability Limit

Further correlation of data obtained on the a-c network analyzer makes it possible to express the steady-state-stability limit as a function of a quantity which for convenience is denoted as β, thus providing a family of curves for quick estimation of the stability limit of the system. The interpretation is simple and provides a sufficient degree of accuracy in estimating the stability limit of a great variety of trunk-line systems differing in details from those investigated.

The stability limit is plotted as a function of the quantity

$$\beta = \frac{E_s \cdot E_r}{X} \tag{1}$$

where E_s and E_r are, respectively, the sending- and receiving-end line-to-line voltages in kilovolts, and X is the total system reactance as taken for the steady-state calculations and expressed in ohms on the system generator base. More specifically, X is the sum of the generator saturated synchronous reactance, the reactances of the sending-end transformer, the transmission line under either normal or emergency conditions as the case might be, the receiving-end transformer, and the load reactance as taken for the steady-state study.

Reactances are calculated on the system base and are represented on the high-voltage side.

The curves are represented in Figure 3 for normal circuit conditions of the transmission line. Separate lines are drawn for the systems equipped with intermediate synchronous condensers.

While it is true that the kilovolt-ampere generator capacity has an effect on the system stability limit, this does not preclude the possibility of using the curves for transmission systems whose relative generator and line reactances are different from those which served as a basis for the β curves. The curves are applicable to any fairly economical combinations of kilowatts, mileages, and voltages, and may be used with a degree of accuracy well within normal engineering estimates. They cannot be expected to give reliable figures (if, indeed, any can be given) in obviously uneconomical and impractical cases such as the transmission of 50,000 kw over a distance of 500 miles at a voltage of 345 kv, or the transmission of 800,000 kw over 250 miles at 138 kv.

The metropolitan-system load of the transmission line for which the β curves are used has unquestionably an effect on the system-stability limit, but, as may be seen from the systems investigated, the load reactance constitutes a relatively small percentage of the total reactance X in the equation 1. Considering that the load on the systems designed was carefully determined with a view to representing actual cases as nearly as possible, it may be said that the method of proposed β curves may be used with the customary degree of engineering accuracy for systems having loads such as are encountered in actual practice. The gaps between the separate β curves could have been filled, had a greater variety of cases been investigated, or had other voltages been used. In the expression for β, excitation voltages could have been made use of instead of the sending- and receiving-end voltages. This, however, would introduce a great many additional calculations which are not justified by the ultimate accuracy possible of attainment.

Discussion of the Transient-Stability Limit

In the process of determining the transient-stability limit on the a-c network analyzer, it was found that the transient-stability limit of a system B may be calculated to a high degree of accuracy from the known transient-stability limit of a system A similar to it in configuration, by using the following expression:

$$(\text{Transient-stability limit})_B = \frac{P_A}{P_B} \cdot \frac{X_A}{X_B} \cdot \left[\frac{E_B}{E_A}\right]^2 \cdot (\text{transient-stability limit})_A \qquad (2)$$

where P is the system rating determined solely from consideration of the conductor size and installed transformer capacity, X is the total system transient reactance of the emergency circuit, and E is the nominal system voltage. The subscripts refer to system A or B. More specifically, X is the sum of the generator transient reactance, the reactances of the sending-end transformers, the transmission line under emergency circuit conditions, the receiving-end transformers, and the load. Equation 2 gives a good check with the data obtained by actual measurement on the analyzer, the error not exceeding five per cent. In applying it, the intermediate condensers, if any, may be disregarded. This is explained by the comparatively small increase in the transient-stability limit caused by these condensers (see

part II of paper), the increase itself being counterbalanced by the error inherent in equation 2. Thus, by a judicious use of this expression, a saving of time may be effected in estimating the transient-stability limit of one system through the known stability limit of another similar system.

The transient-stability limit of the designed systems is given in Table IV. The table also gives the stability limit for zero-duration time of a double line-to-ground fault. This calculation is made by using the appropriate curve of Figure 11 of the First Report of Power-System Stability.[8] The latter curve represents a

The 250-mile lines are equipped with one intermediate synchronous condenser; the 500-mile lines, with two intermediate condensers, in capacity sufficient for 100 per cent load

long and heavy line, and it has been checked on the writer's systems, resulting in data confirming it.

In Figure 4 the transient-stability limit is represented as a function of the length of the transmission line. In like fashion it may be shown as a function of the sending-end voltage, or of the kilovolt-ampere capacity of installed generators. The representation is similar to that of the steady-state-stability limit (see Figure 2). The curves are also susceptible to interpolation and may be used for similar objectives (see discussion of the steady-state-stability limit).

The relative effect, however, of the system reactance and the transmission voltage is different in the case of the transient-stability limit from that of the steady-state limit. In the transient state the generator reactance is much smaller and the line reactance greater than in the steady state. Therefore, while in the steady state the generator reactance predominates even in the longer lines, in the transient state the reverse is true; here the line reactance is of greater significance, the line length assuming the controlling influence. In the greater majority of cases the total system reactance in the transient state is smaller than in the steady state under normal circuit conditions. As an indirect result, the transmission voltage is a considerably more powerful factor in fixing the magnitude of the transient-stability limit than in fixing that of the steady-state limit.

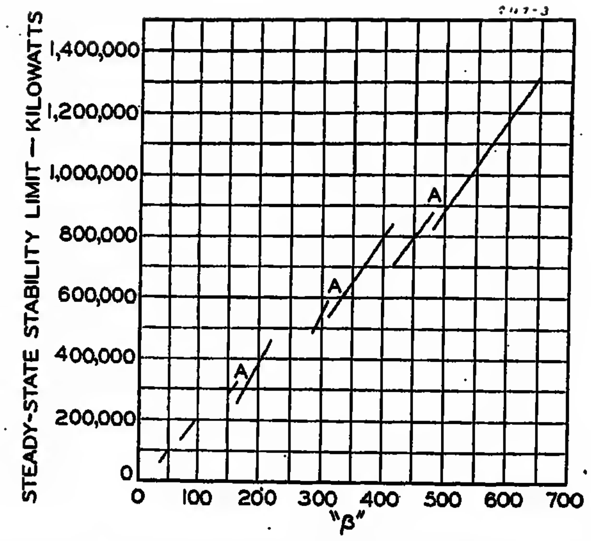

Figure 3. Estimating curves for the steady-state-stability limit

Normal circuit conditions

Curves for systems with installed generator capacity of 55,000 to 950,000 kva, transmitting power to a metropolitan-load center 50 to 500 miles distant, at sending-end voltages of 69, 138, 230, and 345 kv. All systems with receiving-end synchronous condensers in sufficient kilovolt-ampere capacity to maintain a five per cent voltage drop in the line. The 250-mile lines are equipped with one intermediate synchronous condenser; the 500-mile lines, with two intermediate condensers, in capacity sufficient for 100 per cent load. Curve sections denoted *A* are for systems with intermediate condensers. No other means are used for the increase of system stability limits. For explanation of quantity "β," see text of paper

Curves for Estimating the Transient-Stability Limit

As a result of further analysis, the transient-stability limit is represented as a function of the quantity β similar to that used for the representation of the steady-state limit. Thus a curve is obtained for the rapid estimation of the transient-stability limit.

In this case the quantity β has a different meaning from that of the denominator in equation 1, in that X is the total system reactance as taken for the transient-stability calculations, expressed in ohms on the system generator base. The transient reactance of generators and the transmission-line reactance under emergency circuit conditions must now be taken.

The curve thus obtained (Figure 5) permits the estimation, within engineering accuracy, of the transient-stability limit for a system with a double line-to-ground fault cleared in 10.5 cycles. For reasons mentioned above, there is no need for a

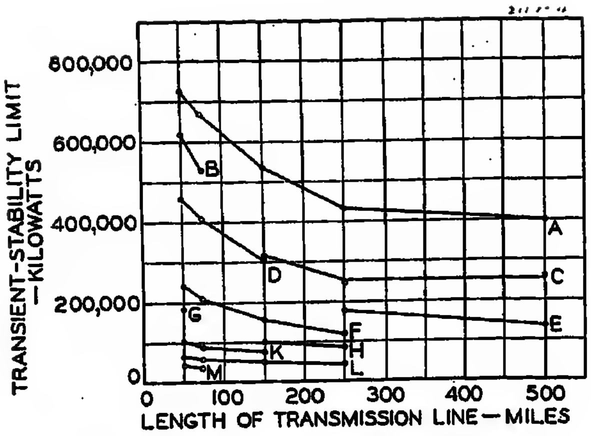

Figure 4. Transient-stability limit

Double line-to-ground fault at the sending end cleared in 10.5 cycles, with loss of circuit or a section of it. For explanation of identification letters, see Figure 2. For circuit condition after fault is cleared, see Figure 1

separate curve for lines equipped with the intermediate synchronous condensers.

The discussion of the β curve and its application in the case of the steady-state-stability limit applies equally well to the transient-stability limit. In addition, it may be said that since the inertia constant of machines in the metropolitan-load center was chosen so as to be representative of actual systems, an additional argument exists for the statement that the curve may be used on systems with loads met in actual practice.

The transient-stability limit given by the curve of Figure 5 may be expressed as follows:

$$\text{Transient-stability limit} = 800 \cdot \beta \text{ kilowatts} \tag{3}$$

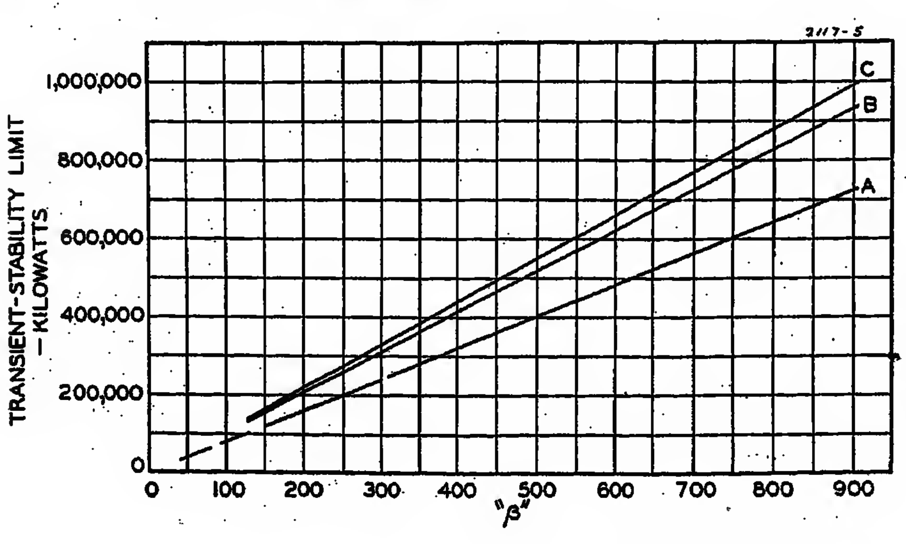
with β as defined above. When use is made of the relationship between the

Figure 5. Estimating curves for the transient-stability limit

Sending-end fault cleared in 10.5 cycles

A—Double line-to-ground
B—Line-to-line
C—Line-to-ground

In using the curves for estimating purposes, no distinction is made between systems with and without intermediate synchronous condensers. For general note, see Figure 3



severity of various types of faults, such as are given by the curves of Figure 11 of the First Report of Power-System Stability, the following expressions may be obtained for the transient-stability limit at 10.5 cycles' fault-clearing time:

For a line-to-line fault

$$\text{Transient-stability limit} = 1{,}040 \cdot \beta \tag{4}$$

For a line-to-ground fault

$$\text{Transient-stability limit} = 1{,}100 \cdot \beta \tag{5}$$

with β as defined above, and the transient-stability limit expressed in kilowatts.

The above expressions may be easily modified to apply for faults of any duration, by using a curve representing the variation of the transient-stability limit with the clearing time of the particular fault. For this purpose, the curves of the First Report of Power-System Stability may be used for trunk transmission lines.

Criteria of the Margin of the Transient-Stability Limit Over the Test Load

In cases where the transient-stability limit of a system is determined on the a-c network analyzer, the better the guesses as to the probable stability limit of the system, the fewer the total number of swing curves to be taken. The procedure may be shortened considerably if use is made of the relative time when, on the one hand, the maximum angle between the generator and the load machines is reached, and on the other hand, the change in the rotor angle of the generator, $\Delta\delta_n$, becomes negative.

When the angle between the machines reaches its maximum before $\Delta\delta_n$ becomes negative, there is a comparatively large margin between the transient-stability limit of the system and the test load. When the maximum machine angle is reached simultaneously with $\Delta\delta_n$ passing through zero, there still is a margin—though a small one—between the stability limit and the test load. When, however, the angle $\Delta\delta_n$ becomes negative before the maximum value of the angle between the machines is reached, then, practically speaking, there is no margin, and the test load may be taken as equal to the transient-stability limit of the system. Observation of the time relationship given makes it possible to reduce considerably the effort required for the study of the system on the network analyzer.

Part II

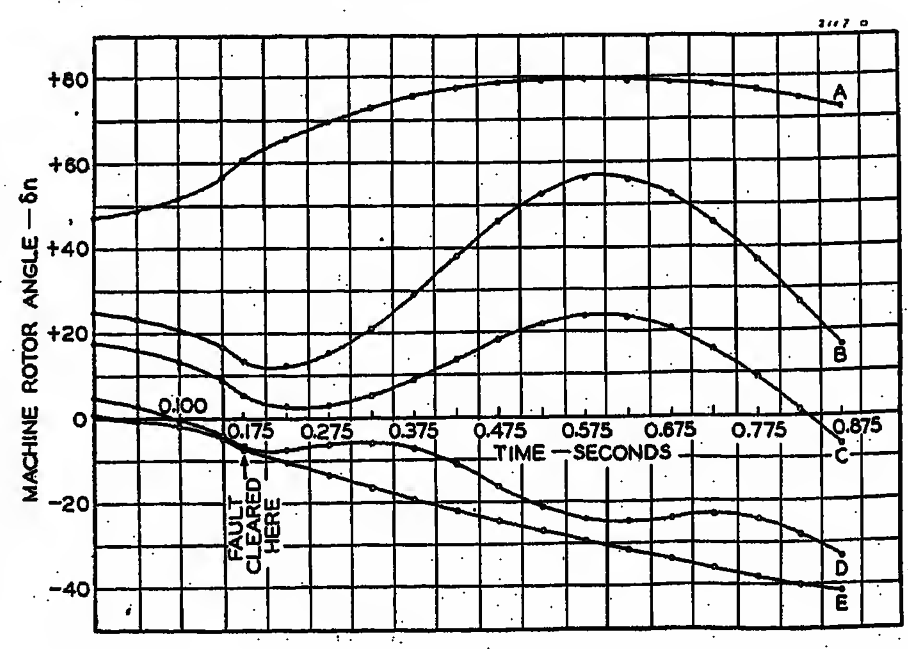
From the data on stability limits of the transmission systems investigated on the a-c network analyzer, given in part I of the paper, it may be seen that only a handful of the systems will deliver the 100 per cent block of power to the metropolitan-system load under the fault conditions prescribed, without the use of special design features. Special designs must be applied to the great majority of systems in order that their transient-stability limits may be increased.

It is the purpose of part II of this paper to investigate, on the a-c network analyzer, some of the means for improving the stability limits of transmission systems, and then to apply the various means to the systems whose transient-stability limits had to be raised to the 100 per cent rating.

Figure 6. System swing curves, taken on the network analyzer (system 0-25a)

13 per cent resistance in sending-transformer neutral. Double line-to-ground fault at the sending end. System stable

A—Generator
B—Intermediate condenser at point two thirds from receiving end
C—Intermediate condenser at point one third from receiving end
D— Receiving-end condenser
E—Load



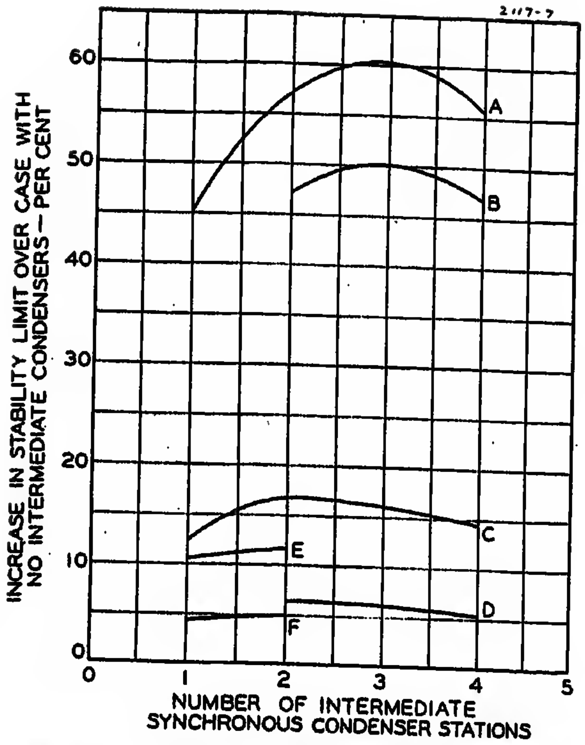


Figure 7. Effect of intermediate-synchronous-condenser stations on system stability limit

Intermediate-condenser stations so located as to divide the line into sections of equal length

A—Steady-state-stability limit—500-mile line
B—Steady-state-stability limit—500-mile line. Reactors substituted for condensers
C—Transient-stability limit—500-mile line
D—Transient-stability limit—500-mile line. Reactors substituted for condensers
E—Steady-state-stability limit—250-mile line
F—Transient-stability limit—250-mile line

The intermediate synchronous condenser, the resistance in the neutral of the sending transformer, and the reactor on the generator bus are the three devices for increasing the stability limits which were investigated. They were chosen, because the available data in the literature on their application are either incomplete or nonexistent, and also because they were within the means available for the type of academic study made by the writer.

Systems have generators of normal design and are not equipped with devices for stability improvement, except with intermediate synchronous condensers, as indicated under "Remarks."

IC indicates an intermediate synchronous condenser, placed for 100 per cent load.

For list of systems, see Table I.

The Intermediate Synchronous Condenser

There are relatively few power-transmission systems on which intermediate synchronous condensers are installed. Wherever this is the case, however, satisfaction is generally expressed with the part the intermediate condenser plays in the system operation. Since in most systems the installation of the intermediate condenser was made previous to the time when the full significance of the problem of transient stability was realized it may be presumed that the primary reason for installing the condenser was its contribution to the steady-state-stability limit and to the maintenance of voltages at certain points of the transmission line. Indeed, the studies published by Baum,[10,11] Fortescue,[12,13] Fortescue and Wagner,[14] Evans and Bergvall,[15] Petersen,[16] Piloty,[17–19] and Rüdenberg[20,21] deal exclusively with the effect of the intermediate condenser on the steady-state-stability limit of the system. None of these studies were made on the network analyzer, and consequently the method of approach necessitated simplifying assumptions; for instance, in their study of the intermediate condenser, Wagner and Evans[22] assumed an infinite bus (that is, a bus to which so large a synchronous capacity is connected that its frequency and voltage are absolutely unaffected by any conditions external to that bus). There are practically no published data on the effect of the intermediate condenser on the transient-stability limit. Summers and McClure[23] mention the subject briefly, and Tchernycheva and Lavrov[24] discuss the effect of the intermediate condenser on the system stability limit for the case of a three-phase fault.

From the study of system operation it appears that all intermediate condensers on a line may operate either primarily leading or primarily lagging; or that some will operate mostly leading, requiring a 1.0 to 0.5 lead-to-lag ratio, while others will operate only lagging, requiring a 1.0 to 1.0 lead-to-lag ratio. This depends on the length of the line, on the number of condenser stations, and on the ease with which the line carries its 100 per cent load. For instance, on the 500-mile lines with two intermediate condensers, both condensers have a 1.0 to 1.0 lead-to-lag ratio; while with three condenser stations, two condensers have a 1.0 to 1.0 lead-to-lag ratio and the third has a ratio of 1.0 to 0.5. In every case the larger condenser kilovolt-amperes are required under emergency circuit conditions. The kilovolt-ampere capacity of the inter-

mediate condensers and the total synchronous-condenser capacity for the systems under design, for the number of intermediate-condenser stations as finally adopted, are given in Table V.

The swing curves of two intermediate condensers on a 500-mile line loaded almost up to its transient-stability limit are shown in Figure 6.

The results of a study of the effect of the intermediate synchronous condensers on the stability limits of the 250-mile and 500-mile systems may be summarized as follows: On an average 250-mile line, with one intermediate-condenser station in the system, the steady-state-stability limit is about ten per cent greater than in the system with no intermediate condensers. The stability limit of a 500-mile line, under the same conditions, is 45 per cent greater. On a 250-mile line carrying its 100 per cent load very easily, the beneficial effect of the intermediate condenser may be considerably greater; for instance, in the system 0-11*a*, which typifies a light line, the steady-state-stability limit is increased by about 20 per cent.

The increase in the transient-stability limit caused by one intermediate-condenser station is far smaller than the increase in the steady-state limit. On an average 250-mile line the increase is less than five per cent; on a 500-mile line it is about 12 per cent. Thus it is seen that the intermediate condenser is more effective on the longer lines than it is on the shorter ones.

As the number of intermediate-condenser stations on the line is increased, the stability limits increase until a certain theoretical optimum is reached. On a 250-mile line the difference in stability limits when one or two intermediate stations are installed is so small that from the economic viewpoint one station will give the best solution. On a 500-mile line, however, the largest increases in the steady-state-stability limit seem to take place with a different number of condenser stations than is best for the transient-stability limit. Economic computations, however, will show that two stations are the optimum. Two stations will increase the steady-state-stability limit by about 57 per cent and the transient limit by about 16 per cent.

Irrespective of the number of intermediate-condenser stations in the system, their location is most advantageous when they divide the entire line into sections of equal length; thus, for a 250-mile line, a mid-point condenser gives the best result.

Doubling the size of the intermediate condenser required to maintain specified

Condenser kilovolt-amperes given leading.

Intermediate synchronous condensers located so as to divide line into sections of equal length, and placed for 100 per cent load.

voltages increases both the steady-state- and the transient-stability limits by slightly less than ten per cent over the case of a condenser of normal size. The same general result is obtained when intermediate condensers of lower reactance are used.

Study of the substitution of reactors for lagging intermediate condensers was made on systems where all condensers operate fully lagging, as well as on those where some condensers operate lagging while others are leading. The results show that when lagging condensers are replaced by reactors, the stability limits are considerably lowered, especially the transient-stability limit. While in a certain 500-mile system the increase in the steady-state limit obtained from reactors was only ten per cent less than that obtained from synchronous condensers, the increase in the transient-stability limit was less than half that obtained with condensers.

Reactors therefore can be substituted for lagging intermediate condensers only when the steady-state stability is considered of greater importance than the transient stability, and provided the lower initial cost and lower losses make the over-all economic balance in favor of the reactors. The effect of intermediate condensers on system stability limits is represented in Figure 7.

When the load in a 500-mile system drops below the 100 per cent level for which the intermediate condensers are provided, then the voltage at the intermediate points may rise considerably above the desired level and thus endanger the insulation of the system and the continuity of operation. This may also take place in some, though not all, 250-mile lines. Intermediate condensers of sufficient capacity for the 100 per cent load are insufficient to prevent the rise in voltage in these lines with smaller loads. On a 500-mile line, with a 50 per cent load, the intermediate-condenser capacity needed is about double that required for the 100 per cent load; on the 250-mile line it is approximately 25 per cent greater, when equal voltages are to be maintained with both the 50 and 100 per cent loads. It is not economical to provide intermediate condensers large enough to keep normal voltages at very low loads; yet they should be placed for a load smaller than 100 per cent. This will put the system in a more favorable operating condition and will facilitate the charging problem of the line. A corresponding increase in the stability limits of the system will result; this will compensate for the additional cost of the condenser.

Resistance in the Neutral of the Sending Transformer

It has been recognized for some time that the grounding of the neutral of the sending transformer through a resistance has a distinctly beneficial effect on the transient-stability limit of the system. Although this method of grounding has been applied to existing systems, the published data on its effect on the transient-stability limit are very meager. It has been reported,[8] however, that with the sending-end double line-to-ground faults, which are also assumed for the present study, the same percentage gain in the transient-stability limit is obtained when either the neutral of the sending-end

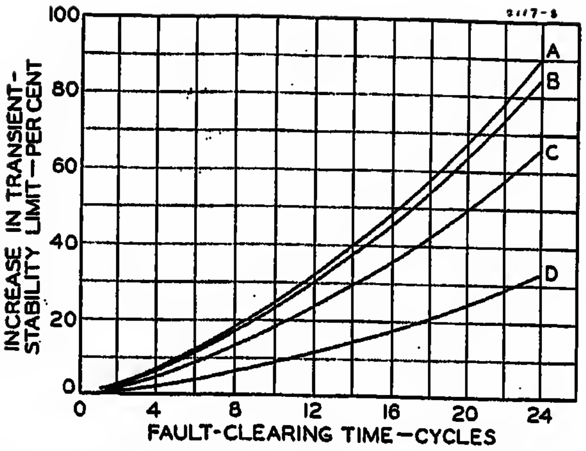

Figure 8. Effect on transient-stability limit of a 13 per cent resistance in the sending-transformer neutral

Double line-to-ground fault at the sending end

A—50-mile line
B—75-mile line
C—150-mile and 500-mile lines
D—250-mile line

transformer alone is grounded through a resistance, or when, in addition to it, the neutral of the receiving-end transformer is grounded through a reactance. Hence, so far as the transient stability is concerned, the grounding of the receiving-transformer neutral is not necessary with the type of fault being considered.

In grounding the sending-transformer neutral of a 50-mile line with various resistors ranging from 5.8 to 17.5 per cent, it was found that the smallest angle between the machines at the ends of the system at the transient-stability limit occurs with a 13 per cent resistance. This optimum resistance, however, is not particularly critical, since the observed variations in the angles between the machines with the various resistor sizes are accompanied by very small differences in corresponding transient-stability limits. This leads to the conclusion that the ultimate selection of a resistance—whether it should be 13 per cent or should differ somewhat from it—must be based on considerations other than stability; namely, on the effect of the size of the resistance on the insulation of the transformer. On this basis, in all systems designed, the study of the effect on the transient-stability limit of grounding the sending-transformer neutral was made with grounding through a 13 per cent resistance.

The increase in the transient-stability limit obtained at various fault-clearing times on lines from 50 to 500 miles along is given in Figure 8. The curves may be judiciously interpolated for any length of line up to and somewhat exceeding 500 miles.

It is seen from the data obtained that the resistance in the sending-transformer neutral makes a very substantial contribution to the transient-stability limit. The percentage increase secured on a 50-mile line is the largest; it then decreases as the line length increases, reaching a minimum on lines somewhat over 250 miles in length. This is due to the fact that as the line gets longer, its zero-sequence impedance increases. A decrease in the zero-sequence current follows and causes in turn a smaller I^2R loss in the grounding resistor. As a consequence, the power output of the generator under fault conditions is not maintained so well on the longer lines as on the shorter. The resultant increase in the transient-stability limit in the 250-mile lines is smaller than in the 50-mile lines.

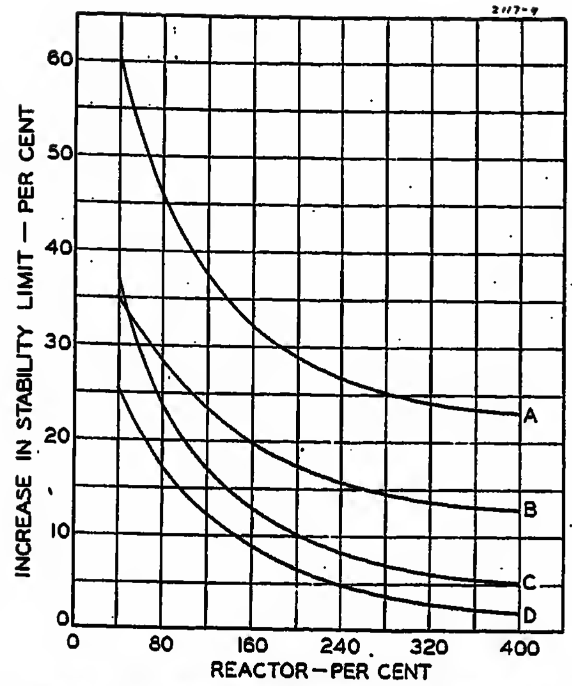

Figure 9. Effect of shunt reactors on generator bus on stability limits of 250-mile to 500-mile lines

Lines equipped with intermediate synchronous condensers

A, *B*—Steady-state-stability limit

Shunt Reactors on the Generator Bus

It was suggested some years ago that shunt reactors be used on the generator bus[25] in order to increase the stability limits of the system, and views were expressed to the effect that this method has some real possibilities. There are, however, no published data on the subject.

The writer does not know of any case where such reactors are installed on systems in this country. From a sketchy description[26,27] of the Kembs–Creney 220-kv, 173-mile line in France, it appears that there is a 15,000-kva shunt reactor on the generating bus of the station at Kembs. A statement is made that the reactor renders a very satisfactory service in helping to maintain stability of the line.

The shunt reactor on the generator bus

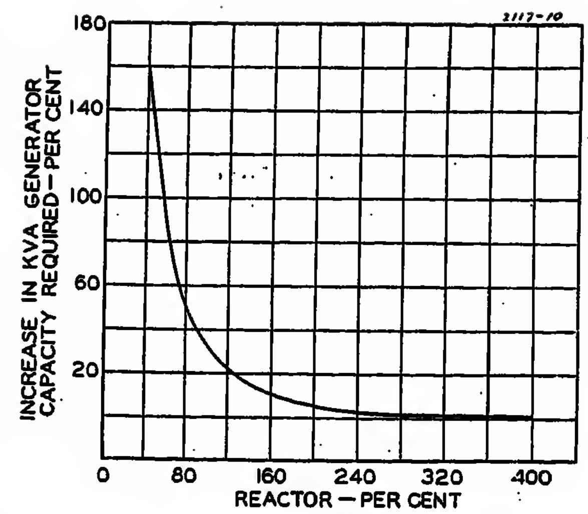

Figure 10. Effect of shunt reactors on generator bus on required kilovolt-ampere generator capacity on 250-mile to 500-mile lines

Lines equipped with intermediate synchronous condensers

is connected directly from the low-voltage sending-end bus to ground. The reactor increases the total system transfer reactance, it lowers the power factor on the generator, and increases its excitation voltage. The increase in the total system transfer reactance lowers the system stability limit, while the increase in the excitation voltage raises it. As a result, an important increase in the system stability limit is obtained. Since the generators must supply the transmission line with the same amount of active power when the generator bus is loaded with reactors as when they are not used—and this without overheating during the operation with full-load normal field currents—the installed kilovolt-ampere capacity of generators, in the case when reactors are used, must be greater than when there are none.

The study of the shunt reactor on the generator bus was made on the 250-mile and 500-mile systems on the network analyzer and was checked by analytical calculations. Reactors of from 40 to 400 per cent were placed on the 250-mile systems, equipped with one intermediate condenser, and on the 500-mile systems with two condensers. When the reactor was connected to the generator bus, the kilovolt-ampere generator capacity was increased to satisfy the new conditions. The increases in the steady-state- and transient-stability limits obtained on these systems are represented in Figure 9.

It is seen that the shunt reactor on the generator bus greatly increases the system stability limits. In the systems investigated, a 40 per cent reactor increased the steady-state limit as much as 60 per cent, and the transient limit as much as 37 per cent. The increase in the transient limit is considerably smaller than that in the steady-state limit; still it is very sub-

stantial. Figure 9 gives two curves for the steady-state- and two for the transient-stability limits. The upper of each pair of curves is obtained for systems where the relationship between the reactor and the system reactance is such that the introduction of the reactor, accompanied with a corresponding change in generator reactance, causes little change in the total system transfer reactance, while the lower of each pair of curves is for systems where this change is appreciable. Thus the percentage increase in the steady-state- or transient-stability limits obtained from a reactor of a certain size lies between the upper and lower curves of a pair, depending on the system. As the size of the reactor increases, its effectiveness declines. The curves of Figure 9 may be used for estimating the range of the increase in stability limits caused by the presence of a reactor on the bus.

A part of the increase in the stability limits of a system with a shunt reactor on the bus is due to the larger kilovolt-ampere capacity of generators required by the reactor. A study of the two factors, made separately on a system having a steady-state-stability limit of 118 per cent, with a normal kilovolt-ampere generator capacity, gave the following results: With a reactor on the bus and the generator capacity correspondingly increased, the steady-state limit rose to 157 per cent; when the reactor was removed, with the increased generator capacity still connected to the system, the stability limit dropped to 132 per cent. The contribution of the reactor itself to the stability limit is plainly evident.

The increase in the steady-state-stability limit caused by the shunt reactor on the bus, as measured on the network analyzer, may be checked in the following fashion: The ratio of the generator excitation voltages for the system with and without a reactor on the bus is first determined. This may be calculated from the voltage vector diagram. The increased kilovolt-ampere generator capacity and the actual angle between the line current and the reference voltage (line sending-end voltage) must be properly represented. The ratio of the total system transfer reactance, without a reactor on the bus, to that with it is then calculated. The product of the two ratios will indicate the increase in the steady-state-stability limit. The result differs from the measured figures by 15 to 20 per cent. This is due to the fact that the excitation voltage is determined for the condition of 100 per cent load, and not at the pull-out for which the stability limit is determined on the network analyzer.

The pull-out condition is approached to a greater extent when the steady-state maximum power limit of the system is calculated at the rated voltage in a manner similar to that employed when the maximum power limit is determined of a long transmission line and synchronous-motor load, with the sending- and receiving-end voltages given and reactances only considered.[9] The kilovolt-ampere generator capacity required by the presence of the reactor on the bus, and the actual angle between the line current and the reference voltage must be taken. The receiving-end condenser and the intermediate condensers may be neglected. The line sending-end leak also is neglected, and the receiving-end leak may be assumed to equal infinity. This method of calculation does not represent a rigorous solution; still it gives a satisfactory check with the data obtained on the network analyzer.

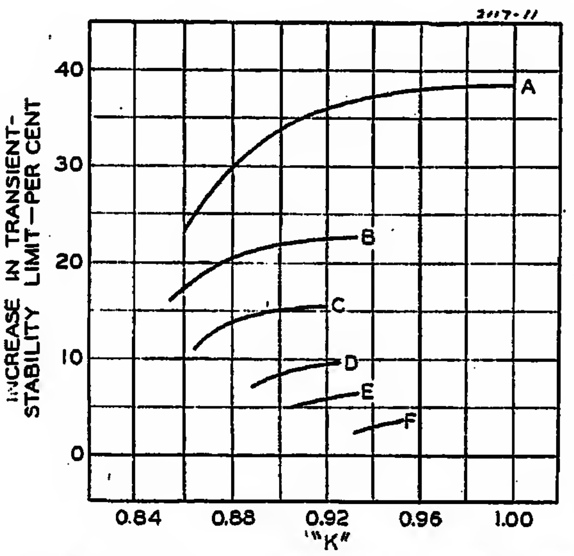

Figure 11. Curves for estimating the increase in transient-stability limit due to shunt reactors on generator bus

Based on study of 250-mile to 500-mile systems with intermediate synchronous condensers. For explanation of quantity k see text of paper

Reactor size

A—40 per cent
B—90 per cent
C—130 per cent
D—200 per cent
E—260 per cent
F—400 per cent

The kilovolt-ampere generator capacity required by shunt reactors on the bus is easily calculated when the angle by which the line current leads the sending-end voltage is known. On the 250- to 500-mile lines studied, with one or two intermediate condensers, this angle varies within narrow limits. The increase in generator kilovolt-amperes required by reactors of various sizes in the systems under design is given in Figure 10. With a 40 per cent reactor the increase is over 150 per cent, dropping rapidly as the size of the reactor increases. With a change in the number of intermediate-condenser stations in the line, the generator kilovolt-amperes required by a reactor on the bus will undergo a slight change.

From the effect of shunt reactors on the transient-stability limit of various systems, a set of curves of Figure 11 is obtained from which the increase in the transient-stability limit of the system due to the presence of a reactor on the bus may be estimated when the ratio k of the total system transfer reactance without the reactor to that with a reactor is calculated. In determining the ratio k, the transient reactances of the generators and the reactance of the line under emergency circuit conditions must be taken. For the system transfer reactance, with the reactor on the bus, the increased generator kilovolt-amperes should be taken as required by the reactor, and the architrave of the equivalent π circuit of the entire circuit must be known. It is also possible to determine from the curves the proper size of reactor to be placed on the generator bus when it is desired to increase the transient-stability limit of the system by a certain percentage, when the system reactances are known. The curves may be applied to double line-to-ground, line-to-line, and line-to-ground faults, and are subject to interpolation.

The increase in the steady-state- and transient-stability limits caused by the presence of the shunt reactor on the generator bus is substantially independent of the length of the line. The increase in the transient-stability limit caused by the reactor is essentially independent of the type of fault and of the fault-clearing time.

In view of the large increase in the kilovolt-ampere generator capacity required by some shunt reactors on the generator bus, the economic benefits from the increase in stability limits due to their presence must be balanced against the cost of the reactors, as well as the expense of the incremental generating capacity which must be installed, including associated housing and other equipment. It should be borne in mind, however, that it is necessary to increase the capacity of the prime-mover equipment only to the extent of supplying the losses in the incremental generating capacity and in all reactors. In so far as reactors are concerned, air-core units may be used. In general, the installation of shunt reactors on the generator bus would be economical in cases of which the following may be representative:

1. When the reactors require a comparatively small increase in generator capacity.
2. When they are to be installed in a system where the total installed generating

capacity is small, so that the addition to it of the high percentage required by the reactors is not excessive.

3. When a transmission line is fed from a bus of a large generating system supplying a large local load at a small annual load factor, so that reactors may be installed without adding to the existing generating capacity.

Other Methods for the Increase of Stability Limits

Various means have been proposed to increase the stability limits of transmission systems. Of these, such methods as shunt static condensers, series synchronous condensers, inductive compensating generator, series loading resistors, quadrature booster transformers, tuned line, neutralizing networks, frequency changers, and other conversion equipment have not been used in the present study. High-speed exciters are not used, because they bring about a very small gain in the stability limit at fast fault-clearing times. The construction of additional circuits or the shortening of the line sections provides only a slight increase in the stability limit, and hence both are hardly economical.

Series capacitors are another major device proposed to overcome stability limitations of long lines. It has recently been shown[28] that series capacitors offer great promise so far as the steady-state-stability limit is concerned. They should, however, be studied under fault conditions in order not only to ascertain to what degree they are effective in overcoming the transient-stability limitations, but also to make sure that they operate properly at the high voltages which under fault conditions may take place in the 230- and 345-kv lines. The means for such an investigation were not at the disposal of the writer, and so this device was not applied to the systems reported in this study.

Four additional methods which are used for the increase of stability limits of the systems designed are:

1. The decrease of the transient reactance of the generators.
2. The increase of their inertia constant.
3. Generator damper windings.
4. High-speed switching.

All these methods are well known; nevertheless the following will be pointed out:

The increase in the transient-stability limit, because of the decrease of the generator transient reactance, is essentially independent of the fault-clearing time, while that obtained from the increase of the inertia constant does depend upon it. On the other hand, the beneficial effect obtained from lowered transient reactance is usually secured at a slightly higher cost. In some systems the inertia of the receiving-end machines may be controlled by the system designer; in the systems of this study the constants of the receiving-end rotating equipment are assumed to be fixed. Damper windings of both high and low resistance serve to improve the transient-stability limit; the former provide negative-sequence damping while a dissymmetrical fault lasts, while the latter have an appreciable positive-sequence damping action after the fault is cleared. Whenever, in the systems reported, dampers are said to be required, they are assumed to be of high resistance. It is felt, however, that the type of dampers to be used must be decided on the merits of the individual case, and that this has little effect on the magnitude of the stability limit. It should be borne in mind that the increase in the transient-stability limit due to the dampers depends on the switching time as well as on the type of grounding of the sending-transformer neutral. By far the most effective factor affecting the transient-stability limit of a system is the fault-clearing time; the high-speed circuit breaker may hence be considered the major device for this purpose. The effect of the fault-clearing time on the increase of the stability limit, with various types of faults, is well known and has already been reported.

In every long transmission system the tower-footing and fault resistance makes a small contribution to the increase of its transient-stability limit. In the zero-sequence network represented on the network analyzer, the tower-footing resistance was omitted. Still, in each system a small fraction of the ultimate limit of its transient stability is credited to the improvement caused by the tower-footing and fault resistance.

Design Features Required by the Transient-Stability Conditions Imposed

From the transient-stability limit of systems at 10.5 cycles fault-clearing time, as given in Table IV (part I of paper), it will be seen that there is a group of six systems, namely, systems 0-2*a*, 0-4*a*, 0-5*a*, 0-7*a*, 0-10*a*, and 0-13*a*, whose transient-stability limit is either very close to 100 per cent or exceeds it. These systems therefore require no special devices for the increase of stability limits. In fact, in some cases the fault-clearing time could exceed 10.5 cycles and still the condition of 100 per cent transient stability would be met. In spite of this, standard eight-cycle circuit breakers are provided for these systems, thus securing in some of them a margin between the rating assigned and the transient-stability limit. The additional generators and transformers which this would permit are not installed at this time; however, these systems will be somewhat more economical when full advantage of transmission capacity is taken. The problem of system expansion is not considered in this study.

The remaining systems are divided into two groups. To the first group belong systems whose transient-stability limit is below 100 per cent but which have a reasonable margin—from 16.0 to 62.5 per cent—between the line rating and its steady-state-stability limit under emergency circuit conditions. These are systems 0-1*a*, 0-3*a*, 0-6*a*, 0-8*a*, 0-9*a*, 0-11*a*, 0-12*a*, 0-14*a*, 0-17*a*, 0-19*a*, 0-20*a*, 0-26*a*, 0-27*a*, and 0-29*a*. Here, as a rule, the high-speed circuit breaker is used to increase the transient-stability limit; and in addition to this, where it is found necessary, either the generator transient reactance is reduced from 35 per cent standard value to 30 per cent, or a damper winding is added. In some systems of this group it sufficed to lower the generator transient reactance to 30 per cent, without having to apply high-speed circuit breakers. On the three 250-mile lines the mid-point intermediate condenser of kilovolt-ampere capacity necessary for a 50 per cent system load has been installed. This is resorted to primarily for the purpose of increasing the transient-stability limit rather than for any other reason.

To the second group belong systems with a small margin between the line rating and its steady-state-stability limit under emergency circuit conditions. These are systems 0-15*a*, 0-16*a*, 0-18*a*, 0-22*a*, 0-23*a*, 0-24*a*, 0-25*a*, 0-30*a*, 0-31*a*, and 0-32*a*. Here the steady-state-stability limit under emergency circuit conditions is either 4.0 to 8.5 per cent above the line rating or 4.5 to 20.0 per cent below it. In these systems the steady-state-stability limit is raised first by lowering considerably the generator transient reactance. This affects the short-circuit ratio of the generator, and through it the steady-state-stability limit of the system. For the same purpose, the generator bus is loaded with shunt reactors, where necessary, with a corresponding increase of the kilovolt-ampere generator capacity. On all the 250-mile and 500-mile lines of this group, intermediate condensers are installed for a 50 per cent load on the system.

Where not specifically indicated, generator transient reactance and generator inertia are standard (as taken in the study).

Per cent reactor on generator bus is on the generator base prior to the increase in generator kilovolt-amperes required by the reactor.

Intermediate synchronous condensers placed in kilovolt-ampere capacity for 50 per cent load.

Although here the primary purpose is to prevent the voltage from rising with a smaller than 100 per cent load, the installed intermediate condensers serve well the purpose of increasing the system steady-state-stability limit. The margin between the system rating and its steady-state-stability limit under emergency conditions having been improved, means are applied which increase primarily the transient-stability limit, such as grounding of the sending-transformer neutral, increased generator inertia, damper windings, and high-speed circuit breakers. It will be noted that the transient-stability limit of these systems as originally obtained is well below 100 per cent; hence the application of several devices is required. System 0-28*a*, although by definition not in the second group of systems, is treated substantially in a similar manner.

Since the opening time of the high-speed circuit breakers is not standardized, their speeds have been specified as required by the system analysis. In every system, from one to three per cent of the stability limit attained is credited to the tower-footing and fault resistance.

Table VI gives the list of the various methods for overcoming stability limitations which were applied to the systems studied. With these design features the transient-stability limits are brought to the 100 per cent system rating with a double line-to-ground fault. Additional calculations will show the changes necessary when other types of faults are considered. The methods applied in particular cases may be somewhat modified, according to the preference of the designer.

The table shows very interesting examples of the various methods required for the improvement of stability when either the magnitude of the block of power transmitted, the transmission voltage, or the length of the line is modified. The results of changing the transmission voltage alone may be observed in comparing system 0-3*a* with 0-4*a*, 0-12*a* with 0-13*a*, or 0-16*a* with 0-17*a*. In case 0-16*a*, for example, it was necessary to apply practically all methods of improvement in order to transmit 250,000 kw at 230 kv over a distance of 250 miles; in case 0-17*a*, however, when 345 kv was used as the sending-end voltage, the same result was accomplished with generators of standard design using three-cycle circuit breakers.

Summary and Conclusions

Results of the system study may be summarized as follows:

1. The steady-state-stability limit is given for a number of systems transmitting 50,000 to 800,000 kw (at the receiving end) over distances ranging from 50 to 500 miles at sending-end voltages of 69 to 345 kv. When represented in the form of curves, the data permit the determination by interpolation of the stability limit of various systems whose transmission distance, voltage, and power are within the range investigated.

2. For the same systems, the transient-stability limit is obtained for the condition of a double line-to-ground fault near the sending-end bus, cleared in 10.5 cycles, with the loss of a circuit or a section of it. The data may be used to determine by interpolation the transient-stability limit of various systems in a manner similar to that used in determining the steady-state limit.

3. The transient-stability limits of two systems of similar configuration are related by a simple expression (equation 2) permitting the calculation of the transient-stability limit of one system from the known transient-stability limit of another system when basic data on both systems are available.

4. A set of curves is suggested from which it is possible to estimate rapidly the steady-state-stability limit of transmission systems of a certain type.

5. Curves and expressions are given from which the transient-stability limit of a system may be estimated for double line-to-ground, line-to-line, and line-to-ground faults (equations 3, 4, and 5) cleared in 10.5 cycles. The possibility of modifying the expressions to be used with faults of any duration is indicated.

6. It is suggested that possibly the time required for determining on the network analyzer the system transient-stability limit may be shortened, by making observations on the angles of the system machines.

7. The intermediate synchronous condenser is far more effective in increasing the steady-state-stability limit of the line than in increasing its transient-stability limit. While on a 500-mile line the optimum number of intermediate-condenser stations increases the steady-state-stability limit by 45 per cent, it increases the transient-stability limit by only about 12 per cent.

8. The intermediate synchronous condenser is more than twice as effective on the 500-mile line as it is on the 250-mile line.

9. On a 250-mile line the optimum number of intermediate-condenser stations is one; on a 500-mile line, two. The location of

intermediate-condenser stations is best where they divide the line into sections of equal length. Doubling the size of the intermediate condenser raises the system stability limits by about ten per cent.

10. Substitution of reactors for lagging intermediate condensers lowers considerably the system stability limits.

11. The primary purpose in placing the intermediate synchronous condensers on long lines should be to raise the steady-state-stability limit of the line, and to prevent the voltage at the intermediate points from rising with smaller than 100 per cent loads. Since the kilovolt-ampere capacity of the intermediate condenser required by the 100 per cent load is smaller than that required by lighter loads, the intermediate condensers should be installed as required by the latter condition.

12. The resistance in the neutral of the sending transformer increases substantially the transient-stability limit. Within the range of the systems investigated, the increase is the largest on a 50-mile line, and reaches a minimum on lines about 250 miles long. As the line length approaches 500 miles, the effectiveness of the resistance increases.

13. Within the investigated range of resistances in the sending-transformer neutral—from 5.8 to 17.5 per cent—no particularly critical value affecting the stability limit has been found, thus leading to the conclusion that selection of the resistance size should be based on considerations other than stability.

14. The shunt reactor on the generator bus increases the stability limits very appreciably. The increase obtained in the steady-state-stability limit is considerably greater than that secured in the transient-stability limit. With a 40 per cent reactor, the steady-state limit increases about 60 per cent, while the transient-stability limit increases more than 35 per cent. The larger the reactor, the smaller its effectiveness. Curves are given showing the increases in stability limits obtained from reactors of various magnitudes.

15. The increase in the stability limits caused by the shunt reactor on the generator bus is essentially independent of the length of the line, the type of fault, and the fault-clearing time.

16. The shunt reactor on the generator bus requires that the installed kilovolt-ampere capacity of generators be correspondingly increased. The smaller the reactor, the larger the required additional generating capacity. Curves are given showing the size of the shunt reactor to be placed when a certain increase in the transient-stability limit is desired; a curve is also given for the required additional kilovolt-ampere generator capacity.

17. The transient-stability limit of each system studied has been raised, where required, to the desired 100 per cent value by applying the various methods serving this purpose. The methods depend on the margin between the desired rating of the system and its steady-state-stability limit under the emergency circuit condition. The results illustrate (Table VI) the effect of the line length and its transmission voltage on the means to be applied.

Emergency Overloading of Air-Cooled Oil-Immersed Power Transformers by Hot-Spot Temperatures

V. M. MONTSINGER
FELLOW AIEE

P. M. KETCHUM
ASSOCIATE AIEE

Synopsis: The paper points out that during the period of the war the need for obtaining maximum transformer overload capacity is very great, particularly under rare emergency conditions. From a thermal standpoint, the amount of overload is limited by the hottest spot in the transformer winding. To obtain accurate data

1. On the actual hot-spot temperatures under rated load conditions

2. On the increase of the hot spot with load under both ultimate moderate overload and heavy short-time overload conditions

approximately 50 heat runs were made on several power transformers of different ratings, representing a wide variety of design conditions. The results of the tests are given in the paper.

The subject of how heavy overloads affect the life of transformers, is discussed and temperature limits somewhat higher than those given in the American Standards, Guides for Operation of Transformers, are suggested. Calculated short-time overloads are given to show the effect of transformer characteristics on overload values.

THE subject of overloading power transformers has been discussed in several AIEE papers,[1-3] and the American Standard *C*-57 gives recommendations on overloading transformers continuously in cool ambients, and in applying short-time overloads under recurrent and emergency conditions.

When the recommendations were first drawn up by the AIEE transformer subcommittee, considerable conservatism was used in the curves for short-time overloading, for two reasons:

1. It was a departure from a long-standing practice of permitting no overloading, a practice based on the assumption that temperature was the only factor that caused the aging of insulation. That is, "time" had not yet been recognized as an important factor. In fact, until 1922 the AIEE Standard stated that the name-plate rating must not be exceeded, "whatever be the ambient," and 105 degrees centigrade was considered the ceiling for hottest[a] spot temperatures for class *A* insulation until as late as 1934 or 1935.

2. The overload curves were purposely made safe for transformers having the highest hot spots under overload conditions.

While the practice of overloading transformers has been on the increase during the past few years, the importance of taking advantage of the maximum overload capacity has never been so great as it is today. It is important in two ways:

1. In many cases the demand for additional electric power has caught up with or even exceeded the present transformer capacity—when operated in the usual manner—and additional capacity is needed. A great many loading curves show that the load factor of most power transformers ranges from 50 to 65 per cent. A large reservoir of capacity is therefore available which could be used without causing a serious shortening of transformer life. This problem was discussed by one of the authors in 1940.[3]

2. We now have the important problem of taking care of rare emergency conditions caused either by electrical failure or by a saboteur. In the past it has generally been considered necessary to carry a spare transformer or a spare bank of transformers to pick up the load in case of a failure. Today many users are considering the use of, and are relying on, the short-time overload capacity of their transformers to carry them through rare emergency conditions. In fact, under some conditions it may be economical and necessary to use up 25 per cent, 50 per cent, or more of the transformer life to prevent a shutdown. To do this intelligently requires reliable information on how to calculate hot-spot temperatures and how the life of the transformer is affected by heavy overloads. The purpose of this paper is to discuss this problem.

I. Hot-Spot Temperatures in Transformers

Heat Runs Made

Since the rate of the deterioration of insulation in a transformer is governed by the hot-spot temperature in the winding, it is quite important to have accurate data on:

1. The value of the hot-spot temperature in various classes of transformers at rated load.

2. A practical method of calculating the hot-spot temperature with changes in the load under both ultimate and short-rime overload conditions.

To obtain such data, approximately 50 heat runs were made during the past year on three transformers of different ratings, one of which was operated

(*a*). As self-cooled.

(*b*). As forced-air-cooled.

The transformers were of the following ratings:

1. *H*-60-2,000 kva—34,500-volt class.

2. *H*-60-2,500 kva—34,500-volt class.

3. OAP[b]-60-2,500/3,125 kva—50,000-volt class.

Some of these tests were made using the loading-back (bucking) method, and some using the short-circuit method, to supply the losses.

Measurement of Hot-Spot Temperatures

Before the heat runs were made on the above transformers, a series of tests was made on a few coils in which thermocouples were embedded between turns to determine the most practical method of measuring the hot-spot temperature, since it is not practical to insert thermocouples between the turns of transformer windings. Figure 1 gives time-temperature curves for three heat runs with 1,500, 2,240, and 4,510 amperes per square inch. These tests showed that a thermocouple inserted under a spacer and in contact with the top surface of a horizontal coil represented very closely the hot spot in that coil. The coil second from the top was used for hot-spot measurements in each of the transformers mentioned above. No extra insulation, such as tape often placed on buffer coils, was used on these coils.

Effect of Change in Viscosity of Oil on Temperature Rise

To determine the effect of changes in viscosity of the oil with temperature on the winding rise over adjacent oil, several tests holding a constant loss were made on the previously mentioned small coils immersed in oil, whose temperature ranged from 35 to 100 degrees centigrade. The curves shown in Figure 2 were derived from these test data, together with the data given in Figure 21b, page 314, of reference 4. These curves are in close

a Referred to hereafter as "hot spot."

Paper 42-115, recommended by the AIEE committee on electrical machinery for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted April 13, 1942; made available for printing May 19, 1942.

b Oil-immersed air pressure.

agreement with similar data given in reference 5.

Determination of Average-Winding Rise at Shutdown

All initial winding temperatures were obtained by cooling curves taken for at least ten minutes' duration. A comparison of the values tested and values calculated by the American Standards Association method (based on Figure 13 of reference 8) showed exceptionally close agreement, being within 0.1 to 0.5 degree centigrade in practically all cases. Extreme care was taken to obtain accurate cold winding temperatures.

Determination of Hot-Spot Temperatures

The determination of hot-spot temperatures in transformers either by tests or by calculation, must be considered in two stages:

1. Oil rise over ambient.
2. Hot-spot rise over oil.

The first stage is easier to determine than the second stage. The principal purpose in making the tests was to investigate the second stage—the hot-spot rise over oil and its variation with load.

Methods have been available[4,7] for several years for calculating either ultimate or transient oil rises. That is, for ultimate conditions $\theta = KW^n$ where $n = 0.8$, and for transient conditions,

$$\theta=\theta_u(1-\epsilon^{-\frac{T}{B}}) \qquad (1)$$

Where

θ = oil rise in degrees centigrade
θ_u = ultimate rise, degrees centigrade
ϵ = 2.718
T = time in hours
B = time constant[c] expressed in hours

$$=\frac{\theta_u C}{W}$$

$$C=\frac{3.5\text{ lb (copper+core+}^2/_3\text{ tank)}+90\ G}{60}$$

W = loss in watts
G = gallons oil (U. S.)

There are two points, however, in the calculation of transient oil rises that need mentioning. When using equation 1, it was found that the calculated oil rises checked quite well the test rises obtained by the loading-back method, but did not check the test values obtained by the short-circuit method of loading. The principal difference in the two methods of loading is, of course, that in the loading-back method the temperature of the core keeps well ahead of the temperature of the oil due to excitation losses. On the other hand, in the short-circuit method, the temperature of the core lags the oil temperature. It was found that if the core weight was not used, the calculated values checked quite well the short-circuit test values. For example: for the OAP-60–2,500/3,125 kva size tested, $B = 3.7$ when the core weight was included, and 3.0 when the core weight was omitted. The calculated and tested top oil rises using the two methods of loading, are shown in Table I.

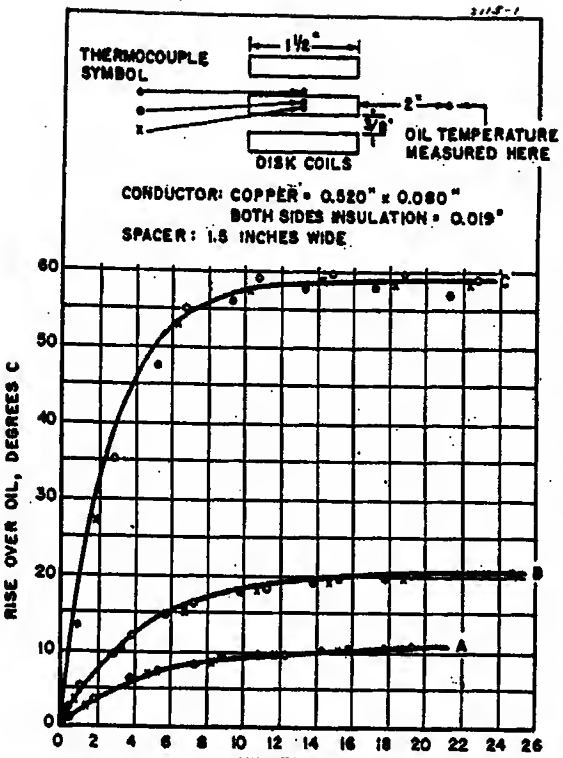
Short-circuit runs are, of course, of no importance under service conditions. They are discussed here, because it is more convenient to use this method when making heat runs (*a*) to measure hot-spot temperatures, and (*b*) to obtain transient oil-rise data (sometimes requested by customers); and it is well to remember that equation 1 should be modified (by omitting core weight) when calculating the oil rise. This same modification has been found necessary in other cases where the short-circuit method was used to obtain transient oil rise data.

The other point found was that for heavy short-time overloads the best results are obtained by using the time constant corresponding to that for ultimate rated load, although theoretically it should be based on ultimate (calculated) conditions using the initial loss in

$$B=\frac{\theta_u C}{\text{loss}}$$

and the final oil rise θ_u for the ultimate loss corresponding to the final winding temperature. While this method can be used for moderate overloads as was done in reference 7, it did not give even ap-

c Time to reach 63 per cent of the ultimate rise, or time to reach ultimate rise if all heat is stored.



RUN	AMPS./SQ.IN.	θ_u °C	B*	FINAL OIL TEMP. °C

Ultimate	33.9	33.9	Ultimate	42.9	42.9	42.9

* Core weight not used in deriving this value.

proximately correct results for the 200 per cent and 270 per cent loads. The method that gave approximately correct results was to base θ_u in equation 1 on the calculated ultimate rise for the loss at the end of the overload and use the time constant derived from rated load conditions. This was done for the two overloads shown in Table II, which gives comparative tested and calculated oil rises for the *H*-60–2,500-kva transformer.

The calculations given in Table II show that fairly accurate results were obtained using the rated load (total loss) time constant of 3.17, and indicate that results close enough for practical purposes can be obtained by the simpler method 1 instead of method 2 (described in the footnote). Heat runs made on other transformers confirmed these findings. However, if the initial rise is changing (that is, not ultimate for a given loss) and is well along—over 30 to 40 per cent of the ultimate rise—method 2 should be used. The use of the same (rated load) time constant simplifies the calculations of transient oil rises for short-time overloads.

Table II. Comparison of Tested and Calculated Top Oil Rises—Short-Circuit Runs—2,500-Kva Transformer

$B=3.17$—Time Constant Computed by Omitting Core Weight

Method 1			Method 2		
	Top-Oil Rise Over Initial Rise (Degrees Centigrade)			Top Oil Rise Over Ambient (Degrees Centigrade)	
Time (Hours)	Test	Calculated	Time (Hours)	Test	Calculated*

0	0.0	0.0	0+1.0	11.9	11.9
2	14.8	15.0	2+1.0	26.7	26.7
4	22.0	22.6	4+1.0	33.9	34.6
6	27.0	27.0	6+1.0	38.9	38.8
8	29.4	29.2	8+1.0	41.3	41.0
10	31.0	30.4	10+1.0	42.9	42.4
Ultimate	31.8**	31.8	Ultimate	43.7	43.7
			Time to reach 11.9 C rise=1.0 hour		
200 Per Cent Rated Load Current Run (Final Loss 91 Kw)					
0	0.0	0.0	0+0.35	12.0	12.0
1	25.3	27.9	1+0.35	37.3	40.4
2	46.7	48.5	2+0.35	58.7	60.4
2.75	59.3	59.7	2.75+0.35	71.3	72.1
Ultimate (Calculated)		103.0	Ultimate (Calculated)		115.0
			Time to reach 12.0 C rise=0.35 hour		
Calculated final oil rise=115 C. Initial oil rise=12.0 C. θ_u=115.0−12.0=103.0 C for method 1, and 115 C for method 2.					
270 Per Cent Rated Load Current Run (Final Loss 170 Kw)					
0	0.0	0.0	0+0.36	20.3	20.3
0.50	23.1	25.1	0.50+0.36	43.4	45.2
0.92	40.4	42.7	0.92+0.36	60.7	63.9
Ultimate (Calculated)		169.7	Ultimate (Calculated)		190.0
			Time to reach 20.3 C rise=0.36 hour		
Calculated final oil rise=190 C without resistance correction. Initial oil rise=20.3 C. θ_u=190.0−20.3=169.7 C for method 1 and 190 C for method 2.					

* Calculated by finding time from Figure 3 to attain rise over ambient at start of overload and then continuing from this time on to end of overload. For example: for the total loss runs, it would require one hour to reach 11.9 degrees centigrade rise. One hour is then added to each succeeding time period and 43.7 degrees centigrade is used for θ_u instead of 31.8 degrees centigrade.

** 43.7−11.9=31.8

* By using calculated hot-spot rise over top oil for self-cooled rated load and then varying rise over top oil as loss$^{0.8}$.

Determining Hot-Spot Rise Over Oil

The determination of the actual hot-spot rise over the oil (and over the average winding temperature) at rated load for different design conditions, and the variation of the hot spot with load, involves several factors not so easy to determine as they are for oil temperature rises. Among these are:

1. Vertical oil gradient as affected by the center of heat[d] with respect to the center of the cooling circuit (radiators, tube headers, and so forth).

2. Accurate determination of the oil temperature adjacent to that part of the winding having the maximum temperature rise.

3. Effect of blanketing of
   (*a*). Part of coil area by spacers.
   (*b*). Total coil area by tape.
   (*c*). Extra turn insulation often used in buffer coils

4. Effect of change in viscosity of oil and change in resistance with temperature—minor factors, as one tends to counteract the other.

5. Transient temperature rise (when the duration of time is under 15 to 20 minutes).

As previously mentioned, it was for the purpose of obtaining more accurate data on these factors (than have been available heretofore) that tests were made during 1941 on five different design conditions—three different designs, one of which was tested under three different vertical oil gradient conditions.

First Series of Heat Runs (Loading-Back Method)

Figure 4 shows the location of thermocouples in the *H*-60–2,000-kva transformer tested first, as self-cooled, and second, as OAP–2,660-kva with temporarily mounted fans. In both series of tests 53 degrees centigrade high-voltage winding rise was produced by blanketing some of the tube headers. To protect the ther-

d Usually a point half-way up the coils and core.

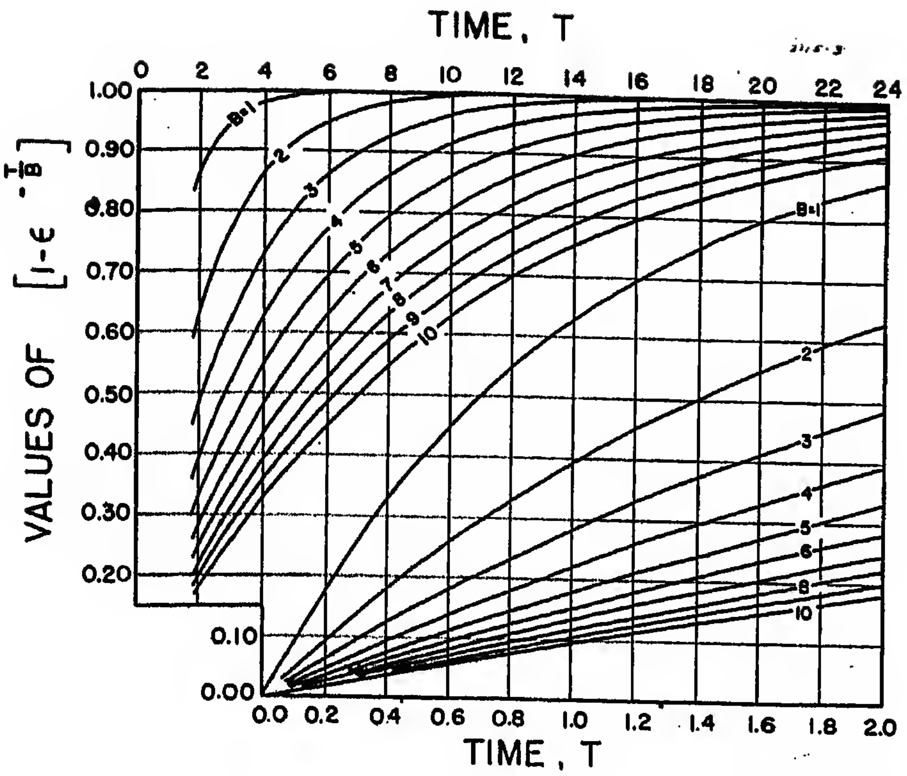

Figure 3. Transient heating curves

mocouples placed under the spacers resting on the next to top coil from dangerous voltages, the coil crossover at this point was grounded during the tests. Figure 4 also shows the vertical temperature gradient of the oil for the 100, 125, and 200 per cent load self-cooled runs. The OAP oil gradients were essentially of the same shape.

Table III gives the final temperature readings. Figure 5 shows in curve form the hot-spot rise:

1. Over average winding temperature.
2. Over top oil.
3. Over high-voltage oil duct temperature.
4. Average winding rise over average oil temperature.

These data show:

1. The hot-spot rise over average winding temperature was between four and five degrees at rated load and varied as $\text{loss}^{0.75}$.

2. The hot-spot rise over top oil (and over maximum observed oil) varied as loss raised to approximately 0.8 power.

3. The average winding rise over average oil temperature[e] varied as $\text{loss}^{0.7}$.

4. The temperature throughout the main body of oil above the top of the core was approximately constant.

Second Series of Heat Runs (Short-Circuit Method)

The second series of heat runs was made on the transformer rated *H*-60–2,500 kva under three different design conditions, namely:

1. With core and coils resting on bottom of tank—"normal position."

2. With center of heat (half-way up core and coils) raised to be level with center of cooling tubes—"maximum raised position."

3. With center of heat in "intermediate position."

Figure 6 shows the locations of the windings, thermocouples, and vertical oil gradients for each of the three conditions tested. It will be noted that raising the core and coils increased the vertical oil gradients, these being indicated in Table A.

[e] The average oil temperature is taken as the top oil minus one-half the temperature drop through the cooling tubes.

Table A

Position of Core and Coils	Difference Between Top and Bottom Oil Inside Tank (Degrees Centigrade)
Normal	15.0
Intermediate	25.0
Maximum raised	40.0

Figures 7, 8, and 9 show the oil and winding rises for this series of tests. Curve *E* shows the effect of raising the center of heat on the hot-spot rise over the average winding temperature. At rated load the rises, as read from the curves, were:

(*a*). 5.1 degrees centigrade for the normal position.

(*b*). 14 degrees centigrade for the intermediate position.

(*c*). 18 degrees centigrade for the maximum raised position.

It is, of course, proper to point out that most power transformers fall in the (*a*) condition where the center of heat is well below the center of cooling tubes. The (*c*) condition, where the center of heat and center of cooling tubes are at the same level, is one that seldom exists in practice.

Table IV gives the final readings for 20 of the 32 runs made. The 12 additional tests were check runs of two to three hours' duration, made only for obtaining winding temperatures, and were not run until the top oil rises again became constant.

The Thermal Circuit

The thermal circuit in a self-cooled transformer is composed of the tempera-

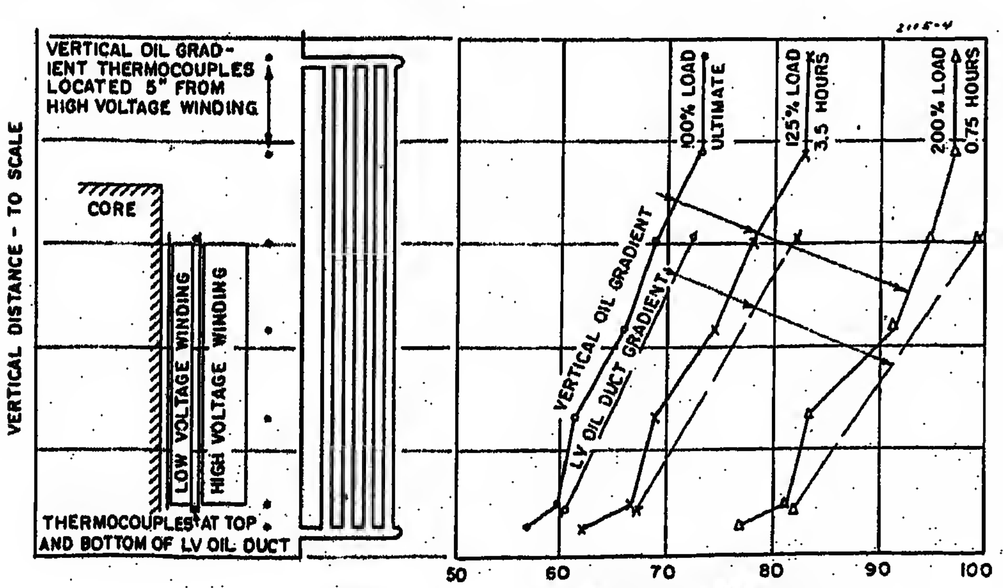

Figure 4. Temperature gradients during loading-back heat runs on *H*-60–2,000-kva transformer

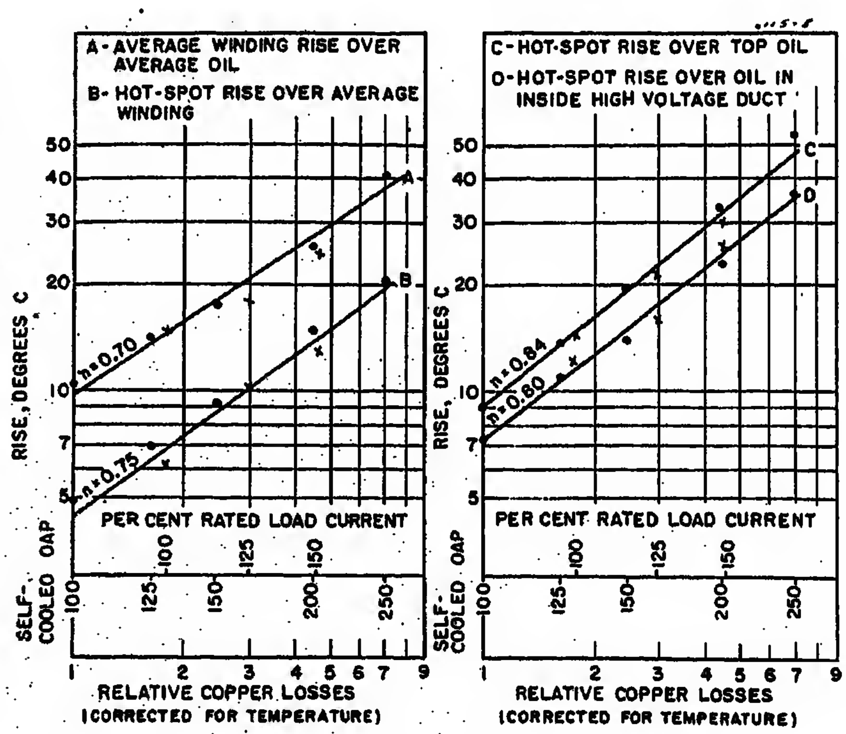
Figure 5. Temperature rises during loading-back heat runs on *H*-60–2,000-kva transformer



ture rise of the oil flowing upward through the coil stack and the temperature drop in the oil flowing downward through the attached tube headers or radiators.

The height of the center of heat (center line of core and coils, or of coils only, for short-circuit runs) with respect to the center of the cooling agent, controls the temperature rise and temperature drop of the thermal circuit for ultimate conditions. Also, when the center of heat is well below the center of the cooling agent, the temperature rise and temperature drop in the thermal circuit are small and do not appreciably increase within a reasonable range of loads for ultimate conditions. But, for short-time heavy overloads, while the temperature drop in the cooling circuit may not appreciably increase in value, the temperature rise of the oil flowing upward may greatly increase. For example: for the normal position, there was no appreciable change for all the ultimate runs in either the temperature rise or temperature drop of the thermal circuit. On the other hand, for the 200 per cent and 270 per cent short-time runs, the temperature drop in the cooling tubes remained essentially the same as for the ultimate runs—while the temperature rise of the oil flowing up through the windings increased approximately 100 per cent over the rise for the ultimate runs. This increase in the oil temperature flowing upward increased the hot-spot rise over the average winding temperature, Figure 7, whereas, if the constant temperature drop in the cooling tubes had been the controlling factor, the hot spot would not have increased with load.

When the center of heat was raised, both the temperature rise and the temperature drop in the thermal circuit definitely increased with load under both ultimate and short-time overload conditions. The temperature drops in oil flowing down through the tube headers, shown in Figure 10, were predicted within one degree for the total loss ultimate heat runs for all three conditions before the tests were made, by the thermal circuit calculations (which have been in use during the past eight or nine years) developed by L. Wetherill and given in his discussion of reference 5.

The following conclusions can be stated:

1. For the normal position, the hot-spot rise over the average winding temperature was between five and six degrees at rated load and increased with load at approximately the same rate as the hot-spot rise over the top oil.

For the two raised positions, the hot-spot rise over average winding temperature defi-

*112 per cent load loss = total (core + copper) loss.

**By using calculated hot-spot rise over top oil at rated load and then varying rise as loss^n where n = 0.8 for normal position, and 0.53 for intermediate and maximum raised positions.

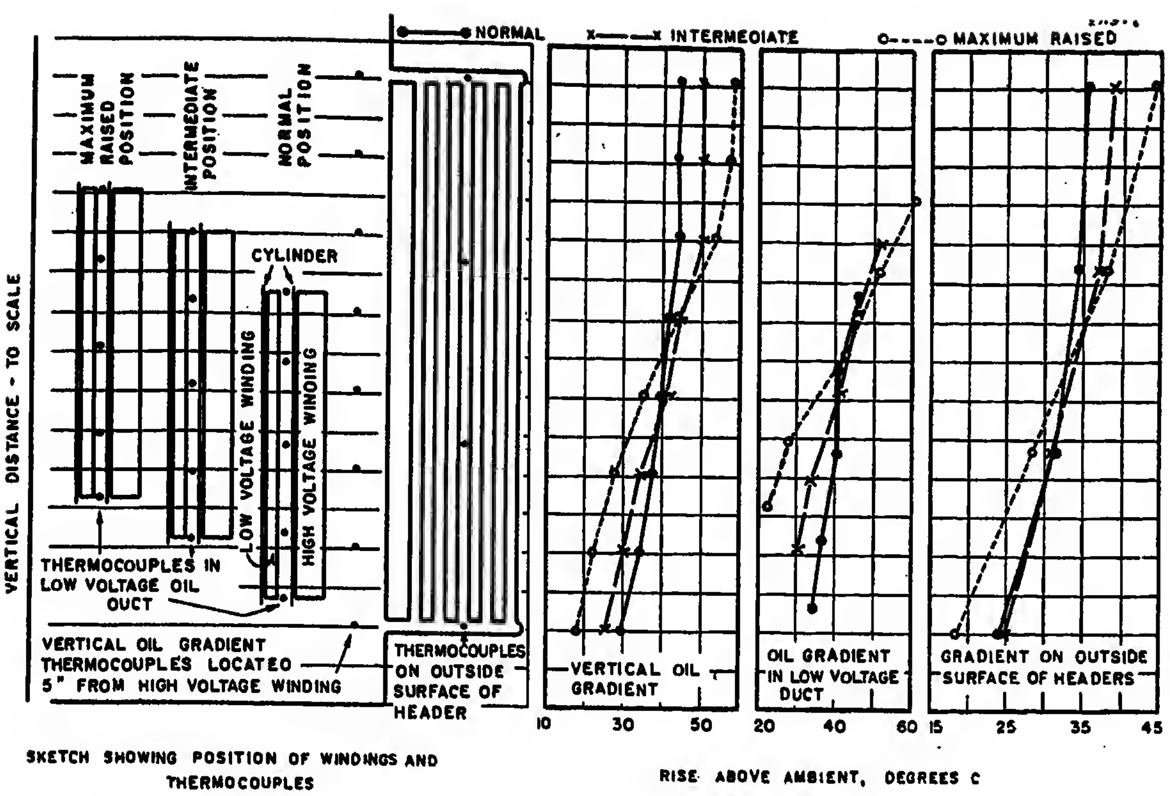

Figure 6. Temperature gradients during short-circuit heat runs on *H*-60–2,500-kva transformer

nitely increased with load for all ultimate conditions, but under short-time overload conditions, the hot-spot rise over average winding was only slightly above the rises for the 135 per cent load ultimate run—see Figures 8 and 9.

2. The ultimate average and top oil rises varied as loss raised to a power ranging from approximately 0.75 to 0.85—the general average being about 0.8.

3. The difference between the top and bottom temperature of the oil in the cooling tubes for ultimate conditions was approximately constant from 100 per cent to 135 per cent load for the normal position, but increased with loss raised to approximately 0.4 power for the intermediate position, and to approximately 0.7 power for the maximum raised position.

4. The hot-spot rise over top oil for both ultimate and short-time overloads varied as loss raised to a power of approximately 0.75 (test points scattered) for the normal position, and approximately as $loss^{0.53}$ for both intermediate and maximum raised positions.

5. The main body of oil above the windings (not core yoke) was at approximately the same temperature.

Third Series of Heat Runs

A third series of heat runs was made on an OAP-60–2,500/3,125-kva transformer in which the losses were supplied

1. By the short-circuit method.
2. By the loading-back method.

Only self-cooled runs were made. The main purpose of these tests was twofold:

1. To obtain comparative tests on short-circuit and loading-back heat runs to determine the effect of the loss in the core (top yoke) on the hot-spot rise over top oil.

2. To obtain additional data on the hot-spot rise over the average winding temperature for both transient and ultimate conditions.

The data for this series of tests are given in Table V, and some of the data are plotted in Figure 11. These data show:

1. The hot-spot rise over the average winding temperature was between five and six degrees at rated load, and increased as $loss^{0.8}$ for both the short-circuit and loading-back runs.

2. The hot-spot rise over top oil (when corrected to the same oil temperature) was approximately the same for both short-circuit and loading-back methods of loading. In other words, the short-circuit method of loading can be used to obtain hot-spot temperatures in transformers. The rise varies as $loss^{0.8}$.

3. The average winding rise over average oil varied as $loss^{0.7}$.

Variations of Hot Spot With Load

Vogel and Narbutovskih[5] reported that the hot-spot rise over average winding rise of a 600-kva transformer was constant from 100 per cent load to 250 per cent load inclusive. These constant hot-spot test values were explained on the grounds that this would be expected since the square root of the product of the losses and oil viscosity was a constant value, which in turn produced an approximately constant difference in the temperature of the top and bottom oil in the radiators. In the tests reported in this paper, Table VI shows the difference between top and bottom cooling tube temperatures and the square root of the product of the loss and oil viscosity for different loads held on the 2,500-kva transformer tested with the center of heat at different levels. These data show that with the core and coils in the normal position this factor was approximately constant except for the 58 per cent load test; but, for the intermediate and maximum raised positions of core and coils, there

*Curve given in Figure 2 of reference 5 used. This curve represents a fairly universal oil.

was a constant increase with load. Yet, the hot-spot rise over the average winding temperature increased with load for all ultimate conditions in all three positions. The temperature drops in the tube headers are plotted in curve form in Figure 10.

The procedure to follow in the general case for calculating hot-spot temperatures with windings similar to those in the transformers tested, is illustrated in the following example.

These assumptions are made:

1. 55 degrees centigrade average winding rise at rated load.
2. 45 degrees centigrade top oil rise at rated load.
3. 10 degrees drop in cooling circuit at rated load.
4. 5 degrees hot-spot increase due to extra coil insulation, spacers, and so forth.

If located at the top the hot-spot rise of the extra insulated coil would be

$$55+\frac{10}{2}+5=65 \text{ degrees centigrade}$$

Under overload conditions after 15 minutes' duration, hot-spot rise would be:

$$A+B\left(\frac{\text{loss at overload}}{\text{loss at rated load}}\right)^{0.8}$$

where

A = temperature rise of the top oil
B = difference between the hot-spot and top oil at rated load

Factors Limiting Short-Time Rare Emergency Overloads

Quite often factors other than the life of the insulation limit heavy overloads for transformers. Among such factors to be considered are, contacts, leads, joints, and oil. Effect of heavy overloads on regulation must, of course, be carefully considered.

Excessive expansion may cause oil to run over. Also, oil deteriorates at high temperatures even for short periods of time, particularly if exposed to air. Figure 12 shows calculated hot-spot and top oil rises for a four-hour 200 per cent load following full load, in a case studied recently. In this case the temperature of the oil was considered the limiting factor.

Effect of Change in Resistance and Oil Viscosity on Hot-Spot Temperatures

Figure 12 also shows the difference in the hot-spot rises obtained when no temperature and viscosity corrections are made as compared with the rises obtained with the corrections. The calculations for 200 per cent load (assuming 20 degrees centigrade hot-spot rise over top oil at 100 per cent load) were made as follows:

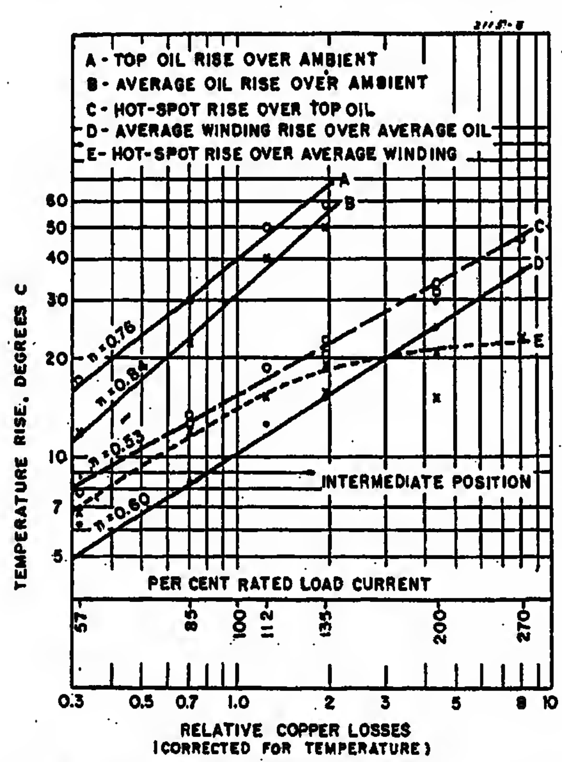

Figure 8. Temperature rises during short-circuit heat runs on *H*-60–2,500-kva transformer

1. WITH NO CORRECTIONS

Hot-spot rise over oil $=20\times 2^{1.6}=60.4$ degrees centigrade after 20 minutes' duration

Hot-spot temperature = top oil + 60.4 degrees centigrade for any time after 20 minutes

2. WITH CORRECTIONS

For $2^3/_4$ hours, oil temperature = 110 degrees centigrade (by Figure 12)
Hot-spot rise over oil =

$$20\left[2^2\times\left(\frac{234.5+177.5}{234.5+95}\right)\right]^{0.8}=72.5 \text{ degrees}$$

centigrade with resistance correction only

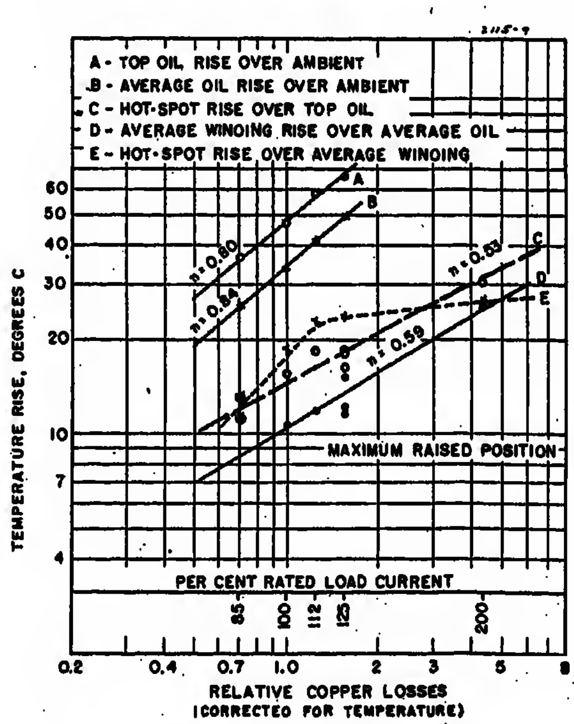

Figure 9. Temperature rises during short-circuit heat runs on *H*-60–2,500-kva transformer

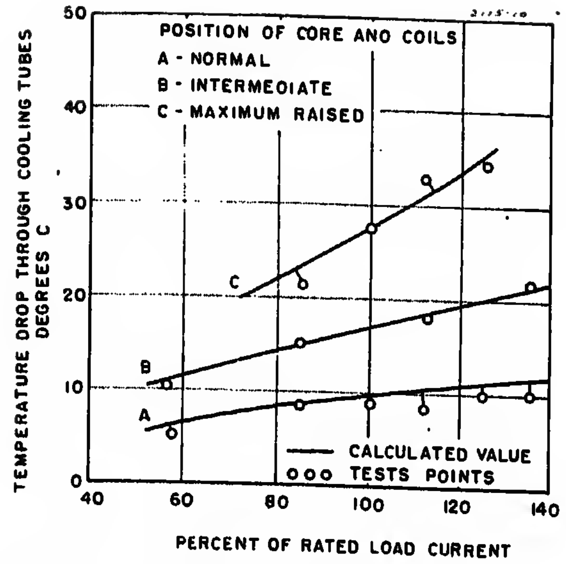

Figure 10. Cooling tube temperatures during short-circuit heat runs on *H*-60-2,500-kva transformer

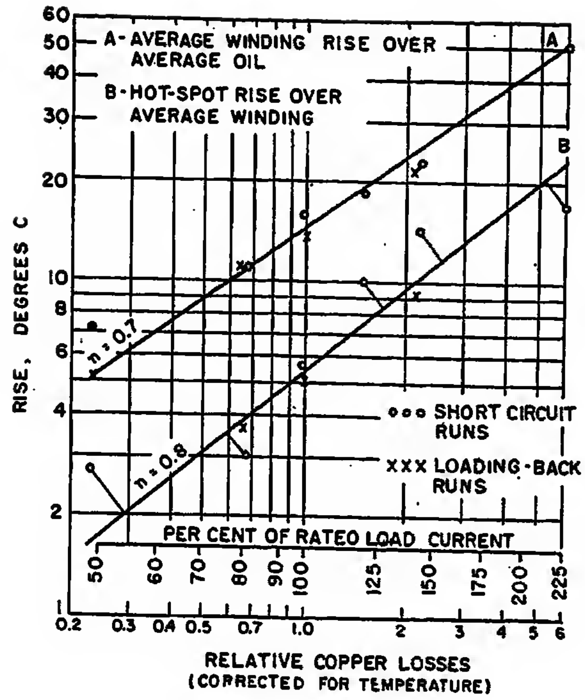

Figure 11. Temperature rises during heat runs on OAP-60-2,500/3,125-kva transformer

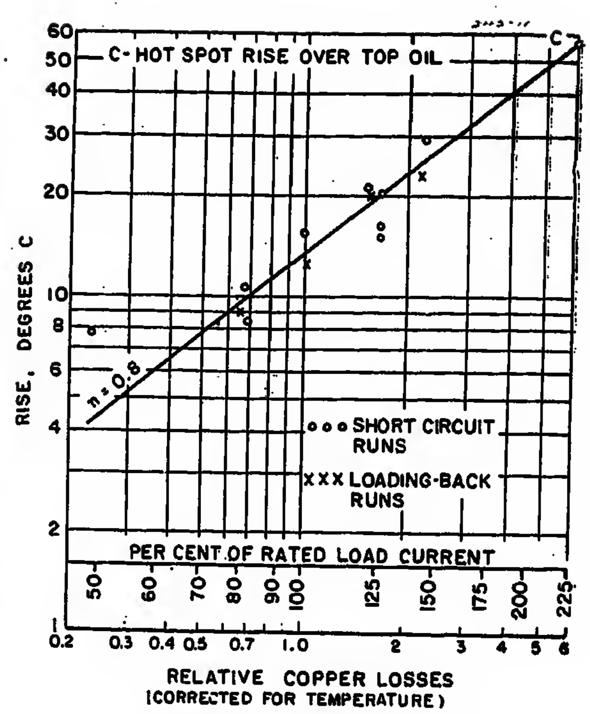

By Figure 2 if the hot-spot rise is 72.5 in 75 degrees centigrade oil, it would be 67.5 degrees centigrade rise in 110 degrees centigrade oil—a reduction of 5 degrees centigrade due to viscosity correction.

The correct hot-spot temperature is, therefore, $110+67.5=177.5$ at $2^3/_4$ hours, as against $110+60.4=170.4$ degrees centigrade without the correction.

These curves show that for strictly accurate results both corrections should be made. But, since in making overload calculations the bases of the assumptions are approximations, it should be satisfactory to neglect the corrections. This was done when calculating the overloads shown in Table VII.

Hot-Spot Temperature Indicator Tests

Temperature indicators have been used for several years to indicate hot-spot temperatures in transformers. Since an indicator can be set for any desired hot-spot rise over average winding at rated load, its ability to follow the hot-spot temperature depends

1. On its variation with load current.
2. On the time constant of its heating coil.

To check these variations with load current, a standard indicator heating coil was placed in the top oil of both the 2,000-kva self-cooled /2,667-kva OAP and the 2,500-kva self-cooled transformer.

Figure 13 shows that on the average the indicator rise over top oil varied as the load current$^{1.70}$ or as loss$^{0.85}$, whereas (on the average) the winding hot-spot rise over top oil varies as loss$^{0.8}$. This means that for heavy overloads the indicator will read a little too high, and it may be well to retain this feature. The time constant of the standard indicator heating coil is approximately the same as the time constant of transformer windings; consequently the indicator should follow the hot-spot temperature under both fluctuating loads and overloads.

General Conclusions on Steady-State and Transient Temperature Rises

1. For rated load conditions of self-cooled power transformers, the hot-spot rise over average winding temperature by resistance ranges from approximately five degrees centigrade upward. For moderate size and voltage rating (below approximately 50 kv), it naturally comes between five and six degrees. But, for large size and high-voltage rating, steps have to be taken by the designer to limit the hot-spot to ten degrees centigrade above average.

2. For transformers having an OAP rating 1.33 times the self-cooled rating, the hot-spot rise over average winding temperature is approximately 40 per cent greater than that for the self-cooled rating (see Table III).

3. The hot-spot rise over average winding temperature increases with load (for both ultimate and short-time overloads), but no definite rate of rise versus loss can be stated (see Figures 7, 8, 9, and 11).

4. The average winding rise over average oil varies as the loss raised to a power ranging from 0.6 to 0.7.

5. The hot-spot rise over top oil varies as the loss raised to a power ranging from approximately 0.7 to 0.8, generally more nearly the 0.8 power for most transformers.

6. The oil time constant used in calculating the temperature rise of the oil for short-time overloads should be based on the ultimate rise and loss for rated load conditions.

7. The winding time constant used in calculating the temperature rise of windings over oil before conditions become constant, should be based on the calculated ultimate rise and loss for the load under consideration.

8. Either loading-back or short-circuit method of loading can be used to determine both hot-spot and average winding temperatures. When calculating the transient oil rises by equation 1, for the short-circuit method the weight of the core should not be used in deriving the time constant.

9. The temperature rise of both the average and top oil varies approximately as the loss$^{0.8}$ for ultimate conditions.

II. Effect of Overloads on Life of Transformers

Life Expectancy of Transformers

The estimated life of a transformer is at best only a rough approximation. The dielectric strength of insulation does not deteriorate until it has become embrittled and cracked. It is possible, therefore, for a transformer to continue to operate long after the mechanical life of its insulation is well used up, unless subjected to excessive mechanical stresses (short circuit, handling, or other mechanical shocks), since its normal stresses are quite low. It does not follow, therefore, that a transformer will fail when its insulation is embrittled; on the contrary, if severely strained, it might fail before the mechanical strength is completely used up.

Rate of Aging of Class-A Insulation

Mr. Clark's paper, presented at this session, shows that for temperatures ranging from approximately 115 to 200 degrees centigrade, the rate of aging is doubled for each six to ten degrees centigrade depending upon the percentage of life used up. That is, near the start a nine- to ten-degree rule applies; at the 50 per cent to 25 per cent life levels an eight-degree rule applies; and near the finish a six- to seven-degree rule applies.

In view of the fact that predicting the life of a transformer, as mentioned above, cannot be exact, the eight-degree rule, which one of the authors has used for several years,[1,3] is a good average value to use.

Mr. Clark's data show also that for temperatures from 75 to 100 degrees centigrade the rate of aging doubles with changes in temperature as low as two to five degrees centigrade. This indicates that it is not possible to use aging data for the higher temperatures and the eight-degree rule to predict the life of a transformer when operating at temperatures of approximately 100 degrees centigrade and below. In fact, Figures 3 and 4 of Mr. Clark's paper indicates that while the life of insulation is a matter of weeks at 120 degrees centigrade, it is a matter of several years if the temperature does not exceed approximately 100 degrees centigrade. While these laboratory tests may not show the actual life of a transformer in weeks and years, they are indicative of the relative life at different temperatures.

Basis for Determining the Life of Transformer Insulation

There is, of course, some question whether laboratory aging tests made on isolated strips of paper in sealed tubes can be applied directly in estimating the life of insulation in a transformer. Such tests should rather be depended upon to furnish the more fundamental data, such as the increase in temperature to double the rate of aging, the effect of the various other factors contributing to the deterioration of insulating materials, and so forth.

In attacking the problem of determining the effect of overloads on the life of transformers, it is felt that for the present it is preferable to rely mainly on past experience in establishing a basis, and then depend upon fundamental laboratory data as an additional aid. For example: we have now had several years' experience in the use of hot-spot temperature limits for emergency overload conditions, and the laboratory tests show how the relative life of insulation is affected by different temperatures.

The hot-spot temperature limits given in section 11.002 of the American Standards Guides for Operation of Transformers under emergency conditions are 115 degrees centigrade for 2 hours, 110 degrees centigrade for 8 hours, and 105 degrees centigrade for 24 hours. When these limits were first set up a few years ago, they were purposely made conservative for the reason that the permitting of overloads on an emergency basis was a departure from a long-standing practice of permitting no overloads, as pointed out in the first part of the paper. Furthermore, no limitations were put on the number of overloads during the life of the transformer.

When the number of operations is limited, it is reasonable to increase somewhat the above American Standards hot-spot limits. Using a rule less than eight degrees for temperatures under 120 degrees centigrade, an eight-degree rule for temperatures from 120 to 192 degrees centigrade, which are in agreement with Mr. Clark's data, and a rule greater than eight degrees above 192 degrees centigrade, in order to reach the present ASA limit of 250 degrees centigrade in five seconds, a schedule of temperatures is suggested in Table B for consideration in setting up emergency overloads.

The use of a rule greater than eight degrees above 192 degrees centigrade appears reasonable, since the actual temperatures (calculated on the basis of all heat stored in the copper) will generally be below the calculated values, for two reasons:

1. The insulation on the conductors will absorb some heat.

2. Most transformer windings start dissipating heat after from three to five seconds' duration.

The temperature limits suggested are in close agreement with values assumed in reference 5 for times of 1/4 hour and longer, being somewhat higher for the short times, and the same for 4, 8, and 24 hours' duration.

Calculation of Emergency Overloads

The overloads for a given hot-spot temperature vary widely, depending on the characteristics of the transformer, such as top oil rise, hot-spot rise over top oil, ratio of losses, and time constant, all of which vary under rated load conditions for power transformers, approximately as shown in Table C.

Based on the temperature limits sug-

Table B

Time, in seconds	5	10	20	30	60	300	
Temperature, degrees centigrade	250	220	200	192	184	165	
Time, in hours	1/4	1/2	1	2	4	8	24
Temperature, degrees centigrade	152	144	136	128	120	115	110

Table C

	Usual Variations	
	Self-Cooled	OAP
Top oil rise over ambient	40 to 50 C	35 to 45 C
Hot spot over top oil	10 to 20 C	15 to 30 C
Loss ratio (copper to iron)	2:1 to 3:1	3.5:1 to 5:1
Time constant	3 to 7	2 to 4.5

gested in Table C, Table VII gives the calculated times rated load current for 1/4 hour to 24 hours inclusive for self-cooled transformers having different characteristics. The present ASA emergency overloads are also shown for comparison. These calculated overloads are given principally for the purpose of showing how they vary for different transformer characteristics. It will, of course, be possible to reduce a group of this kind into three or four classes, since, in several cases, the overload values are of the same order of magnitude. Similar overload values can be calculated in the study of revising the ASA emergency overloads and set up for other types of transformers (OAP, water-cooled, and so forth), which have characteristics different from those for self-cooled transformers.

When calculating the aging during an overload, it may be assumed that the hot spot is maintained during the entire time period. This is not strictly correct, since the hot spot reaches the maximum value only at the end of the time period. The question naturally arises as to how much greater overload could be carried if the aging was based on the actual increasing hot spot and then increased sufficiently to produce the same aging. The increased overload is not so great as might be expected. For example: if we take the 5*a* class of transformer (Table VII) for two hours following full load, and integrate the actual temperature area by the formula given in reference 3, it is found that a maximum temperature of 134.5 degrees centigrade at the end of two hours results by the eight-degree rule in the same aging as 128 degrees centigrade maintained for two hours. The 6.5 degrees centigrade higher hot spot permits a 4.5 per cent greater load. For the eight-hour overload (115 degrees centigrade hot spot) the difference in the overload is only 3.5 per cent, and, for longer times, the difference becomes less and less. Therefore, if it is assumed that the hot spot exists during the entire time period, the error is small and on the safe side.

A Comparison With Laboratory Aging Data

Having arrived at certain temperature limits and overload values, based partly on past experience and partly on the eight-degree rule, it will be interesting to see what per cent of life these proposed temperature limits will use up for a given time period, based on the laboratory tests. The 120 degrees centigrade aging curves shown in Figure 14 of Mr. Clark's paper appear to be the best ones to use for this purpose. For example: using one per cent water content, these curves give the following approximate hours of life at 120 degrees centigrade:

Per cent of original life	50	0
Hours at 120 degrees centigrade	100	430

Taking the 50 per cent life level we have 100 hours/50 per cent = two hours to use up 1 per cent of initial life at 120 degrees centigrade, or one hour to use up one per cent at 128 degrees centigrade which is within eight degrees of the 136 degrees centigrade suggested for one hour. That is, one hour's operation at 136 degrees centigrade would use up between one and two per cent of the life, depending on whether the 136 degrees centigrade temperature was maintained during the entire time, or reached the maximum value at the end of one hour. In the latter case—as pointed out above—the 136 degrees centigrade would be equivalent to several degrees lower continuous temperature. By this process of reasoning and by the assumptions made, the suggested hot-spot limits would use up from one to two per cent of life per operation. Wide variations from these life values would, of course, be obtained for other than one per cent water content. The estimates of life depend entirely upon the assumptions made.

Curve *B*—Corrections made for both temperature and oil viscosity

At any rate, these laboratory tests have brought out very forcibly a new factor that has not been taken into consideration in the past, namely, water content in the insulation. We seem to make progress in steps. In the early days it was assumed that "temperature" alone was the controlling factor, and later it was recognized that "time" was as important as temperature. Now, we have a third factor, "water content," to take into consideration which appears to be fully as important as "time" and "temperature."

Standardizing Emergency Overloads

Before attempting to standardize emergency overloads, the operators' views are needed on some of the factors discussed above. It is recommended that the

ABOUT the year 1929 it first became appreciated that the lightning discharge is not instantaneous. The recognition of this fact had a profound influence upon the theories of lightning protection, the emphasis being diverted from induced to direct strokes[1] as the agent to be guarded against. With the meager information then available the calculations indicated that induced voltages were unimportant when the finite time of discharge was taken into account.[2] The more accurate information available today calls for a critical analysis of this subject, which is the purpose of the present paper.

A brief résumé of our present knowledge of stroke mechanism will be given, which will form the basis for determining simplifying assumptions to be used in calculating the electric field at the ground. The voltage surges produced on transmission lines by these gradients will then be computed. It will be shown that the over-all influence of the variation of stroke characteristics from the simplifying assumptions is not very great and can, in general, be neglected. With these voltage surges established and from other known time-probability characteristics of lightning strokes, a probability curve giving the frequency of occurrence of induced voltages as a function of their crest magnitude will be computed.

Mechanism of Lightning Discharges

Figures 1 and 2 illustrate the essential characteristics of the discharge[3] based upon the work of Schonland and his associates.[4–8] All strokes to ground or to objects as low as transmission towers originate from charge centers in the base of the cloud. At least 90 per cent of the strokes are of negative character. In the course of the heterogeneous formation of the charges the electric gradient finally reaches a magnitude sufficient to initiate a discharge. The original path is blazed by the "pilot streamer" which propagates toward earth at the most frequent velocity of 0.5 foot per microsecond ($^1/_{20}$ of one per cent of the speed of light). Its path is very irregular, and branching occurs frequently in the direction of propagation. The luminosity is low, and the current does not exceed a few amperes. At intervals ranging from 20 to 90 microseconds "stepped leaders" are formed in this same path. These travel at a much higher velocity of about three per cent of light or 30 feet per microsecond. Upon catching up to the pilot streamer these leaders pause. The current seldom exceeds 200 amperes.[7,9] These initial streamers form an antennalike system upon which negative charge is distributed from the original charge center in the cloud.

All available evidence[3] indicates that only very short upward streamers from the earth occur for strokes to open ground or relatively low objects such as transmission lines. They are probably only a few feet in most cases and certainly do not exceed about 100 feet.

The charge on the stroke channel is then lowered much more rapidly the rest of the way to earth by the very brilliant and rapidly propagating "return streamer" which in its visual manifestation appears as a stroke whose head moves upward toward the cloud at a velocity of about 10 per cent of the speed of light or 100 feet per microsecond. The charge on the channel is discharged continuously as the head progresses, which accounts for the high channel and ground currents shown in the lower portion of Figure 2. The ground current rises to a crest ranging from a few hundred amperes to as high as 160,000 amperes[10] in a time of the order of one to ten microseconds and remains at a relatively high value during the period that the return streamer is rapidly discharging the charge in the space between cloud and ground. The wave shape of this current is determined by the rate of discharge of the stroke channel which is a function of the velocity of the return streamer along the channel and the charge distribution.

After the return streamer reaches the cloud, there may occur a more gradual lowering of charge from cloud to ground down the conducting path produced by the return streamer. Charge tapped by streamers into the cloud from the region in which the stroke was initiated may thus produce a current tail of a few hundred or only a few amperes which, however, may persist for 10,000 or 20,000 microseconds.[10]

Multiple strokes consisting of separate discharges down the same stroke channel may be formed by attraction of streamers from another charge center in the cloud. Streamers from this second charge center form a path to the original charge center, and the charge is then lowered by a "dart leader" down the channel blazed by the first discharge. This seldom shows evidence of the stepped character of the first discharge. Its velocity is of the order of one per cent of the speed of light or ten feet per microsecond. Appreciable branching rarely occurs for such subsequent discharges. As the dart leader reaches the earth, its associated charge is further lowered to earth by a return streamer similar in character to that of the first discharge. About 50 per cent of all strokes are multiple, and as many as 40 separate components have been photographed. The time intervals between

components have been found to vary from 0.0005 to 0.5 second with an average of about 0.03 second.

Effect of Distance From Line on Terminating Point of the Stroke

There is a minimum horizontal distance from the line below which all strokes strike the line. As the distance becomes greater, some strokes strike the line and others the ground, and then more and more of them go to ground. Finally all terminate on the ground. The curve of Figure 3 shows this effect as determined from model studies.[11] These studies indicated that for strokes with no appreciable ground streamer the division of strokes is essentially independent of cloud height and a function only of A/h as shown in the figure. The maximum induced voltages occur when the stroke strikes the ground at the minimum distances from the line which are about three times the line height or 75, 150, and 300 feet for line heights of 25, 50, and 100 feet, respectively.

Basic Stroke Mechanism for Induced Voltage Calculations

Although the lightning discharge is quite complex, and the various factors such as the leader velocities, currents, and charges have a wide range of variation, it has been found that the electric field at the ground and the induced voltage on a transmission-line conductor can be determined quite accurately if the stroke discharge is represented by a fairly simple mechanism.

The basic mechanism for the component of a stroke, illustrated in Figure 4, can be divided into three distinct stages.

(*a*) *Condition Before the Start of the Discharge.* The charge, $-Q_0$, involved in the initial high-current portion of a single-stroke component (or that lowered onto the stroke channel by the initial leaders) is assumed concentrated in a point source at a height, H, above ground. A height of 2,000 meters or 6,560 feet was chosen, as it was found to be a mean value for cloud heights.

(*b*) *First Stage of Lowering Charge.* At the initiation of the discharge the charge, $-Q_0$, is lowered as a uniform line charge, q coulombs per foot, onto the stroke channel by an initial downward leader moving at the uniform velocity, v, of $^1/_{20}$ of the speed of light or approximately 0.5 foot per microsecond (the pilot streamer velocity). At the end of this period as the streamer reaches earth, the charge in the original charge center is zero. No initial upward streamer from the ground is considered.

(*c*) *Second Stage of Lowering Charge.* At the instant the pilot streamer reaches ground, the return streamer starts propagating upward toward the cloud at the uniform velocity, V, of $^1/_{10}$ that of light or approximately 100 feet per microsecond It instantaneously discharges each section of the stroke channel reached. The current flowing at ground and at each point of the return streamer is of the same magnitude and constant with time during the period that the return streamer is propagating up to the cloud. A current of 100,000 amperes is used resulting, for the given return streamer velocity, in a leader charge, q, of 1.02×10^{-3} coulombs per foot, an initial leader current, i, of 500 amperes, and (for $H=$ 6,560 feet) an initial cloud charge, $-Q_0$, of -6.66 coulombs.

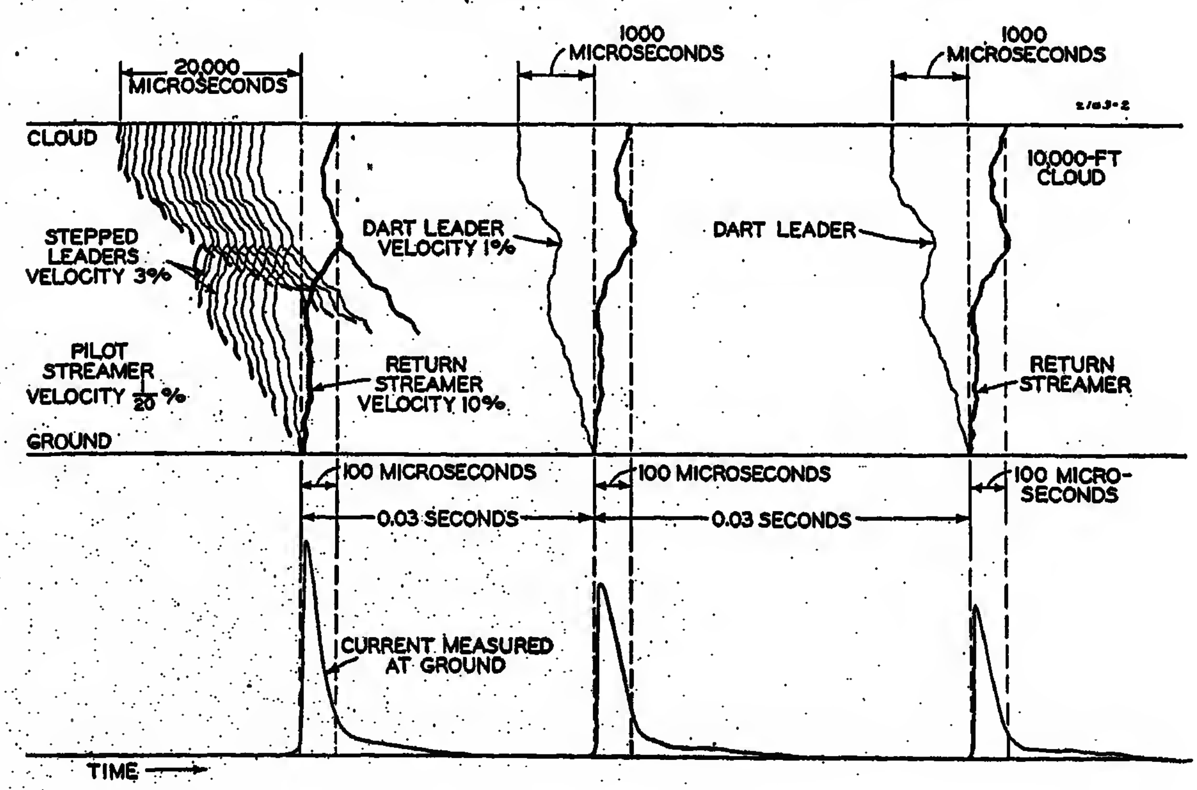

Figure 2. Diagram showing lightning mechanism and ground current

All velocities expressed in per cent of the speed of light which is 984 feet per microsecond or approximately 1,000 feet per microsecond

In all three stages the earth is represented as a perfectly conducting plane by a system of image charges and currents in an image channel.

Ground Gradients

The electric gradient at any point, P, on the ground for the assumption of perfect conducting plane, has only a vertical component that can be resolved into

(a). That due to the instantaneous distribution of charges in the stroke channel.

(b). That due to the instantaneous current in the stroke.

When either of these conditions change rapidly (with the speed of light as a criterion), it is necessary to take cognizance of the finite time required for the disturbance to propagate to the point in space under consideration.

Expressions for the calculation of the three stages of the discharge enumerated in Figure 4 have been derived in appendix I with the following results.

(a) *Before the Start of the Discharge.* Figure 5 shows the initial field as a function of the horizontal distance, d, from the charge center.

(b) *First Stage of Lowering Charge.* The left-hand side of Figure 6 shows the ground gradient due to the electric charges alone for various distances, d. Note that the gradient for strokes near the line increases from the value given in Figure 5 at zero time to the extremely high values, attained at the instant the initial streamer strikes the earth. These are plotted in Figure 7. The contribution of the current during this time is negligible, and the processes involved are so slow that the time for transmission of the effect is negligible.

(c) *Second Stage of Lowering Charge-Return Streamer.* The right-hand side of Figure 6 gives the ground gradient for this stage due to the charges alone, and Figure 8 the gradients due to the current. The polarity of the latter gradients are opposite to those produced by the charges. This phenomenon is so fast that the time required for the disturbance to propagate to the point under consideration must be taken into account. This is shown quite clearly in Figure 8. For distances less than 10,000 feet the gradient due to the current is negligible in comparison with that produced by the charges. For the fixed streamer velocities assumed in Figure 4, the relative contribution of the two components is independent of the current, since the charge is also proportional to the current, I.

Special consideration will be given to gradients at large distances in a separate paper at a later time.

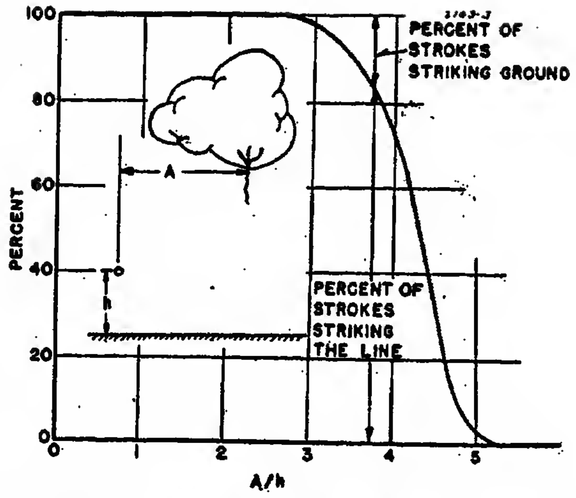

Figure 3. Distribution of strokes for various distances from line as determined by model tests[11]

Voltage Waves on Conductors

If a long horizontal conductor were divided into short sections, and each section insulated from ground and from the other sections, the voltage appearing at any point at any instant would be merely the voltage gradients at the point times the height of the conductor. Actually, however, transmission-line conductors are continuous. If consideration be given first to an extremely long conductor, then the voltages appearing upon the conductor are free to travel in the form of traveling waves. If the conductor is originally at zero potential, and a voltage wave such as shown by the full line in Figure 9a is suddenly induced, then this wave is broken up into two components each of half the value of the original wave, one half traveling to the right and the other half to the left. After the passage of the waves a negative charge remains on the conductor, representing the negative of the positive charge carried away by the two waves. If a second induced wave be applied instantaneously to the conductor before the first wave will have had an opportunity to have propagated beyond the region of the first, the two waves can be added as shown in Figure 9b, giving the resultant wave indicated. The same process can be carried out indefinitely, as shown for four independent waves in Figure 9c. Thus it is necessary only to divide the continuously increasing inducing voltage wave into finite increments for finite increments of time. Each of the increments is then split up into two halves which are superposed upon the previous halves of increments, each displaced in space along the wire in accord-

*For a given crest stroke current (I) in amperes and crest voltage E_m as given by Figure 12, actual voltage is given by the equation $E_m' = \frac{E_m K I}{100{,}000}$.

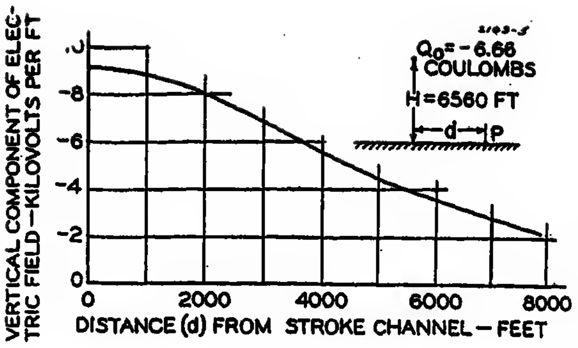

Figure 5. Electric ground gradient just prior to start of discharge

ance with its own increment of time. The increments of field at each time interval as a function of distance, x, along the line can be obtained from curves similar to those of Figure 6 where the distance, d, to be used is the square root of the sum of the squares of the distance along the line and the minimum distance, A, of the stroke from the line. The time intervals which must be chosen to give sufficient accuracy depend upon the rate of change of the field both with time and distance along the line. The greater the rate of change with both of these quantities, the smaller the time intervals have to be. For stroke distances in excess of the minimum at which indirect strokes can occur, as given by Figure 3, the rate of change of field with time is so small for the mechanism of Figure 4 compared to its decrease with distance along the line, in the period the initial streamer is propagating to ground, that the induced voltage is insignificant. The very small increments of voltage, which are negative for negative strokes, and carry away negative charge, move away so rapidly that they do not accumulate an appreciable voltage. If the line is of finite length and open-circuited at both ends with no leakage paths to ground, the successive waves considered in this graphic analysis will produce positive re-

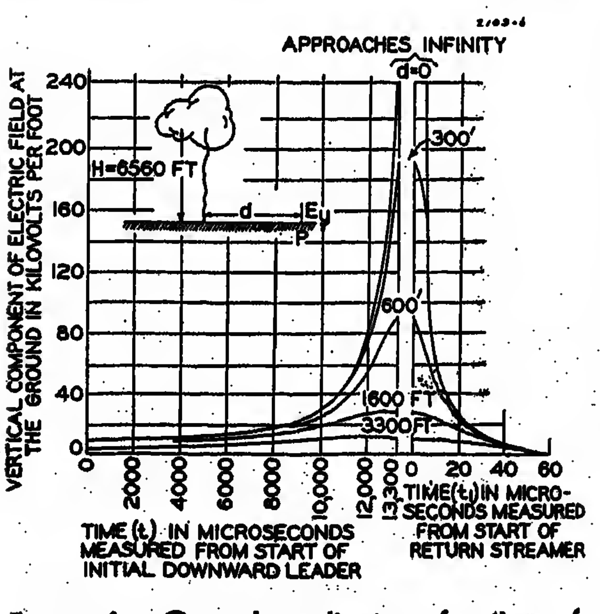

Figure 6. Ground gradient as function of time and distance from stroke channel

Stroke mechanism of Figure 4 (I=100,000 amperes)

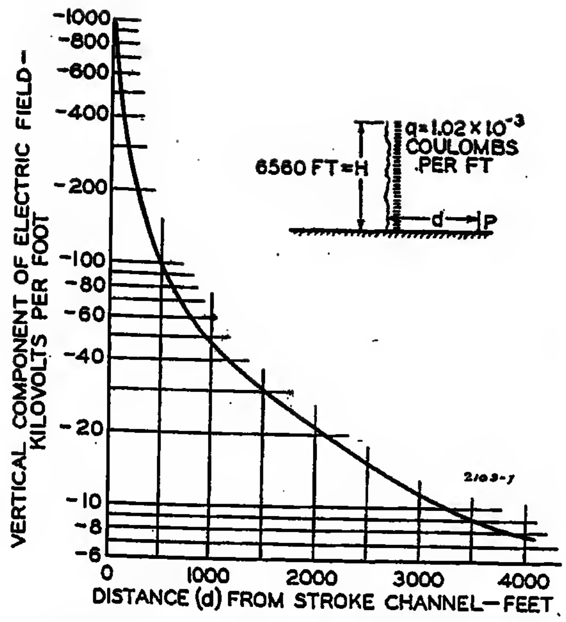

Figure 7. Maximum value of ground gradient that occurs at instant initial streamer reaches earth

Stroke mechanism of Figure 4 (I=100,000 amperes)

flections at the line ends which will propagate back to the region under the cloud, return the negative charge, and allow the conductor to rise in potential. However, for actual transmission lines the terminal equipment and other leakage paths will allow charge to flow onto the line and keep it at zero potential during this initial phase of the stroke discharge.

During the progress of the return streamer, the rates of field change with time are sufficient to induce a voltage. The negative field is decreasing, so that the rate of change is positive, inducing a positive voltage which propagates off along the line carrying away the positive charge accumulated in the previous period of the discharge. Time intervals of 0.2 microsecond were found small enough for accurately calculating the induced voltage for return streamer velocities of the order of 100 feet per microsecond. Figure 10 shows the voltage induced along an infinitely long conductor 50 feet above the ground at successive intervals of time after the start of the return streamer for a stroke 300 feet from the line. The maximum voltage in all cases is induced at or very near the point on the line closest to the stroke channel. The magnitude of the voltage propagating down the line is, before being attenuated by propagation, only slightly less than the maximum voltage and has the same wave shape. In this case it is 86 per cent of the maximum.

In Figure 11 are shown curves of the maximum voltage waves induced by strokes in conductors at various distances from the stroke. These occur at approximately the point in the line nearest the stroke channel. Since the voltage is proportional to the conductor height, the curves can be applied to heights other

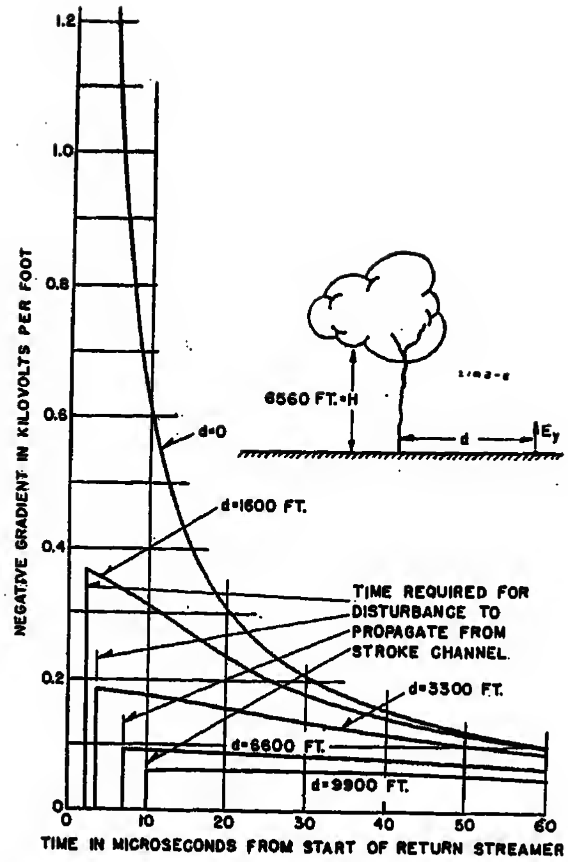

Figure 8. Ground gradient due to current in return streamer

Stroke mechanism of Figure 4 (I=100,000 amperes)

than 50 feet. Both the time to crest and time to half value increase with stroke distance. They range from 2 to 20 microseconds and 6 to 36 microseconds, respectively, for distances from 150 to 1,600 feet. In Figure 12 are curves showing the maximum crest voltage induced on lines of various heights as a function of stroke distance. The maximum voltage which can be induced by a stroke with a current of 100,000 amperes and the mechanism of Figure 4 is 970 kv for a 100-foot conductor and 1,070 kv for both 50-foot and 25-foot conductors. The voltage is higher for the latter two, be-

cause indirect strokes can occur closer to the line.

The voltage curves of Figures 11 to 13 are for a stroke current of 100,000 amperes. The voltage, however, is directly proportional to the current for the stroke mechanism of Figure 4 since the charge, q, for fixed streamer velocities is also directly proportional to the stroke current.

Effect of Factors Differing From Basic Stroke Mechanism

It is now possible to determine the accuracy of the assumed basic stroke mechanism and the effect of the variation of the important factors.

Height of Stroke Channel

The only data[11] available pertaining to stroke channel height are that on cloud base heights. Although the cloud source of a stroke may not coincide with the cloud base, the effect of stroke channel height is so small that the difference is not important. For relatively flat terrain the bases of cumulo-nimbus or thunder clouds are usually higher than 1,000 feet with an upper limit of about 30,000 feet and a mean of about 2,000 meters or 6,560 feet. Occasionally, however, strokes to ground occur from cumulus clouds as low as 500 feet, and in mountainous regions the clouds may envelope peaks. The basic calculations have been made for the mean cloud height. Only low channel heights will give a significant variance from the calculations made for a height of 6,560 feet.

For the same current and the typical streamer velocity of Figure 4 the minimum channel height for which the variance from the mean stroke length can be neglected depends upon the distance from the stroke channel. For d equal to 150 feet a 1,000-foot stroke gives a maximum ground gradient only ten per cent less than for the mean (6,560) height. For d equal to 300 feet, the corresponding height is about 2,000 feet, and for d equal to 1,000 feet, about 4,000 feet. The percentage effect of channel height on the crest value of the induced voltage is even less. In Figure 13 are shown the effect of cloud height upon the induced voltage for I equal to 100,000 amperes and a constant uniform distribution of charge and return streamer velocity, the total charge, of course, being proportional to height. The approximate minimum cloud heights for which only a ten per cent variance is produced in the crest magnitude of the induced voltage are H=500 feet for d=150 feet, H=1,000 feet for d=300 feet and H=3,500 feet for d=1,000 feet. One thousand feet is the maximum distance for which significant voltages will be induced on lines of practical heights. Lower cloud heights do, how-

ever, shorten the duration of the tail of the voltage as shown in Figure 13. The number of strokes to relatively flat terrain which will have low enough heights to cause a significant variance from the crest voltages calculated by the formulas of Figure 4 is very small.

Charge Centers in Cloud

As shown by comparison of Figures 5 and 6, the ground gradient due to the charge in a single charge center, whether it be concentrated at a point or distributed over a finite volume, is negligible compared to the total field during the period in which an appreciable voltage is being induced on a conductor. A large amount of charge in other regions of the cloud may produce an appreciable ground gradient but, so long as it is constant, cannot contribute to the voltage wave on the conductor. The probability of two simultaneous discharges occurring sufficiently close to affect the induced voltage wave is extremely small.

Upward Streamers From Ground

Upward streamers from ground which meet the initial downward streamers are probably seldom over a few feet (and definitely not over 100 feet) in length for strokes to open ground or to relatively low objects. Calculations have been made of the effect of such ground streamers by expressions which can readily be developed from what is already given in appendix I. The stroke mechanism assumed is shown in Figure 14. It is assumed that the initial streamer from the cloud has the same character as the basic case given by Figure 4. When it reaches a height above earth of twice the ultimate height, L, of the ground streamer, a streamer is initiated from the ground and propagates upward at the same uniform velocity, v, depositing positive charge on its channel of the same density, q, as for the downward leader. When the two streamers meet, return streamers are formed at the junction point which propagate in both directions at the uniform velocity, V=100 feet per microsecond. In Figure 15 are plotted curves of the electric field during the period of progress of the return streamer for a 50-foot and a 100-foot ground streamer compared with the case of no ground streamer. After the return streamer has reached earth and thus discharged all of the positive charge on the ground streamer, the field is the same as for the case of no ground streamer for corresponding heights of the return streamer channel above ground. The curves of Figure 15 have been plotted with this corresponding portion coinciding for better comparison. Thus, the time of starting of the return streamer (or the zero for the time axis) in Figure 15 must be shifted a different amount for each length of ground streamer to make the curves coincide. The black dots indicate the points of zero time for each case.

The upward ground streamer decreases the maximum ground gradient. However, calculations of the induced voltage, as shown in Figure 16, indicate that even streamers 50 to 100 feet long have little effect upon the crest magnitude of the induced voltage wave. A 100-foot streamer affects the crest only at distances less than 300 feet. For some cases the field tends to increase before decreasing, and this produces a negative peak on the induced voltages. The higher effective velocity of the return streamer during the initial period decreases the front of the wave somewhat. Since most ground

streamers do not exceed a few feet in length their effect can be neglected.

Irregularities in the Shape of the Stroke Path

The basic mechanism assumes a straight vertical channel. For strokes whose mean path is about vertical, the tortuousness of the path is unimportant when the effective vertical velocity of the return streamer is used. Placing the same charge in a given vertical section of the channel also gives the same result, regardless of the shape of the path or distribution. Strokes having an appreciable slant cause a greater variance when the channel is not in a perpendicular plane parallel to the line. If the base of the stroke channel toes toward the line, the magnitude of the ground gradient is smaller, and if it toes away, larger than if the channel were vertical. However, the rate of change of the ground gradient with time will be increased in the first case and decreased in the second case, producing a compensating effect on the induced voltage waves. Model tests indicate that those strokes which strike the ground near the transmission line have channels which are not attracted significantly toward the line. In any statistical analysis the only reasonable assumption is a vertical straight channel.

Branching

Schonland, Malan, and Collens[5] have found two characteristic types of branching, those occurring high enough above ground that they do not reach the earth, and those close to ground which contact the ground and form additional channels at the stroke base. This type of branching has been called by them "root branching." The branches leave the main channel at a distance of from 60 to 500 feet above the ground and are from 60 to

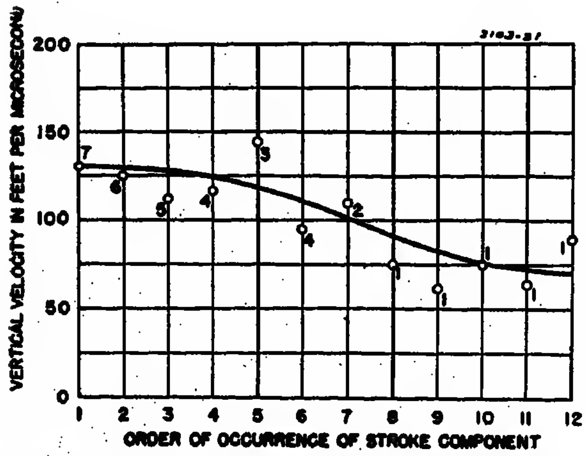

Figure 21. Variation of average return-streamer velocity with order of occurrence of stroke component[4]

Each point is the mean of the indicated number of records

150 feet apart at ground. Branches of the first type of appreciable length seldom reach lower than 2,500 feet from ground. Branching usually occurs for the first component of a multiple stroke, but appreciable branches are seldom present in successive components. Of 57 Boys camera[5] records of first components, 54 had branching with an average of five branches each; and of 33 subsequent components, 14 had an average of one very short branch each while the rest had none.

For strokes close to transmission lines, "root branching" will exert some influence on the induced voltage. However, the branches occur practically simultaneously, and for a given configuration of branching an effective location can be determined where practically the same result will be obtained with a single channel. A higher voltage will be induced by an unbranched stroke at the same distance as the nearest branch. If the branches are all the same distance from the line, the difference will be negligible. As shown in the previous section, the character of the stroke within the first 100 feet of ground has little effect on the induced voltage.

Branches 2,500 feet above ground will not appreciably affect the crest magnitude of the ground gradient or the crest magnitude of the induced voltage wave. They may, however, produce additional peaks on the voltage wave. In Figure 17 is shown a calculation made for a horizontal branch 500 feet in length (the average recorded with the Boys camera[5]), 2,500 feet above ground and pointing directly toward the conductor which is 1,600 feet from the main stroke channel. The same uniform charge density is assumed for the branch as for the main channel. It is assumed that when the main return streamer reaches the branch, the branch charge is lowered by a return streamer propagating at the same uniform velocity, $V = 100$ feet per microsecond, as for the main channel. This case will produce an abnormally high current peak because of the direction of branching and the high relative charge density on the branch. For the case illustrated in Figure 17, a second peak of 110 kv is produced 33 microseconds after the start of the return streamer. Its magnitude and time of occurrence will be practically the same for shorter stroke distances, so that, to determine the effect of the branch at shorter distances, the increment due to the branching can be superposed on the voltage waves of Figure 11. For d equal to 1,600 feet, the second crest is 22 per cent higher than the first. However, for d less than 1,000 feet, the second crest is less than the first. For most cases of branching, the second crest will be much smaller. Cathode-ray oscillograms of induced voltage waves showing such double peaks that were definitely not due to reflections on the line have been recorded by Perry, Webster, and Baguley.[12] The second crest was in all their records smaller than the first.

Velocity of Initial Leaders

In the basic stroke mechanism it was assumed that the charge was lowered uniformly onto the channel by a single downward moving leader with a constant current. For the first component of a

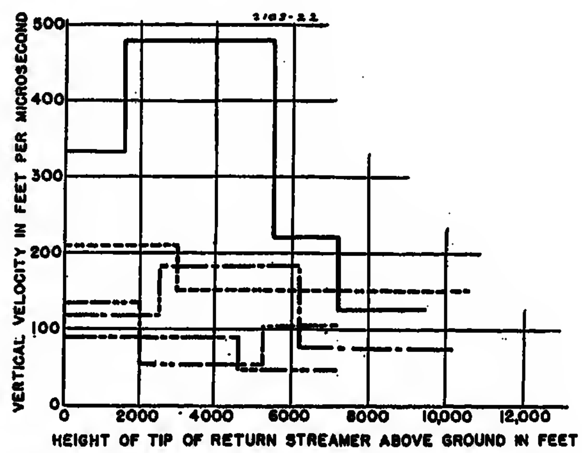

Figure 22. Variation of return-streamer velocity with height above ground for the five strokes recorded by Schonland and Collens[5] for which this analysis could be made

stroke the charge is lowered in steps, some of it by the pilot streamer and some by the stepped leaders. A continual process of recombination of the negative ions with positive ions is probably taking place along the channel. It is this process which very likely causes the building up of sufficient gradient along the channel to start each successive stepped leader. This fluctuation of charge and stepped leader current produces pulses in the ground gradient and has been recorded by Schonland, Hodges, and Collens.[8] It is probably more pronounced in records obtained at large distances but does not alter the mean field. This effect is not present in the dart leaders of successive components, as these leaders are either continuous, or the pulses occur so close together that they can be considered as continuous. Schonland, Hodges, and Collens[8] found evidence that in some cases the pilot streamer of first components slowed up considerably after propagating to within a certain distance above ground. However, the velocity of the leader over the whole stroke path was in all cases too low to induce voltage on a conductor. For most cases the pilot streamer velocity, although having ir-

regularities, had the same mean velocity over the entire stroke path.

An initial leader velocity of 0.5 foot per microsecond was used for the basic calculations. In Figure 18 are percentage distribution curves, plotted from the Boys camera records of Schonland, Malan, and Collens,[5] showing the range of variation of the average effective vertical velocity of both the pilot streamer and the dart leader. These values (as were all vertical velocities) were calculated from the two dimensional velocities obtained from the Boys camera photographs by dividing them by 1.3 the average ratio found[5] to exist between this and the straight line path on the film. Only the extreme upper range of the pilot-streamer velocities is high enough to induce appreciable voltage during this period of the discharge. The dart-streamer velocities are, however, high enough to produce a significant voltage. The most common value for this velocity is ten feet per microsecond and the upper limit is 50 feet per microsecond.

In Figure 19 are plotted the voltages induced by leaders of these velocities on a conductor 50 feet above the ground at a distance of 300 feet. For dart-leader velocities of 10 and 50 feet per microsecond the crest magnitude of the negative voltages are 14 and 63 per cent, respectively, of the subsequent positive crest voltage produced during the return-streamer period. For the extreme pilot-leader velocity of three feet per microsecond it will be about four per cent. The duration of the negative induced voltage is about proportional to the velocity of the leaders as shown in Figure 19.

Velocity of Return Streamer

Figures 20 to 22 give data on the range of variance of the velocity of the return streamer as obtained from Boys camera records.[4,5] Here also the one dimensional vertical velocity is considered. In Figure 20 part of the data are for records for which only the average velocity for the total stroke path could be determined, and part for records for which the average velocity of the initial bright luminosity portion could be measured. This is the portion of the stroke path below the first main branch. As shown by Figure 20, the average velocity for the total path varies from 50 to about 330 feet per microsecond with a most common value of about 80 feet per microsecond. For the bright luminosity portion the range is the same with a most common value of about 240 feet per microsecond. The data[5] from which Figure 20 was plotted did not permit segregating the stroke components in their order of occurrence. This could be done, however, for some of the records as published earlier,[4] and in Figure 21 is shown the variation of average return-streamer velocity with the order of occurrence of the stroke component of a multiple stroke. The velocity of successive strokes is generally less than the previous one with the initial component having the highest value. It has also been found that the stroke luminosity generally decreases with successive components in the same manner, and that the higher velocities are associated with the higher luminosities. Stroke-current measurements show the same general trend, so that the evidence is quite strong that higher return-streamer velocities are associated with higher stroke currents. Also, the higher return-streamer velocities of first components are associated with considerable branching. It is probable that the increased ground gradient produced by the branches accounts for the higher velocities and stroke currents of first components.

In Figure 22 are plotted the velocities of five Boys camera records published by Schonland and his associates[5] for which the distribution of velocity along the channel could be determined. It is questionable that the base of the stroke channel below about 100 feet was recorded. However, the crest magnitude and wave shape of the tail of induced voltages are not affected by the character of the stroke mechanism at the base of the channel. This was well illustrated by the effect of ground streamers, which would have the maximum effect of any condition which would occur at the base. The lowest portion of the stroke channel which need be considered in determining the crest magnitude and the

Curve 2—Uniform charge distribution and uniform $V=480$ feet per microsecond

Crest current = 100,000 amperes for both cases

tail of the voltage wave depends upon the stroke distance from the line. For 150 feet it is about 75 feet above ground, for a distance of 300 feet it is about 150 feet, and for a stroke distance of 600 feet, about 400 feet. In general, the abrupt decrease in velocity of the return streamers in Figure 22 is associated with the streamer reaching a branch point. It probably also varies somewhat between branches but not enough to be recorded. The maximum known effective vertical velocity is the 480 feet per microsecond of the stroke represented by the solid curve of Figure 22. The maximum velocity along the channel also occurred for this stroke and is about 600 feet per microsecond.

Calculations have been made of the effect of return-streamer velocity on the induced voltage wave. In Figure 23 is shown the effect of velocity, with the charge density so adjusted as to maintain the same stroke current. Increasing velocities decrease the crest magnitude, time to crest and duration of the voltage. As shown in Figure 23d, the effect on the crest voltage is most pronounced at the short-stroke distances and lower velocities. For a stroke distance of 150 feet the upper limit of vertical velocity of $V=480$ feet per microsecond causes a decrease in the crest voltage, as calculated for $V=100$ feet per microsecond, of 44 per cent. At 300 feet it is 40 per cent and at 600 feet, 19 per cent. For greater distances the effect is unimportant. However, the wave shape is affected more at large distances as shown in Figures 26 and 27.

Calculations have also been made to determine the effect of velocity variation along the stroke channel. Figure 24 shows a comparison of the voltage induced by a stroke having a uniform return-streamer velocity of 480 feet per microsecond and a uniform distribution of charge, q, and the voltage induced by a stroke with the same charge distribution but the velocity given by the solid curve of Figure 22. The effect of variation is small, producing a change in crest voltage of 14 per cent at $d=150$ feet, 6 per cent at $d=300$ feet and 8 per cent at $d=600$ feet. The variation has no effect on the front of the wave and little effect on the time-to-half value, although the extreme tail of the wave is decreased by the decreasing velocity.

The variation of return-streamer velocity along the stroke channel is not important, because it does not vary greatly until it reaches the first branch point which is usually at least 2,500 feet above ground. As pointed out earlier, the character of the stroke mechanism above this height has no important effect on the induced voltage. It is then the velocity of the bright luminosity portion or that below the first branch which should be used for voltage calculations.

Variation of Charge Distribution Along Channel

The two principal factors governing the stroke current flowing at ground are the charge distribution, q, and the return streamer velocity, V. The variations of streamer velocity of the five cases of Figure 22 are sufficient to account for the decrease of current recorded for the tails of lightning-stroke currents. Independent data regarding the time for the current at the ground to decrease to half value are given in Figure 25. The normal variance of this time is from 15 to 100 microseconds, with an average of about 50 microseconds. The solid velocity curve of Figure 22 would, for a uniform charge distribution, give a time-to-half value of 16 microseconds; the other curves give times of about 40 microseconds.

Calculations have been made to determine the effect of nonuniform charge distribution on the induced voltage wave. In Figure 26 are compared the voltages induced by a mechanism with a uniform charge and velocity distribution and by the same uniform velocity distribution but a charge distribution such that the current decays exponentially to half value in 40 microseconds. The effect on the induced voltage wave shape and crest magnitude is slight, as would be expected since the charge cannot decrease greatly in the first 1,000 or 2,000 feet and still give the proper current wave shape.

Rate of Discharge of Stroke Channel by Return Streamer

In the fundamental stroke mechanism of Figure 4, it is assumed that, as the return streamer reaches a given height above ground, it immediately discharges all the charge on the channel at that point. It has been suggested by Bruce and Golde[14] that this is not the case. They believe that the charge, after being lowered onto a given section of the channel by the initial leaders, spreads out radially and thus occupies a larger cross section than is immediately made con-

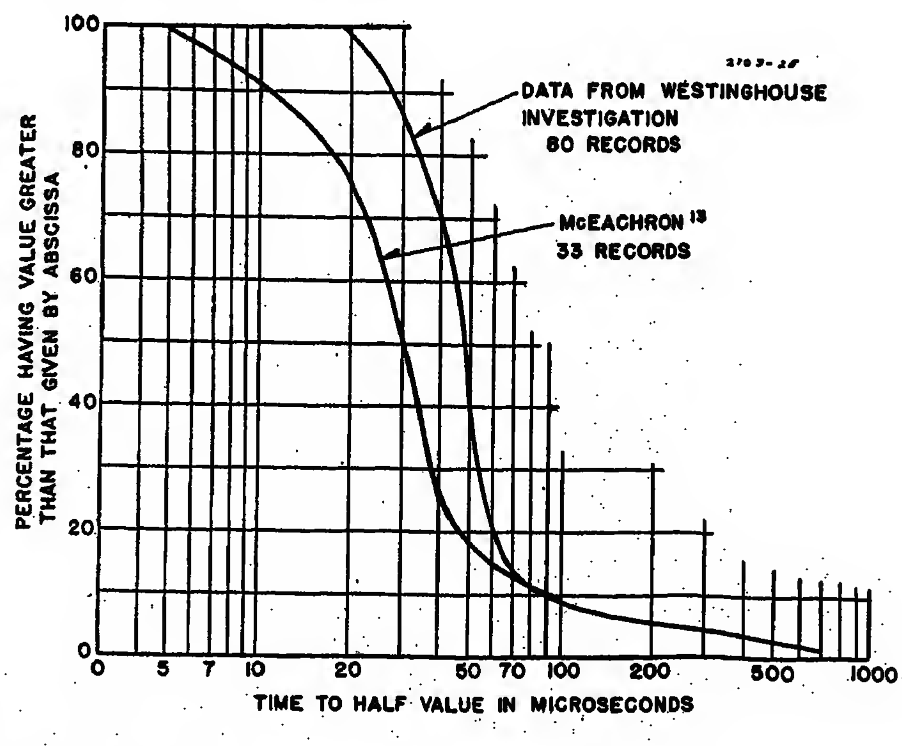

Figure 25. Percentage distribution curves of time-to-half value of lightning-stroke currents

ducting by the return streamer. They further assert "that the darts associated with the leaders of first strokes result from lateral conduction from the initial channel outwards as the tip progresses and the potential at each point behind it rises," and that: "During the return stroke this ionization in each horizontal layer cannot be recombined instantaneously, since the lateral progression of this process will again take time."

Schonland[7] found that the duration of high luminosity at any point after it is reached by either the initial bright portion of the stepped leader (which Bruce and Golde refer to as the "dart leader"), or by the return streamer is of the order of five to ten microseconds. After this the luminosity suddenly diminishes. This is the period in which Bruce and Golde assume the channel to be widening out. Schonland[7] himself has pointed out that luminosity of this duration cannot be due to the excitation period of nitrogen (the principal element involved in the ionization process). Its period is only about 0.1 microsecond.

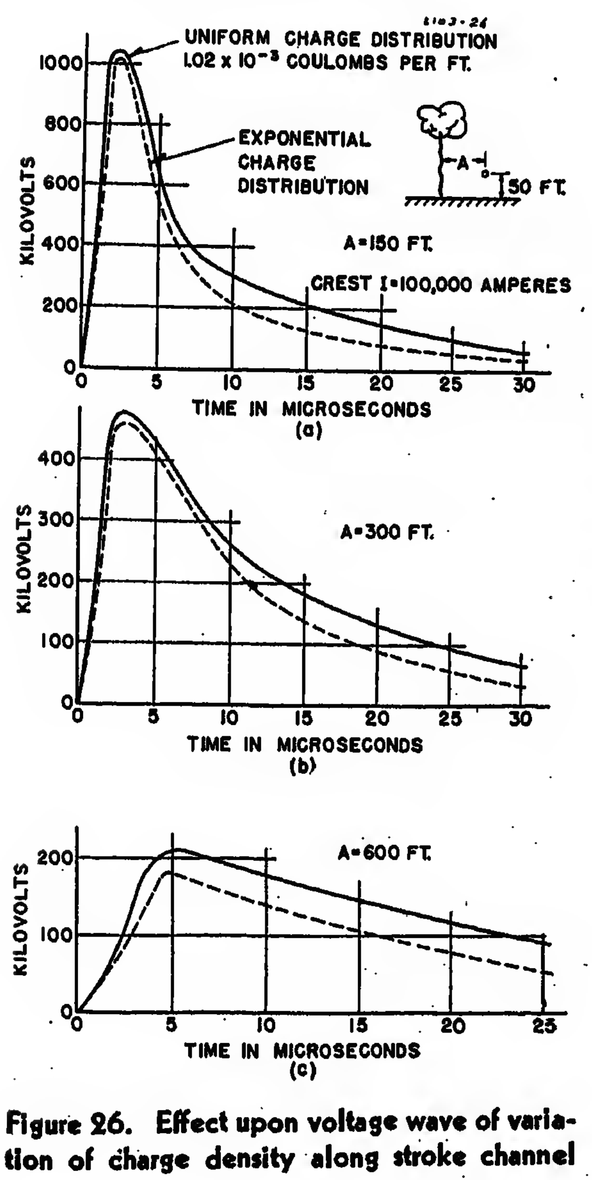

Figure 26. Effect upon voltage wave of variation of charge density along stroke channel

Solid curve—Uniform charge distribution of 1.02×10^{-3} coulombs per foot

Dotted curve—Exponential charge distribution with maximum charge density of 1.02×10^{-3} coulombs per foot at the ground and decreasing to half value 4,000 feet from ground to give current wave at ground with 40 microsecond tail

For both curves V=100 feet per microsecond and crest current=100,000 amperes

Such lateral ionization may take place. However, even if the return streamer does (as shown in Figure 27) first blaze a conducting channel of smaller cross section than that occupied by the initial charge on the channel, positive charge must immediately flow onto the outer surface of the initial highly conducting channel to maintain it at the low potential it will have by virtue of being in contact with the earth. For the ground gradient calculations, all of the return-streamer portion of the stroke channel can be considered as being at earth potential as the arc drop is small. As shown in appendix II, the amount of positive charge on a given channel section required to maintain the core of the return streamer at earth potential in the presence of estimated surrounding charges of the downward leader is at least 70 per cent of the negative charge left in the space not yet made conducting by the return streamer. Most of the charge is neutralized rapidly by recombination with charges rising in the ground leader; and even if a remaining charge exists, as Bruce and Golde purport, that is not immediately neutralized by this process, additional positive charge to the extent of at least 70 per cent is drawn into the section to maintain the arc core at earth potential. Thus, positive charge flows up the stroke channel at a rate determined by the return-streamer velocity and charge density, q, on the stroke channel, and the effect is essentially the same as though the combination of the two sets of charges were consummated instantaneously.

Positive Charge on Return-Streamer Channel

The analysis of appendix II considers only the relationship the positive charge on the channel must bear to the negative charge in a horizontal section of the conductor. Symmetry about a vertical axis is assumed, and the end effects at the tip of the return streamer are neglected. Because of electrostatic induction with the negatively charged leader that has not yet been discharged, the upwardly extending channel and ground which are all at the same potential, do not have equal charge distribution. Thus, there must be a net distribution of positive charge on the upward streamer. If this charge were uniform, it would produce no effect on the induced voltage, as calculated by the mechanism of Figure 4 for a fixed stroke current. For the same current, the negative charge on the stroke channel would have to be decreased by an amount proportional to the assumed positive charge, and the net field change with time would be the same. The density of this positive charge on the return streamer should be greatest near the tip and should decrease down the channel. Thus, as the streamer is forming upward, the current at ground feeding the streamer will decrease with time. Since the variation of return-streamer velocity alone is sufficient to account for the measured current wave shapes, the variation of charge along the stroke channel cannot be very great, especially for the first 1,000 or 2,000 feet above ground. It probably does not produce so great an effect as the variation of negative charge for the case illustrated in Figure 26.

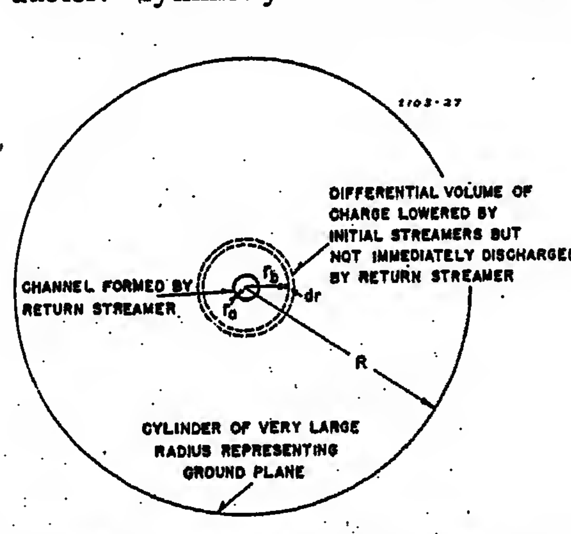

Figure 27. Diagram showing cross section of stroke channel

Relation Between Maximum Induced Voltage and Voltage Propagating Along Line

In the previous discussion only the voltage induced on the line at the point nearest the stroke channel, or the maximum voltage, has been considered. For the range of variation of the several factors controlling the induced voltage, the ratio between the voltage which propagates away from this point and the maxi-

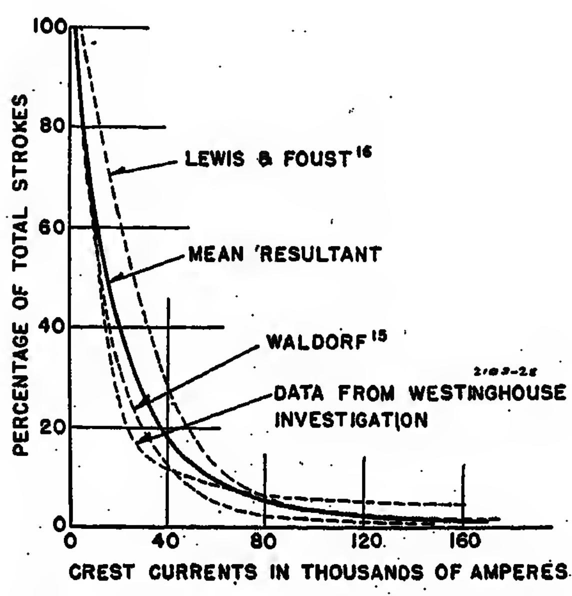

Figure 28. Percentage distribution curves of crest currents at ground in lightning strokes as obtained by various investigators

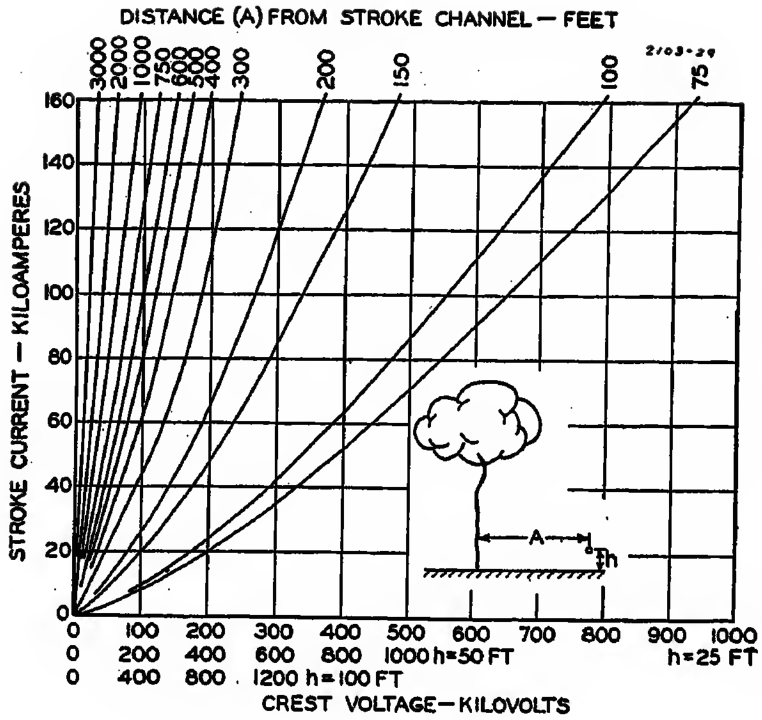

Figure 29. Crest of induced voltage wave as a function of stroke current, distance from channel, and height of conductor

mum (as illustrated in Figure 10) is never less than about 0.8 and is usually greater than 0.9. Thus, for practical purposes it is considered best to use the maximum voltages for both cases.

Summary

The foregoing analysis shows that induced voltages on transmission lines can be calculated to a good degree of accuracy by the stroke mechanism of Figure 4 where the distribution of charge and the return-streamer velocity is assumed constant along the channel. These are the primary factors determining the voltage wave shape and magnitude, and they in turn determine the stroke current. Wave shape is little affected by anything but the return-streamer velocity as summarized in Figures 23e and 23f. As shown in Figure 23d, the effect of velocity upon the crest voltage may be considerable, but it can be taken into account to a good degree of accuracy. The velocity increases with the magnitude of the stroke current. The exact manner in which it does is not known. However, if the measured range of the velocity and the stroke current are each divided into only three equal ranges, and a mean velocity used for each current range, the voltage can be calculated to good accuracy as a function of the crest stroke current only.

Figure 28 gives what is considered to be the best mean probability curve on the relative crest magnitudes of currents in lightning strokes. The maximum current which has been reliably measured is 160,000 amperes.[10] In Table I is shown the segregation of stroke current and return-streamer velocity into the three ranges together with the mean velocities for each range. Correction factors, determined from Figure 23d, applicable to the mean velocities for different distances, are also given in Table I. In Figure 12 are given crest voltage curves based on a stroke current of 100,000 amperes and a streamer velocity of 100 feet per microsecond. The curves of Figure 12 can be used for calculating the induced voltage as a function of crest current, together with the equation and the mean correction factors of Table I. In this manner the curves of Figure 29 were obtained which give the induced voltage as a function of stroke current for various conductor heights and stroke distances.

Effect of Other Conductors and Line Terminal Conditions

As has been shown previously,[27] the voltage induced on an ungrounded conductor is not affected by the presence of other ungrounded conductors. Ground wires, which are perfectly grounded so that their potential remains at zero at all points, reduce the voltage induced on a conductor by the factor $(1-K)$, where K is the coupling factor between the conductor and the ground wires.

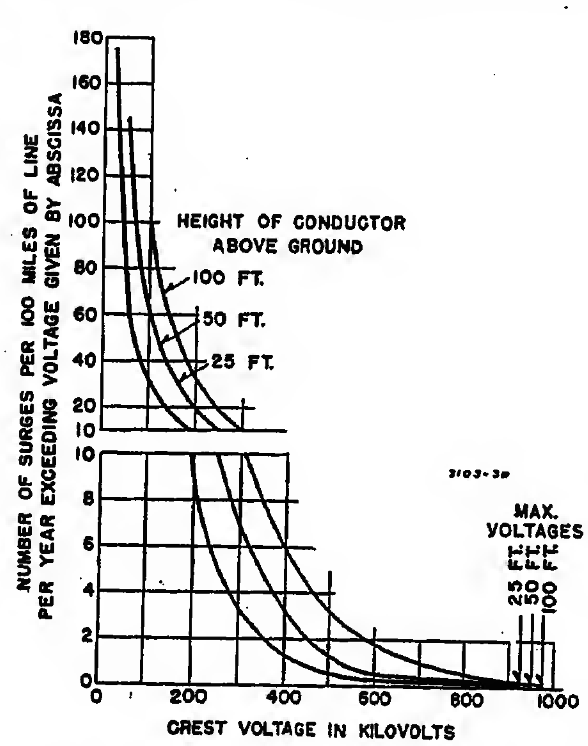

Figure 30. Probability of occurrence of induced voltages

Isokeraunic level = 30

However, for long spans and strokes of high current magnitude occurring close to the line, appreciable voltage appears for a short time on the ground wire. Consider for example, a line with 1,000-foot spans and a ground wire 100 feet above ground. As shown by Figures 29 and 23e, a voltage of 975 kv with a 1.2-microsecond front can be induced at mid-span. The rate of rise is too rapid for the reflection from the towers to limit the crest appreciably. Approximately the same potential is induced on both conductor and ground wire. Until the waves reach a tower, there is little potential difference across them. Upon reaching a tower, the voltage wave on the ground wire is reduced sharply, and thus the voltage across the string of insulators is practically the same as though there were no ground wire present. For shorter spans, reflections on the ground wire induce voltages on the conductor that reduce the crest voltage, the limiting value to which they can be reduced being $(1-K)$ times the original value as mentioned above for the ground wire grounded at many points.

It is interesting to note that the voltage induced on the ground wire for this case can produce appreciable positive current in the towers. For an incident surge, e, propagating to a tower whose footing resistance is R, the current, i_t, flowing down the tower before reflection can arrive from other towers is

$$i_t = \frac{2}{Z+R}e$$

where Z is the surge impedance of the ground wire, or the effective surge impedance if there are several. For one ground wire Z is about 500 ohms; for

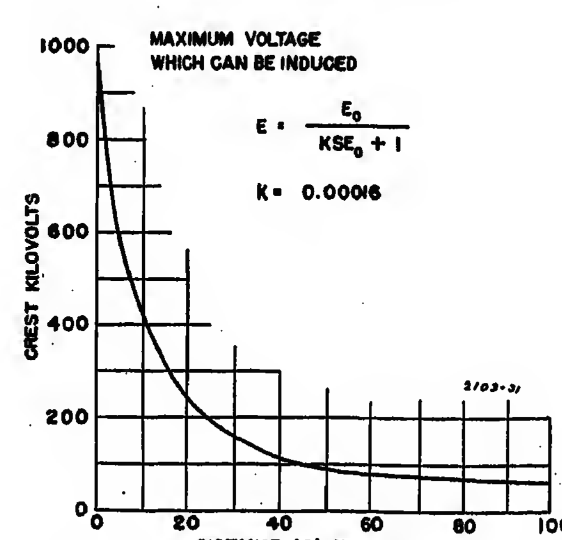

Figure 31. Foust and Menger[20] formula for determination of attenuation of crest magnitudes of voltage waves

two, about 350 ohms. The maximum current would occur if $R = 0$. Then for the case being considered i_t would be 3,900 amperes for one ground wire and 5,600 amperes for two ground wires, respectively. This represents the upper limit of the current which can be induced in the tower of a high-voltage line.

For lines of finite length or containing points of discontinuity such as connected apparatus at various points along the line, the voltage will, of course, be modified by reflections. These can be taken into account by conventional traveling wave theory in which the initial incident wave is that considered here.

Probability of Induced Surges on Transmission Lines

Number of Induced Surges Originating on Each Mile of Line

With a knowledge of the stroke density for a given region or the number of strokes originating from each square mile of sky area, it is now possible to determine the number of surges of a given crest magnitude which will be induced on a line. An average value for the stroke density in a region of flat terrain where the isokeraunic level averages about 30 storm days per year has been found to be ten strokes per square mile.[18] This value and the curve of Figure 3 determine the number of strokes which strike ground within finite bands a given distance from each side of a line of a given height. Figure 28 determines how many of such strokes have a current magnitude of a given value, and Figure 29 how much voltage each induces. By dividing the ground (from the minimum distance from the line for which strokes will strike earth to the maximum distance for which significant voltages will be induced) into such finite bands parallel to the line and adding up the number of strokes in each band which will produce voltages of a given value, probability curves such as given in Figure 30 are obtained. The curves of this figure give the number of surges exceeding each magnitude which is induced at the point nearest the stroke channel per 100 miles of transmission line.

The curves of Figure 30 indicate, as has been pointed out previously,[19] that the number of surges of a significant magnitude which are induced on a transmission line is of the same order of magnitude as the number of strokes which strike it directly. Waldorf[15] has found that on the average 100 direct strokes per mile per year can be expected to lines in the voltage class between 66 and 220 kv with line heights of from 60 to 110 feet and in regions of the same isokeraunic level as given for Figure 30.

The curves of Figure 30 can be used for determining the number of times flashover may occur on a line at points remote from the ends where reflections do not modify the surge voltage. As can be seen from Figure 23f, for distances at which voltages sufficiently great to produce outages (above about 300 kv) are developed, the time to half value varies between 5 and 20 microseconds. The critical flashover voltages for waves of this character are from 10 to 30 per cent higher than for a standard $1^1/_2 \times 40$ wave. Thus, for a 50-foot line with a critical standard impulse value of 300 kv, it is equivalent to 330 to 390 kv on the shorter waves. From Figure 30 this will produce about five outages per 100 miles per year due to induced voltages.

The data of Figure 30 must be distinguished from the total number of surges exceeding each magnitude which will appear at each point on the line, due not only to those originating at the point, but also to those propagating from other points. If it were not for attenuation and reflections, this would be equal to the number per mile times the length of the line in miles. Attenuation is a function not only of voltage magnitude but also of wave shape. However, an estimate of the probability of surges of various magnitudes appearing at any one point on a line can be made with the use of the empirical decrement curve of Figure 31. This curve[20] represents the mean of records obtained on the attenuation of lightning surges. The length of the line and terminal conditions, of course, affect the magnitude of the surges, so that they vary for different line conditions. Each particular line can be studied by traveling wave analysis. Use Figure 30 to determine the number of surges of each magnitude originating from each section of line and Figure 31 to determine its magnitude after propagation. However, two conditions are sufficiently representative that they can be applied to most cases.

Number of Surges at Point Remote From Ends of Line

The first of these is the case for which the line is sufficiently long in both directions from the point under consideration that it can be considered as infinite. Voltage probability curves calculated for this case are given in Figure 32. These were determined by dividing the line on each side of the point being considered into one-mile sections, after deciding from Figure 30 the number of surges of each magnitude which will originate from each section, and from Figure 31 their magnitude by the time they reach the point. A mean distance is assumed for each section. The accuracy of these curves for lines of finite length depends upon the voltage being considered. Figure 31 indicates that no induced surges in excess of 100 kv propagate more than 40 miles; for 200 kv, 25 miles, and for 400 kv, only 10 miles. Thus, the length of line for which these curves may be used varies in an inverse manner with the voltage. For voltages less than 100 kv, the attenuation is so small that for estimating purposes the number of surges of such magnitudes can be considered as proportional to line length and determined directly from Figure 30. These curves are based upon the premise that none of the surges reaching the point under consideration produced flashover before reaching the point.

Number of Surges at Open End of Long Line

If a line is open-circuited at its end, the magnitude of the crest voltage at the end is twice that of the incident surge. This is approximately true for lines with transformers connected to the end. Also, since the line extends in only one direction from the point under consideration, only half as many surges can originate from a given distance from the end as for the previous case. The probability curves of Figure 33 were, therefore, obtained from those of Figure 32 simply by picking a particular voltage, doubling it, and assigning to it one-half the number per year as read from the curves.

Comparison With Field Data

There are very little field data on lightning-surge voltages for which the induced surges can be segregated from those produced by direct strokes. From the data submitted by Cox, McAuley, and Huggins,[21] the authors have chosen the Klydonograph records obtained at the ends of four long lines of voltage class of 110–140 kv without ground wires. Only those records that did not produce flashover were included. The results are plotted by the dotted line of Figure 33. Undoubtedly some of the high-voltage records were due to direct strokes, and at low voltages some surges were not recorded because of the lower limit of sensitivity of the instrument.

Conclusion

The velocity of the initial downward leader of lightning strokes is too slow to produce significant voltages on transmission lines by induction. Only the

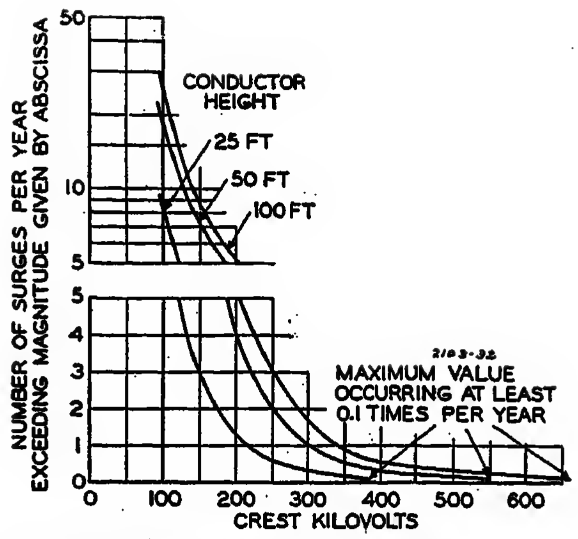

Figure 32. Probability of occurrence of induced voltage at a point remote from the ends of a line

Maximum voltage which can appear:

h = 25 feet—925 kv
h = 50 feet—950 kv
h = 100 feet—975 kv

return streamers are of importance. The voltages produced by the latter can be determined to sufficient accuracy by representing the return streamer as a vertically propagating conductor whose tip moves with uniform velocity, neutralizing, as it progresses, the uniformly distributed charges on the initial streamer. In spite of the high currents and the short duration of the return streamer, only the charge and not the high rate of change of the current is important. The voltages so produced are proportional both to the height of the transmission-line conductor and the crest of the current in the stroke at ground. It has been found possible to represent strokes by the characteristics enumerated in Figure 4. Of all the factors considered, only variations in velocity of the return streamer affect induced voltages significantly. Return-streamer currents vary with the magnitude of stroke current. By choosing the probability of occurrence of stroke currents and corresponding return-streamer velocities, the probability of occurrence of induced voltages as a function of their magnitude can be determined. Although the voltages induced by lightning on transmission lines may be quite high, those of sufficient magnitude to produce flashover occur so infrequently as to be of little practical importance.

Appendix I. Equations for Electric Field Produced at Ground by Lightning Strokes

During the period in which the initial leaders are propagating toward earth, the change of electrical conditions with time are slow enough that neither the velocity of propagation of the disturbance from the stroke channel to the point at the ground under consideration nor the magnetic effect on the electric field need be considered. However, for the period in which the intense return streamer is propagating up to the cloud, the rapid rate of propagation and high current in the return streamer require the use of electrodynamic equations.

The general solutions to Maxwell's dynamic field equations are given in the practical system of units by the following equations:

$$A_{P,t} = 0.1 \int \frac{[i]_{t-\frac{r}{c}}}{r} dv \qquad (1)$$

$$V_{P,t} = 9\times10^{11} \int_v \frac{[q]_{t-\frac{r}{c}}}{r} dv \qquad (2)$$

$$E_{P,t} = -\nabla V - 10^{-8}\frac{\partial A}{\partial t} \qquad (3)$$

where

dv is a differential element of volume
r is the distance from P to the differential volume (dv)
c is velocity of light (3×10^{10} centimeters per second, or 984×10^6 feet per second)
t is time in seconds
q is charge density
$A_{P,t}$ is retarded magnetic vector potential
$V_{P,t}$ is retarded scalar electric potential in practical volts
$E_{P,t}$ is electric field in practical volts per centimeter

The quantities A, V, and E are given at the point P as a function of time when the integration is carried out over all space occupied by charge except at $r=o$. The retarded values of i and q, $[i]_{t-r/c}$ and $[q]_{t-r/c}$ are their values at the time $(t-r/c)$ at which they produce the field disturbance at P at the time t. The ratio r/c is the time required for the disturbance to propagate the distance r at the speed of light.

1. Electric Field Before Start of Discharge

It is assumed that, as shown in Figure 4a, the charge in any one charge center is confined to a small volume which can be represented by the point charge, $-Q_o$, and that the earth's surface is a perfectly conducting plane as represented by the image charge, $+Q_o$. For this static case the field at the point P has only the vertical component given by the equation where dimensions are expressed in feet.

$$E_{yo} = \frac{5.9\times10^{10} HQ_o}{(H^2+d^2)^{3/2}} \text{ volts per foot} \qquad (4)$$

2. Electric Field Produced by Stroke With No Initial Upward Streamer From Ground

During Progress of Downward Leader

As shown in Figure 4b, it is assumed that the charge, $-Q_o$, is lowered onto the stroke channel by the initial leader at a uniform rate given by the leader velocity, v, and the uniform charge density, $-q$, per unit length of the channel. Thus, if z is the length of the initial streamer channel at a time, t, as measured from the start of the leader

$$z = vt \qquad (5)$$

The current flowing in the channel is

$$i = qv$$

The charge left in the charge center is

$$-Q = -(Q_o - it) = (Q_o - qz)$$

The effect of the ground plane for all of the following cases is represented by an identical motion of the image charge along the image channel. This is accounted for by merely multiplying the field due to the real cloud charges or currents by two. The initial streamer current and the initial streamer velocity relative to the speed of light are so small that the magnetic contribution to the electric field and the retarded potential effect need not be considered.

The field due to the charge left in the cloud is

$$E_{y1} = \frac{5.9\times10^{10}(Q-it)}{(H^2+d^2)^{3/2}} \text{ volts per foot} \qquad (6)$$

The field due to the charge on the leader is, when dimensions are in feet,

$$E_{y2} = 5.9\times10^{10} \int_0^z \frac{q(H-z)}{r^3} dz \qquad (7)$$

If the charge distribution, q, is uniform

$$E_{y2} = 5.9\times10^{10} q \left[\frac{1}{(z^2-2Hz+H^2+d^2)^{1/2}} - \frac{1}{(H^2+d^2)^{1/2}} \right] \text{ volts per foot} \qquad (8)$$

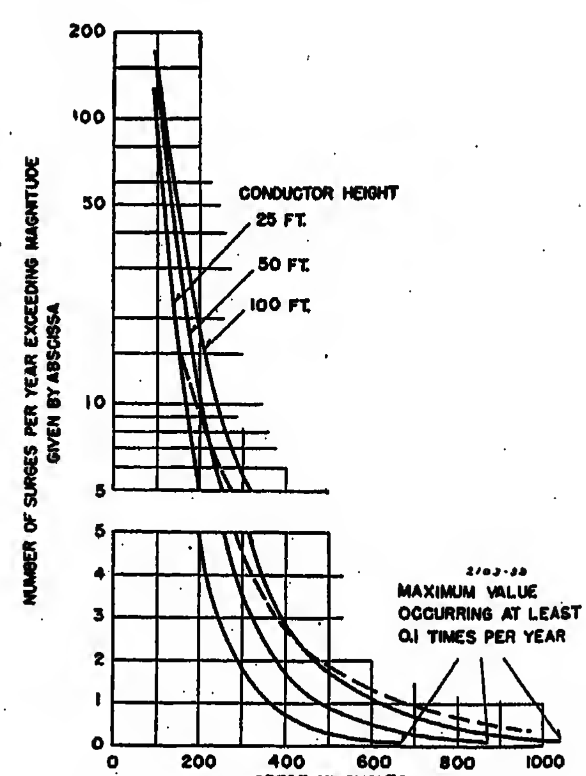

Figure 33. Probability of occurrence of induced voltage at the end of an open-circuit line

Solid curves are calculated
Dotted curve is result of Klydongraph measurements[21]

Maximum voltage which can appear:

h = 25 feet—1,850 kv
h = 50 feet—1,900 kv
h = 100 feet—1,950 kv

ction of time is obtained by the of equation 5. The total field ress of the downward leader is

$$\Sigma_{v_2} \quad (9)$$

instant the downward leader earth Q is zero and

$$.9\times10^{10}q\left[\frac{1}{A}-\frac{1}{(H^2+d^2)^{1/2}}\right] \text{ volts per foot} \quad (10)$$

OGRESS OF RETURN STREAMER

tant that the initial leader reaches eturn streamer shown in Figure ward at the velocity, V, instan- lischarging each portion of the on reaching it. The velocity is (0.1 to 0.6 that of light) so that d potential effect must be con- owever, since the return streamer the initial streamer charge, the where q is changing at any in- the return-streamer tip whose designated by y. Thus, for a t, y, of the return streamer, the electric charge can be expressed on 8 upon the substitution

$$0^{10}q\left[\frac{1}{(y^2+d^2)^{1/2}}-\frac{1}{(H^2+d^2)^{1/2}}\right] \text{ volts per foot} \quad (11)$$

t_1 (as measured from the start n streamer) at which the gradi- iven by equation 11 for a certain s

$$\sqrt{d^2+y^2} \text{ seconds} \quad (12)$$

he time required for the return reach the height y. For a uni- y $V, t_2=\frac{y}{V}$

$$\sqrt{d^2+y^2} \text{ seconds} \quad (13)$$

IELD CAUSED BY CURRENT IN STREAMER

by equation 1 and Figure 4c, potential at P caused by the ribution of current, $+I$, flowing he return streamer channel and I, is

$$\frac{dy}{r_1}$$

$$\frac{y+\sqrt{y^2+d^2}}{d} \quad (14)$$

ident of the units of length used y component of A which con- E_y. Furthermore, its other com- zero. From equation 3

$$\frac{\partial A_y}{\partial t_1} \text{ volts per centimeter}$$

$$\times 10^{-8}\frac{\partial A_y}{\partial t_1} \text{ volts per foot} \quad (15)$$

$$\frac{\partial A_y}{\partial t_1}=\frac{\partial A_y}{\partial y}\frac{dy}{dt_1}$$

Thus

$$E_{yt}=\frac{6.08\times10^{-8}I[1+y(y^2+d^2)^{-1/2}]}{y+\sqrt{y^2+d^2}}\frac{dy}{dt_1} \text{ volts per foot} \quad (16)$$

From equations 12 and 13 for uniform velocity, V,

$$cy=cVt_1-V\sqrt{y^2+d^2}$$

and for the particular case in which $V=0.1c$

$$y=0.10101ct_1-\sqrt{0.000102c^2t_1^2+0.0101d^2} \text{ feet}$$

$$\frac{dy}{dt_1}=0.10101c-\frac{0.000102c^2t_1}{\sqrt{0.000102c^2t_1^2+0.0101d^2}} \text{ feet per microsecond} \quad (17)$$

E_{yt} as a function of time can thus be determined from equations 16 and 17.

Appendix II

The negative charge lowered by the initial downward leader may be distributed over a section that is considerably larger than the core of the upward streamer. Since the upward streamer is essentially at ground potential, to maintain this potential a positive charge must move from earth to neutralize the effect of the negative charge. The magnitude of the positive charge can be determined as follows: Assume the negative charge lowered in the streamer to have circular symmetry of density $-q_1$ per square centimeter per centimeter length and that the radius of the arc core of the return streamer is r_a. Without invalidating the general conclusions, the earth may be represented by a cylinder of large radius, R, symmetrical about the streamers. End effects will be neglected. Both the earth cylinder and the return streamer are at zero potential.

The charge on an elemental ring of radius, r_1, and thickness dr_1 is $(-2r_1q_1dr_1)$ or dQ_1. The field due to this charge external to r_1 is

$$E_r=\frac{2dQ_1}{r} \quad (18)$$

The potential of this ring above the outer cylinder is

$$V_1=\int_R^{r_1}\frac{2dQ_1}{r}dr$$

$$=2dQ_1\log\frac{r_1}{R} \quad (19)$$

The potential due to the charge in the elemental ring for all points within r_1, including the upward leader, is also equal to V_1.

Let dq_u be the charge in the return streamer required to neutralize the negative charge on the elemental ring. The potential of the return streamer above the outer ground cylinder is

$$V_u=\int_R^{r_a}\frac{2dq_u}{r}dr=2dq_u\log\frac{r_a}{R} \quad (20)$$

since the potential of the return streamer is zero.

$$V_1+V_u=0=2dQ_1\log\frac{r_1}{R}+2dq_u\log\frac{r_a}{R} \quad (21)$$

and

$$dq_u=dQ_1\frac{\log\frac{R}{r_1}}{\log\frac{R}{r_a}} \quad (22)$$

To form an idea of the magnitude of this quantity, let R equal 200 feet and r_a equal 0.5 centimeter or 0.016 foot; then for r equal to one foot the positive charge is 0.56 of the negative charge; for six inches, 0.635; for three inches, 0.71; for one inch, 0.79; and for 0.016 foot, 1.0. If the density varies inversely as the distance, the incremental charges in incremental rings of equal thickness are equal, and if the radius of the space occupied by the charge in the downward leader is one foot, then the above values should be averaged over the radius, resulting in a positive charge about 70 per cent of the negative charge. If the radius is not so great, or the core has greater diameter or the charge is concentrated nearer the center (which is probably the case) this value would be larger.

Load Ratings of Cable—II

HERMAN HALPERIN
MEMBER AIEE

Synopsis: Since the author's 1939 paper,[1] further data have been obtained regarding the loading of underground power systems having impregnated-paper-insulated lead-covered underground cable. The results of the studies may be summarized as follows:

1. The factors affecting the setting of maximum safe conductor temperatures are so numerous that no fixed value (or values) can be assumed as applicable to all installations of a given design and size of cable in this country.

2. For some cables, the present temperature limits for normal day-in and day-out operation may be safely exceeded, especially for wartime conditions.

3. For emergency operation safe temperatures may be even higher than listed in the previous paper, especially for wartime operation.

4. Operation in wartimes at special temperatures will mean in some cases substantial shortening of the life of underground circuits and an accompanying increase in service interruptions.

5. Wartime increases in usual maximum daily loading and in load factors may cause large increases in duct and copper temperatures, even if past current ratings are maintained. These temperatures will sometimes exceed those in the present standards.

6. The safe temperature for emergency operation, particularly for extra-high-voltage cables, may be limited by the joints. Also, for all kinds of cable sufficient room must be provided to avoid mechanical damage of cable or joints in manholes with cable movements incidental to emergency loads.

7. Cracking of lead sheaths due to reciprocating cable movement into manholes may limit the temperature range for usual daily loading, but has little effect on the safe emergency loading.

8. For three-conductor solid-type cable, the insulation of the shielded type can safely withstand higher temperatures than the belted type, but the reverse is true as to the allowable daily temperature range with regard to its effect on the sheath in manholes.

9. Cable movement increases with length of conduit sections up to about 250 feet but shows little change with further increases in length up to 1,025 feet.

10. Changes in installation methods and the use of new types of repairs may help to mitigate troubles due to sheath cracking.

11. Copper shielding tape in three-conductor cable with relatively thin insulation has little effect in reducing the thermal drop from the conductor to the sheath.

12. In some cases considerable thermal advantage may be gained economically by making relatively deep installations of conduit.

13. In most cases, the maximum conduit temperature of 50 degrees centigrade given in the previous paper may be safely exceeded.

Paper 42-111, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention Chicago, Ill., June 22–26, 1942. Manuscript submitted April 6, 1942; made available for printing May 11, 1942.

Herman Halperin is assistant equipment and research engineer, Commonwealth Edison Company, Chicago, Ill.

The author is indebted to the following for assistance in the preparation of the paper: H. A. Adler, C. E. Betzer, O. B. Turbyfill, K. O. Bower, F. O. Wollaston, and D. D. Nagley.

The 1939 AIEE paper, "Load Ratings of Cable," by the present author

(*a*). Brought out mainly that the temperatures and allowable loading of underground cable during occasional emergencies could safely be considerably above the past accepted practices.

(*b*). Presented a large amount of detailed data on the limitations due to various factors for different underground cables and conduit systems.

The current war effort and attendant problems on conserving critical materials and labor have increased the importance of this general subject. This paper presents data that are extensions of investigations covered in the previous study and new investigations.

As a general proposition one cannot be dogmatic about the allowable temperatures for a given underground cable circuit. Factors affecting the decision include age and condition of the cable and accessories, effect of heat on the properties of the materials in the circuit, magnitude of usual daily temperature range, size of manhole and training of cable therein, frequency of emergency loading, past history of loading of cable, relation of temperature and temperature range for normal loading to temperature and temperature range for emergency loading, number of cables in conduit, allowable conduit temperatures, thoroughness of field inspection and maintenance work, desired life of the underground circuit, and desired reliability of service. One factor or set of factors may allow one loading while another factor or set of factors for the same cable may allow less loading.

The main purpose of this paper is to present data that, taken along with the data in the first paper and other available information, will aid in deciding the allowable normal and emergency loading for a given cable or system of cables of one design. The data are presented in three parts:

I—Limitations Due to the Insulation.

II—Limitations Due to the Sheath.

III—Heating Characteristics of Cables and Conduits.

I. Limitations Due to the Insulation

Effect of Heat Alone

Since the quality of wood-pulp paper as manufactured had improved since the period of 1920–30 when many tests were made in this country on the effect of high temperatures, it was decided to make further tests. In this series, samples of complete cables of recent manufacture were used in order to make the test conditions more nearly comparable to those encountered in service, instead of using paper tapes as had been usually done in the past.

The samples were 30-inch pieces of three-conductor 500,000-circular-mil solid-type cable from five manufacturers. The ends of each sample were cut square and immediately covered with lead foil which was bound to the sheath with fine copper wire. A lead cap, previously spun to fit the cable, was then placed over each end, beaten to close onto the cable, and sealed to the sheath by lead burning. Tests showed that this method of sealing practically eliminated contamination of the ends of the sample during preparation and also reduced to a negligible quantity the amount of air trapped between the seal and the cable end.

The samples to be aged were placed in ovens—some at 100 and some at 125

degrees centigrade. The effect of aging upon the paper insulation was determined from measurements of

(*a*). The radial power factors of the tapes

(*b*). The tearing strength of the tapes.

The power-factor measurements were on circular areas of single tapes, one half inch in diameter and were made at 60 degrees centigrade and 50 volts per mil. For each sample of cable the power factor of the tapes was measured along a radial path from one conductor to sheath.

The measurements of tearing strength were made with an Elmendorf tearing tester, four to eight pieces of tape being placed together and torn longitudinally at the same time. The tapes were tested immediately after removal from the cable under normal room conditions of temperature and humidity. This seemed warranted since a preliminary investigation showed that variations in relative humidity between 20 and 50 per cent had showed that variations in relative humidity between 20 and 50 per cent had no appreciable effect on the test results so long as the tapes were tested soon after removal from the cable without removing the impregnating oil.

The changes in tearing strength of the paper tapes after various amounts of aging are shown by Figure 1. These data show that for most modern cables, subjection to a temperature of 100 degrees centigrade for 12 months produces negligible depreciation in physical strength of the paper tapes, the average decrease in tearing strength being only 4.6 per cent, as compared with a decrease of 40 per cent in 10 months for the tests reported in 1926–29 by the Massachusetts Institute of Technology.[2]

At 125 degrees centigrade, however, the average deterioration in tearing strength after five months' aging was 43 per cent. At this temperature the rate of decrease in tearing strength of recent paper appears to be of the same order as was found in the 1926 tests. The recent and other tests have shown that tapes which have decreased more than 50 per cent in tearing strength are usually so brittle that their useful life in cable may be considered ended.

The effects of aging on the average power factors of the tapes are shown by Figure 2. For some samples, heating at 100 degrees centigrade for 12 months or at 125 degrees centigrade for five months produced no appreciable change in average power factor. For the best samples, the radial power-factor curves also remained completely flat throughout the tests, with no indications of the common upturns adjacent to the conductor and sheath. For the worst sample, the power factor of all conductor tapes increased from 0.0025 to about 0.01 after 12 months' aging at 100 degrees centigrade; and after five months at 125 degrees centigrade, some of the inner tapes had power factors as high as 0.05. In general, such increases in power factor would not result in a cumulative heating condition for solid-type cable within the present general range of usage but might lower the carrying capacity of the higher-voltage cable by a few per cent.

These data indicate that from the standpoint of deterioration due to heat alone, the maximum safe temperature for modern impregnated-paper insulation is limited by depreciation in physical strength of the tapes rather than by changes in electrical properties. For low-voltage cables where the electrical stresses are too low to have any appreciable effect, therefore, it appears that the insulation could be safely operated almost continuously at conductor temperatures of 90 or 100 degrees centigrade without excessive deterioration; and temperatures as high as 125 or about 140 degrees centigrade during emergencies would be reasonable. The higher limits (100 and 140) would apply for wartime conditions. "Emergencies" or "emergency loading" in this paper means extra heavy loading that would occur on the average of one day per year.

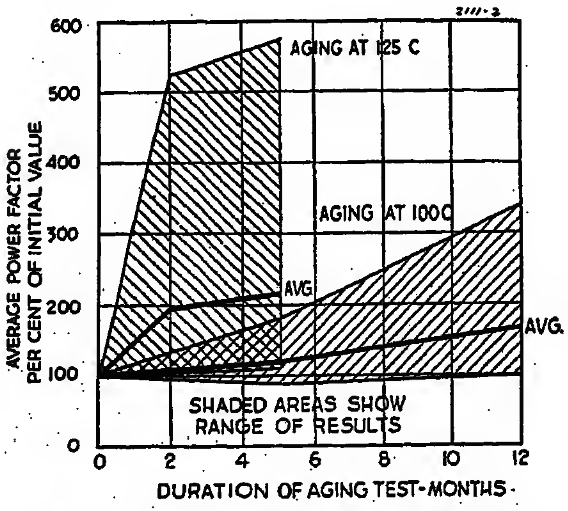

Figure 2. Effect of high-temperature aging on power factor of impregnated-paper insulation as determined from averages of radial power-factor curves at 60 C

Oil-Filled Cable

The 1939 paper included data on tests of three 1,000-foot installations of experimental single-conductor oil-filled cable that was being subjected to high temperatures. This cable was installed in conduit and subjected to 76 kv to ground by means of a tap to a 132-kv three-phase overhead line. After a net time of $8^1/_2$ years of testing, the cables were removed, and extensive investigations were made on samples from various locations.

The three cables are identified as *R*–0.386, *S*–0.400, and *T*–0.500, the number in each case being the insulation thickness in inches. Cable *R*–0.386 had oil feed through both a hollow core and flutes in the inside surface of the sheath, while the other two cables had oil feed through a hollow core only.

As indicated in the earlier paper, the conduit in which these cables were installed was in a very abnormal location and had unexpectedly large variations longitudinally in heating characteristics. As a result, the cables were subjected to widely different temperatures longitudinally. The temperatures were determined from direct resistance measurements of the average conductor temperatures at two- to three-week intervals and by measurements of longitudinal variations in duct temperature on two dates. As a result of this nonuniform temperature distribution, samples of cable were available that had been subjected to maximum conductor temperatures ranging from 95 to 140 degrees centigrade and to periods of heating to 100 degrees centigrade or higher ranging from 0 to 27,000 hours. The heating to which each of the three cables was subjected at the hottest and coolest locations along the conduit is summarized in Figure 3.

After $8^1/_2$ years of testing, cable *R*–0.386 failed because of overheating at the hottest part of the duct run. Figure 4 of the previous paper shows how the

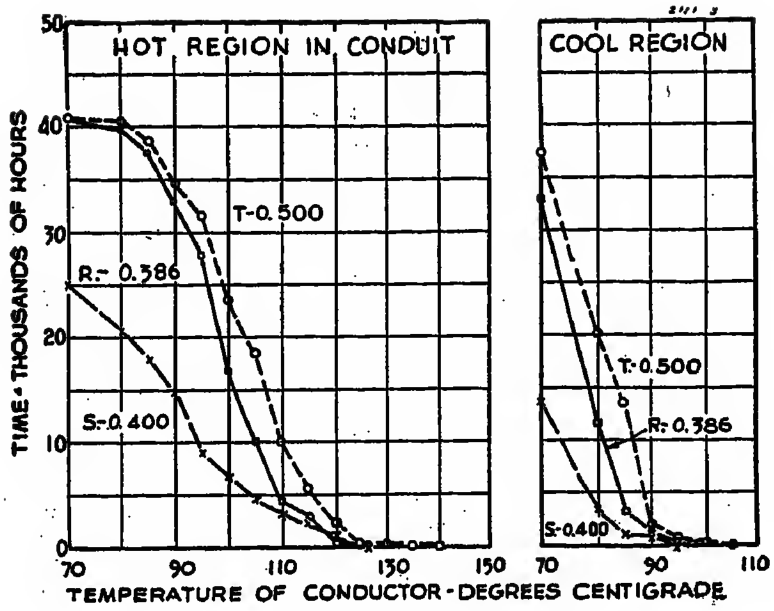

Figure 3. Time of heating at or above various temperatures for experimental oil-filled cables operated at 76 kv to ground

power factors of the cables varied during the tests. Cable *R*–0.386 was electrically stable up to the time of failure, and radial power factors measured on samples of this cable taken from the coolest and the hottest parts showed practically no changes due to all the testing.

On the other hand, cable *T*–0.500 had developed considerable increase in power factor. A sample from the cooler part of the conduit showed power factors at 60 degrees centigrade of the tapes of 0.03 near the conductor and near the sheath, with values dropping down to 0.005 in the middle of the insulation, while a sample from the hotter part of the length had a power factor of 0.025 or 0.03 radially through the insulation. The primary trouble with this cable was the development of an excessive amount of sheath expansion, which increased the internal sheath diameter by 0.06 to 0.26 inch ($2^1/_2$ to 12 per cent) with the greater expansions occurring at the hottest regions. This allowed core oil of high power factor to be drawn radially through the insulation. These excessive amounts of sheath expansion were due mainly to the very high sheath temperatures encountered in these tests and to the fact that the type of alloy used for the sheaths has abnormally high rates of creep, especially at the higher temperatures. Fracture is likely to occur after expansions of four or eight per cent in sheaths, except that the percentage is lower for calcium-type sheaths. This very unusual combination of very high power factors for the core oil and excessive sheath expansion is unique and, according to world-wide experience, is not at all to be expected in commercial installations.

An interesting phenomenon brought out by these tests, although not directly related to the effect of temperature on the insulation, was the fact that, at locations where the gap between the sheath and the insulation resulting from the sheath expansion exceeded about 0.15 inch, severe electric discharges occurred between the outer surface of the unshielded insulation and the inside surface of the sheath. These discharges burned numerous deep pits in the inside surface of the sheath and burned holes through the outer two to five tapes of the insulation. No visible evidence of damage was found below the sixth tape from the outside, and all indications were that the discharges had little if any effect on the power factor of the insulation below that tape. These cables were subjected to lightning and switching surges having crest voltages as high as 600 kv, and it is possible that these surges caused the initial breakdown of the oil gap. From other investigations, it seems possible also that gas was evolved from the paper during the very high temperatures.

The results of measurements of the tearing strength of the paper insulating tapes from samples of cable that had been subjected to various temperatures are summarized in Figure 4. During preparation of this figure, the temperature treatment to which each sample had been subjected was reduced to the equivalent temperature for a period of 12 months, using the assumption that the rate of deterioration in physical strength of the insulation would double for each eight degrees centigrade increase in temperature. Since the tearing strength of the tapes when new had not been measured, the initial values for each cable were taken as the average results for all samples of tape that had been subjected to maximum temperatures of lower than 85 degrees centigrade.

A definite but rather gradual decrease in tearing strength with increasing temperature is shown by these data. The indications are that temperatures equivalent to at least 117 degrees centigrade for 12 months would be required to produce a reduction in tearing strength of 50 per cent (approximate allowable limit for useful life, especially in connection with removal and reinstallation).

The failure in cable *R*–0.386 occurred at a location where the conductor temperature had been at least 140 degrees centigrade for approximately 100 hours prior to the failure. The examination

indicated that the final failure was of the cumulative heating type, but the radial power factors of adjacent samples were low as in new cable. The exact mechanism of failure is not well understood, but it seems likely from other Chicago tests that the high temperature may have resulted in the evolution of some gas from the paper. The failure would then have been initiated by ionization of the gas with subsequent development of a cumulative heating condition.

Aging tests of six oil-filled experimental cables with a conductor size of 500,000 circular mils and 450 mils of insulation have been in progress since 1936 in an indoor laboratory. The cables have been subjected to various steps of heating up to 100 degrees centigrade as shown in Table I. Heating was applied partly continuously and partly in daily cycles. During some test periods a test voltage of 95 kv to ground was applied, and some test periods were without superimposed voltage. As Table I shows, the changes of the insulation, judging from the results of power-factor measurements, were small (0.003 or less).

These tests were continued at an average copper temperature of 110 degrees centigrade. After nine weeks at this temperature step without voltage, 95 kv was applied, and then a failure occurred in one joint due to the effect of overheating.

Experience in aging tests with overvoltage and heating currents on both solid and oil-filled types of cables for extra high voltages has shown in many cases that trouble caused by overheating may develop more readily in joints and potheads than in the cable. This may be due to the use of large amounts of insulating materials, which decrease the dissipation of heat, or due to loosening of metal parts, or other causes. This finding emphasizes the need for careful study of the limitations of the accessories in the determination of emergency ratings for extra high-voltage cables.

From a consideration of the results of these investigations together with other earlier data, the following conclusions may be drawn:

1. Oil-filled cables may be subjected continuously to conductor temperatures of the order of 100 degrees centigrade for at least 30,000 hours without producing any serious increases in power factor.

2. The maximum safe temperature for the *insulation* of oil-filled cable for long periods of time is probably limited by deterioration in the physical strength of the paper rather than by changes in electrical properties. From this standpoint the cable will withstand 115 degrees centigrade for one year or 100 degrees centigrade for at least 30,000 hours.

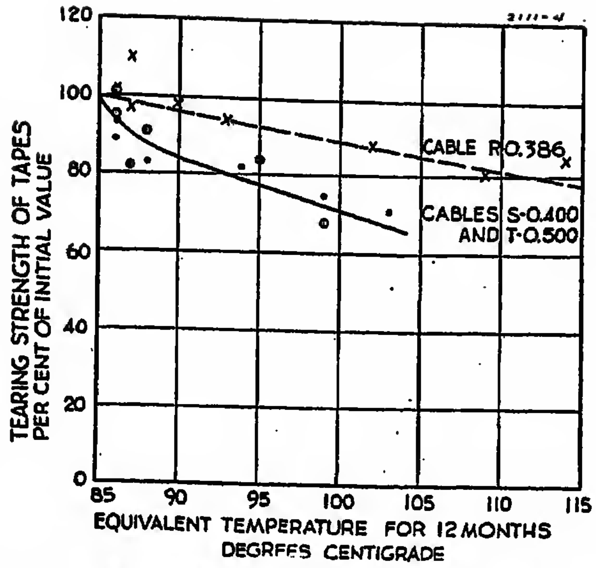

Figure 4. Effect of temperature on tearing strength of paper tapes from experimental oil-filled cables

(The preceding two conclusions are of considerable interest in connection with other oil-impregnated insulation, especially that normally used in transformers, but it must be noted that in oil-filled cable the amount of air present is relatively very small.)

3. At some temperature that is definitely well above 100 degrees centigrade and is probably between 120 and 140 degrees centigrade, there is danger of electrical failure of the cable occurring without previous changes in power factor. Joints and potheads may give trouble at lower temperatures.

4. If oil-filled cables are operated for long periods of time at sheath stresses or temperatures in excess of those for which they were designed, excessive sheath expansion may occur.

Maximum allowable temperatures for oil-filled cable may, therefore, be as high as follows: for usual conditions—85 and 105 degrees centigrade for normal and emergency loading, respectively; for wartime conditions—95 and 115 degrees centigrade for normal and emergency loading, respectively.

Aging Tests of Three-Conductor Solid-Type Cable

A great amount of information on the combined effect of voltage and temperature upon the stability of solid-type cables has been obtained in aging tests of three-conductor cables for operation at 9 or 12 kv, three-phase. As described in the previous paper, the tests consisted essentially in subjecting test lengths of 100 feet or more between pressure-tight terminals for four weeks to 24 kv, three-phase, continuously with 20 superimposed load cycles ranging in maximum temperatures from 60 to 115 degrees centigrade. The compact terminals were filled with heavy mineral oil, such as is used in solid cable.

Since the previous paper, 23 more cables have been tested. Since the inception of these series of tests in 1935, a total of 30 cables has been tested with pressure-tight potheads; five cables have been tested with open potheads, and four cables with old rosin compound made prior to 1920 have been subjected to similar but milder tests. Of the 30 cables tested with pressure-tight potheads, 17 were shielded cables and 13 were standard belted 13-kv cables with 141 mils of conductor insulation and 78 mils of belt insulation.

The net insulation thicknesses of the shielded cables ranged from 90 to 143 mils. Added to these walls of insulation were in most cases two or three special shielding tapes over the conductor and one special shielding tape over the insulation. The special shielding tapes were either metalized paper tapes or carbon black tapes. Based on the results of these aging tests, such as stability throughout tests with 125 mils of insulation, an insulation thickness of 141 mils including special shielding tapes has been adopted as standard for operation on the Chicago 12-kv system as compared with net insulation thickness of 172 mils recommended by the Association of Edison Illuminating Companies Cable Specifications.

Table II shows the effect of the standard aging tests with pressure-tight potheads upon the development of ionization in 25 representative cables. A great superiority in stability of the shielded over the belted cables is evident in spite of the reduced insulation thicknesses of the shielded cables, especially if the five cables with extremely thin insulation are eliminated from comparison. The nine shielded cables with insulation of 108 mils or more showed less increase in ionization than 0.005 throughout these aging tests. As was expected, more severe deterioration occurred in the cables with extra thin insulation. In many cases shielded cables showed only small increases in ionization or even decreases in the 115-degree-centigrade step after deterioration in the 80- and 100-degree-centigrade steps, possibly due to redistribution of compound at the extra high temperatures.

Belted cables showed, in general, progressing deterioration in successively higher temperature steps. Also, higher percentages of the cables tested reached greater degrees of deterioration. However, in contrast to shielded cables, they showed, in general, considerable recovery during days with voltage only and during cycles at only 60 degrees centigrade following the high-temperature cycles.

Failures occurred only in used belted cables and only in the 100- or 115-degree

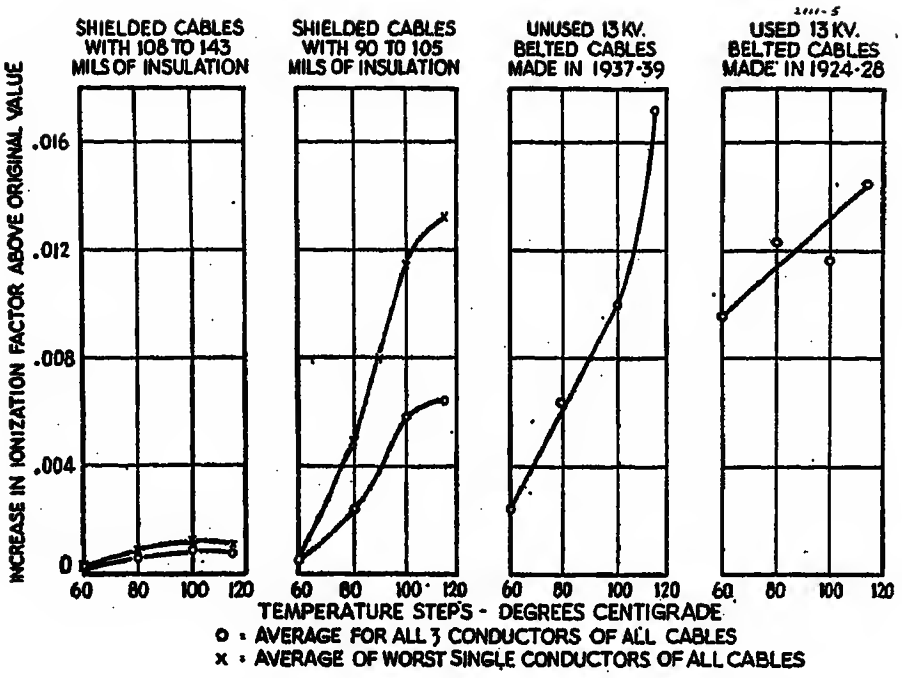

Figure 5. Increase in ionization factor at room temperature during aging tests

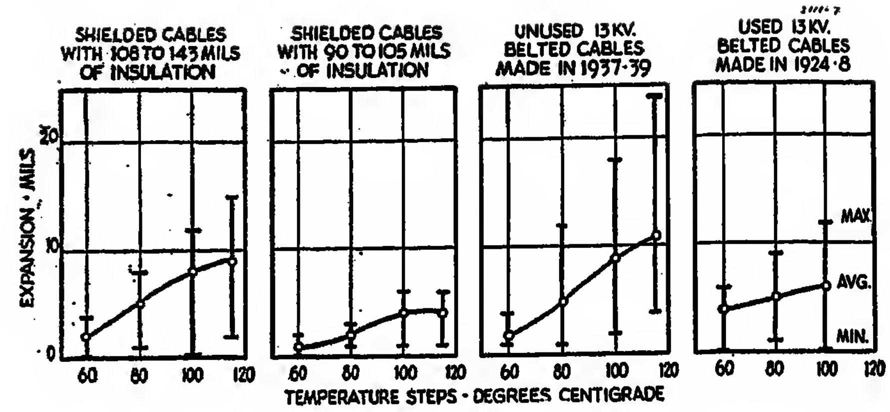

Figure 7. Increase in over-all diameter of three-conductor cables after various temperature steps in aging tests

step. The three failures that occurred were all due to ionization.

Figure 5 gives some indication of the rate of deterioration with increased temperatures, as it shows the average increase in ionization above the initial values for all cables in the various temperature steps. Since in many cases where deterioration occurred in shielded cables only one conductor was affected, both the increases for the worst conductors and the average increases for all three conductors are shown for the shielded cable. For the belted cables, only the average increases for all three conductors are given. The very small effects of the various temperature steps and especially of the 115-degree step are apparent for shielded cables with more than 108 mils of insulation. For unused belted cable the curve becomes progressively steeper with higher temperatures. The used belted cables tested showed greater changes but a flatter slope; the reasons for the shape of the curve are not completely clear.

Taking all data into consideration, and noting that the tests were made at twice operating voltage, one should not expect serious deterioration due to ionization on

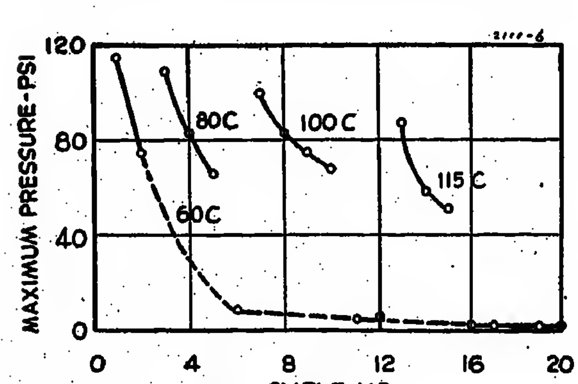

Figure 6. Maximum pressures in various temperature steps during aging tests of a typical sample of 500,000-circular-mil three-conductor shielded cable

lines containing only cables made recently at emergency temperatures of 100 degrees centigrade or somewhat more; but some serious deterioration may occur at such temperatures on lines containing cables made, say, 14 or 18 years ago. The margin of safety is greater for the shielded cables. This conclusion agrees fairly well with the emergency temperature of 98 degrees centigrade recommended for 12-kv operation in the AEIC Simplified Practice Schedule.

As discussed in the previous paper, thermal failures (cumulative heating) due to steep dielectric loss-temperature curves may occur at even moderate temperatures in local spots of some old rosin cables, but such failures should not be expected in cables made later, even at temperatures as high as 120 degrees centigrade, except under abnormal conditions.

War conditions will necessitate increasing use of American wood pulp for insulating tapes instead of the Swedish wood pulp used heretofore. For this reason, comparative aging tests were made on samples insulated with Swedish wood pulp and similar samples insulated with American wood pulp. The samples were purposely made with very thin insulation in order to obtain definite deterioration. While, as expected, all samples showed serious deterioration, the test results as well as examinations and tests after completion of the aging tests showed no appreciable difference in stability of the two types of paper. Experimental lengths of various makes with reduced insulation thicknesses with American and Swedish wood-pulp paper insulation have been installed on heavily loaded 12-kv lines and will be removed after a few years of service for further comparisons.

Compared with the effect of these overload tests on ionization, the effect on the solid losses of the cables was small. As Table III shows, the great majority of the samples showed only small increases in solid losses, and only a few showed moderate or serious increases. It should be noted that the increases shown are the maximum changes; that is, the portions of the test lengths were selected that developed hot spots or showed otherwise the greatest degree of deterioration. The conclusion may be drawn that occasional overloads will not affect seriously the dielectric losses of the impregnated tapes themselves.

In accordance with the results of the electrical measurements, visual examination of aged cables gave evidence that deterioration was mainly due to ionization. Deteriorated samples showed dryness and wax, and in the case of more deteriorated belted cables carbon also.

Figure 6 shows typical pressure readings during the 20 heat cycles in the standard aging tests. The pressures dropped sharply in successive cycles of the same maximum temperatures. In general, the highest pressures occurred in the first week of 60- or 80-degree cycles rather than in subsequent cycles to higher temperatures. These data lead to the conclusion that severe overloads applied to cable that previously carried heavy loads will not produce excessive pressures, assuming that joints are not oil-filled and connected to reservoirs.

The expansion of the sheath produced by the heat cycles is summarized in Figure 7. As should be expected, a comparison of this figure with Figure 5 suggests a relation between sheath expansion and progress of ionization. These expansions are not sufficient to cause fracture in sound sheath. However, there were some cases in these aging tests where leaks occurred in the thin portions of eccentric sheath in old cables. None of these leaks occurred before the 100-degree step. These observations in the aging tests suggest that it must be expected that in service sudden overloads may open up cracks in thin or defective sheaths.

It is difficult to generalize as to allowable temperatures for three-conductor cable for operation at about 12 kv, mainly due to the variety of cables in service. It

* A/W ratio is the ratio of the total copper area in the cross section of the cable expressed in circular inches to the weight per foot of cable expressed in pounds.

** Contains fluted oil channels 94 mils deep.

seems, however, from data in this paper that from the standpoint of the insulation (including radial expansion of the sheath), the normal and emergency temperature limits are, respectively, about as follows for limiting cable types: for modern shielded cable—85 and 110 degrees centigrade; for 1920–25 belted cable—75 and 90 degrees. For single-conductor cable, the limits may be the same as for shielded cable. For wartime conditions, the temperatures could be increased perhaps seven degrees for normal daily loading and ten degrees for emergency loading. For some old cables with relatively heavy insulation (usually containing relatively large amount of voids), allowable emergency temperatures during wartimes might well be 120 degrees or even higher, depending on cumulative heating characteristics and condition of sheath. With the very high cable temperatures, troubles may occur with the joints due to expansion of compound or movement against manhole wall, and so forth.

II. Limitations Due to the Sheath

The main objective in studying sheath life is to find out how to get a reasonably long life out of the sheath under any and all loadings up to the maximum that the insulation will stand. The loading and resulting temperature ranges determine the cable movement, which in turn determines the sheath life in the manholes.

The earlier paper presented some data on magnitudes of cable movement found in the field and theories relating thereto. In addition, some information was given regarding the relation between sheath life and cable movement as determined by the influence of cable size and construction, by sheath material, and by installation conditions in ducts and manholes. Further data and discussions on movement and sheath life are given herein.

As indicated in the previous paper, most underground circuits having material variations in daily temperatures—which is the usual case—are limited in rating for day-in-and-day-out (normal) loading more by the sheath than by the insulation. For example, the insulation might limit the normal daily temperature to 85 degrees centigrade for a given cable, while for the accompanying conduit temperatures and character of daily variation in load, the resistance of the sheath to cracking in the manhole may limit the copper temperature to 77 degrees. The problem of sheath cracking in manholes is affected by so many variables that it is hard to lay down any definite rules and positive numerical conclusions. Nevertheless, a great deal of data have been gathered which lead to more or less general conclusions that may serve well in guiding design and operating practices.

Laboratory Tests

Laboratory tests are mainly useful in determining the general engineering relations between sheath life and cable movement for different variables. The tests relating sheath life to magnitude of movement and to cable training in the manhole have all been made on pieces of cable 4 (Table IV) from one length which had copper-bearing lead sheath and compack conductors. The tests were made in the dummy manhole described in the previous paper with the cable fireproofed in the standard manner there described.

The relationship between sheath life and cable movement is shown in Figure 8. Where the movement at each duct mouth is 0.75 inch or less, the life appears to be inversely proportional to roughly the 1.5 power of the movement. For movements of over 0.75 inch the life is less than would be indicated by this relation; the limited data available indicate that in this range the life is inversely proportional to something more than the square of the movement.

In one set of tests in the dummy manhole, the one variable was the offset between the center line of the joint and the center line of the cable in the duct. The numbers of cycles to sheath cracking for offsets of $9^1/_2$, 19, and $28^1/_2$ inches were, respectively, 3,100, 6,800, and 10,000 cycles. Apparently, then, increasing the offset is very helpful in lengthening the life of the sheath. Of course, there is the attendant problem of finding enough room for the wider manholes thereby required. Also, as indicated in the previous paper, the magnitude of the daily movement at the duct mouth is affected by the restraint of the cable in the manhole; and with large offsets this restraint would be decreased somewhat to nullify part of the apparent advantage in longer offsets.

In another set of tests the one variable was the length of the manhole, the offset being 19 inches. For lengths of $7^1/_2$, 10, and 13 feet between duct mouths the corresponding number of cycles to sheath cracking was, respectively, 4,700, 6,800, and 6,900 cycles. Apparently, if the offset is kept constant, increasing the length of the manhole is of material value only

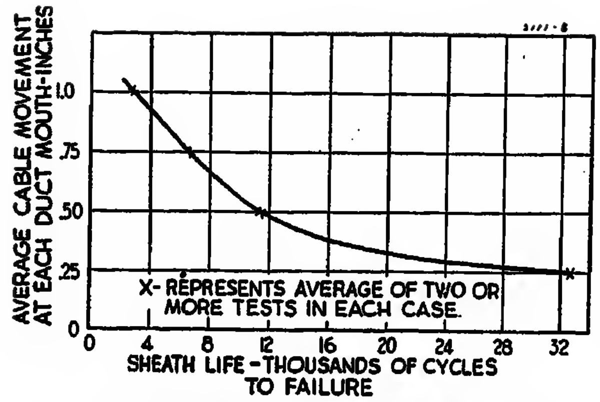

Figure 8. Relation of sheath life in dummy manhole to cable movement

up to a certain point. Beyond that point, apparently, the strain on the sheath is not much affected.

A number of tests have been made to determine the effect of fireproofing on the life of the sheath. The standard fireproofing compound in Chicago is a cement, sand, and asbestos mixture. The standard method is to apply this mixture over plain felted asbestos tape which is one-eighth inch thick and wrapped in a single butted layer over the sheath. With such fireproofing the life of the sheath in the dummy manhole does not seem to be much different, according to tests, from the life with no fireproofing at all. Omission of the asbestos tape, however, resulted in reductions of about one third in the life in the dummy manhole in a pair of tests at a movement of 0.75 inch and in a pair at a movement of 0.25 inch. Apparently, a thick solid fireproofing will shorten the life of the sheath, particularly if the fireproofing itself cracks in service.

In 1940 it was decided that the tests in the dummy manhole apparatus should be supplemented by tests on short pieces of cable and on small strips of sheath in which the magnitude of the cyclic deformation of the sheath could be more accurately controlled than is possible in the dummy manhole test. It was thought that the better reproducibility and relative cheapness of tests of this type would make them preferable for comparative tests of many variables in materials and conditions. In order that the results of such a test be applicable to service conditions, however, it is necessary that the type and the magnitude of the deformation be approximately the same as occur in service or in the dummy manhole test. Therefore, an investigation was started to determine the cyclic deformation of the sheath at various locations along the cable during tests in the dummy manhole apparatus. The investigation was later expanded to obtain deformation data for use in analyzing the effect upon the sheath life of variations in installation conditions and type of cable.

After trials of different schemes, it was found that the most satisfactory method of determining the cyclic sheath deformation was to measure the change in distance between the ends of small copper rivets soldered to the sheath at three-inch intervals along both the front and the back of the cable. A small conical hole was drilled in the end of each rivet, and the distance between the holes in adjacent rivets was measured with a dial gauge reading to the nearest 0.001 inch, thus giving an accuracy of ±0.03 per cent. The tests were made on fireproofed cables.

The early tests showed that the deformation at any given location along the cable might vary considerably during a given dummy manhole test. As a result, it was found necessary to measure the sheath deformations after various periods during the test and to take the average of all measurements at a given location as being the effective deformation at that location.

Figure 9 shows the variation in sheath deformation or strain along the cable for a typical test on cable 4 (Table IV). As shown by Table V, the maximum sheath strain for this cable under these conditions ranged from 0.35 to 0.42 per cent, and usually occurred in the three-inch section adjacent to the joint wipe. The results of tests on the same type of cable under different training conditions are also shown on Table V. The equivalent lives in the dummy manhole test and the maximum sheath strains were in all cases in the correct relative order; that is, higher deformations give shorter lives, but the number of measurements is insufficient to determine the relation between sheath strain and life.

When shielded cables were adopted as standard for use on the 12-kv system in Chicago in 1940, some tests in the dummy manhole were made to see whether the lives under bending were of the same order as for the belted cables which were previously used. As shown by Table V, the life of the shielded cable with standard training and 0.75-inch movement at each duct mouth was only about 4,300 cycles, or 63 per cent of the average life for all comparable tests of belted cable. With 0.50-inch movement at each duct mouth, the life of the shielded cable was about 5,400 cycles or one half of that for belted cable.

For both values of movement the measured sheath strains were slightly higher for the shielded than for the belted cables, but the differences were insufficient to account for the differences in equivalent lives in the dummy manhole test. The shorter lives of the shielded cables appear to be connected with the fact that the sheaths bulge and wrinkle under the repeated bending to a much greater extent than do those of the belted cables. Preliminary investigations suggest that this may be due to

(*a*). A tendency for the metal binder tape to concentrate the sheath deformation at certain spots.

Figure 9. Variations in sheath strain along cable for typical 13-kv belted cable in ten-foot manhole with 0.75-inch movement at each duct mouth

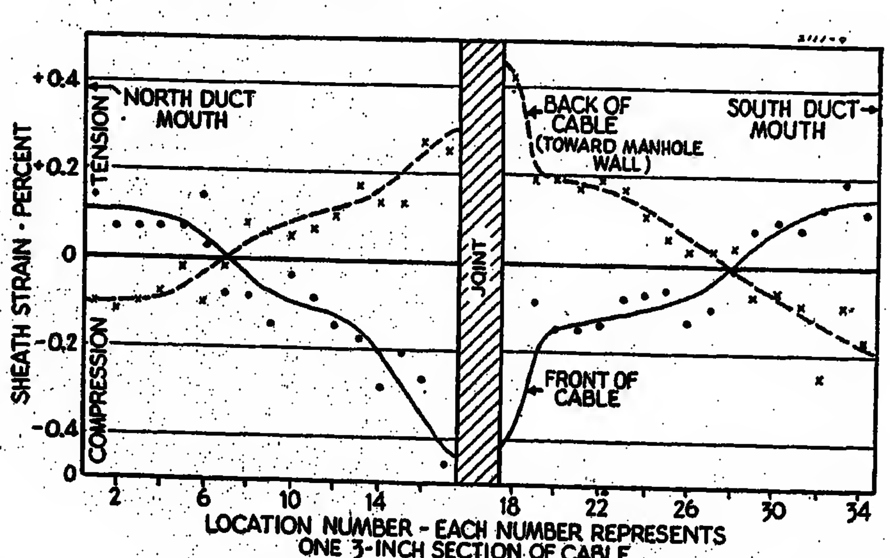

Figure 10 (right). Curves for estimation of average movement and distribution of measurements with respect to curves

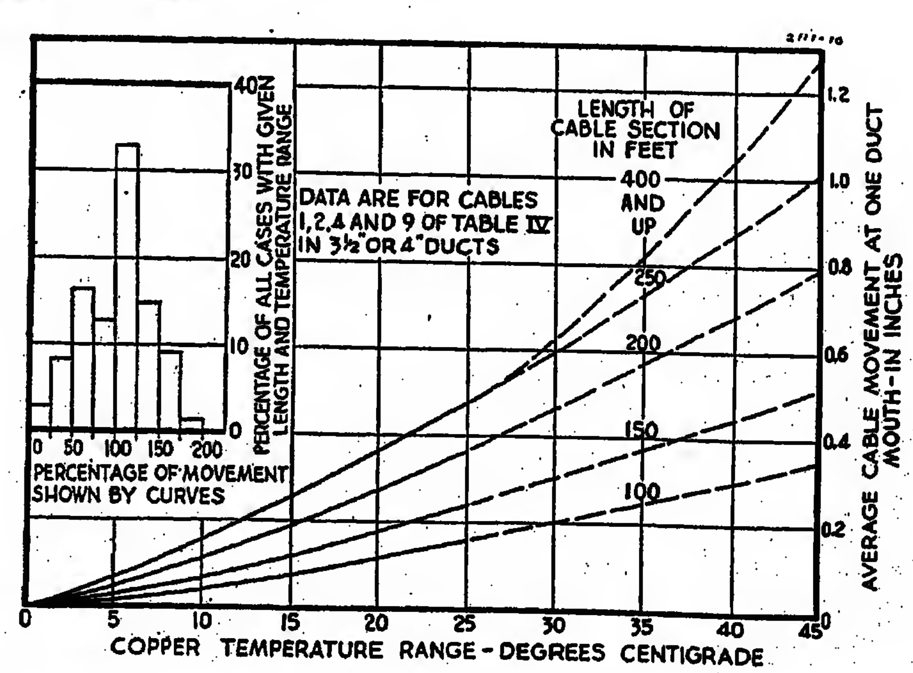

(*b*). The failure of the usual metal binder to hold the conductors as firmly together as does the belt on a belted cable.

(*c*). The tendency for the slightly thinner sheaths used on the shielded cables (117 mils as compared to 125 mils on the belted cables) to wrinkle more easily.

The effects of these factors are being investigated further in an effort to determine what changes in construction of the shielded cables will be necessary to obtain longer sheath lives.

Table V. Tests in the Dummy Manhole Apparatus of Three-Conductor Cables on Which Sheath Strains Were Determined

Type of Cable	Manhole Length—Feet	Cable Training	Movement at Duct Mouth—Inch	Maximum Sheath Strain—Per Cent	Cycles to Sheath Failure
Belted	10	Standard	0.75	0.42	7,080
Belted	10	Standard	0.75	0.35	7,520
Belted	7.5	Standard	0.75	0.60	5,620

Shielded	10	Standard	0.75	0.60	About 4,000
Shielded	10	Standard	0.50	0.50	4,970
Shielded	10	Standard	0.50	0.33	5,740

Field Data

The theory of cable movement, without which field data on movement are largely unintelligible and unusable, has been extended somewhat and brought into better agreement with the field data since the previous paper was published. The most interesting discovery is that long lengths of cable do not move any more than short lengths, within certain limitations. The graph in Figure 10 illustrates the present findings based on field measurements. For copper temperature ranges up to 25 degrees centigrade, all lengths in excess of 250 feet have only as much movement as a 250-foot length. This effect is probably due to snaking and anchoring of the cable in the duct or to duct friction.

The curves in Figure 10, which are almost entirely empirical, can be matched fairly well by using in formula 2 of the previous paper a value of D, the duct-friction coefficient, equal to about 1.6. This happens to be about the right value for the static coefficient of friction of cable in precast concrete duct, indicating that static friction, as well as complete anchoring, may be an important factor in limiting cable movement. When the coefficient of sliding friction, about 0.5, is used in the formula, the calculated movements are much higher than those found in service and exemplified in Figure 10 and, of course, would be still higher with sliding friction coefficients of 0.2 or 0.3, such as are sometimes reported. One case is known where the ducts are clogged with fine silt for several lengths on one part of a heavily loaded line, while on other parts of the line the ducts and cable are identical but free of silt. The daily range of movement at the duct mouth in this latter part of the line is about three times as great as in the silted ducts.

These points are strikingly illustrated by observations on a 500,000-circular-mil single-conductor 69-kv line having lengths up to about 1,000 feet in four-inch ducts. The data, for which the author is indebted to Cincinnati Gas and Electric Company, are given in Table VI. The lengths on which measurements were taken, given in column 1, range from 529 feet to 995 feet. In column 2 the measured total movement for both ends of each length for a copper temperature range of 38 degrees centigrade are given. It is especially interesting that the longer lengths had no more movement than the shorter lengths; in fact, the shortest length moved more than the longest length. The second interesting point is that, as shown by column 3, the observed movement was only about as much as would have been produced by 410-foot lengths, according to calculations using formulas for determining cable movement given in the previous paper. The remainder of each length was apparently immobilized by anchoring. The length of cable that actually moved, 410 feet, is somewhat longer than the corresponding value of 250 feet found for the cables studied in Chicago. One probable reason for this is that the Cincinnati cable was not fireproofed at the time of the field observations, whereas all Chicago cables are fireproofed. The absence of fireproofing increases the movement noticeably.

Data obtained early in 1942 for the Cincinnati line (with fireproofing on the cable in the manholes) showed for daily copper temperature ranges of about 18 degrees centigrade that the range of movement at the duct mouths was almost the same for 250- and 496-foot lengths as for 850- and 981- and 1,025-foot lengths. Also, it was found that slopes of six per cent for some of the conduit did not affect the daily movement.

Similar data on relatively small movement have been furnished by the Montreal Light Heat and Power Consolidated for its recent installation of 650,000-circular-mil 120-kv oil-filled single-conductor cable. Lengths of 682 to 960 feet had movements of $^1/_8$ to $^7/_{16}$ inch at a duct mouth for daily copper temperature ranges of 16 to 22 degrees centigrade. The largest movement was found for the 682-foot length and occurred with the 22-degree range.

The dashed portions of the curves in Figure 10 are for daily temperature ranges exceeding 25 degrees centigrade, which seldom occur in service. For this reason this portion of the curves is not well verified by field data. However, it can be said that the actual movements measured in Chicago have on the average been no greater than indicated by the curves. Any revision in this portion of the curves is expected to be toward smaller values of movement, especially for the longer lengths exceeding 250 feet.

The probability curve in the left-hand corner of Figure 10 gives the relation between the actual field data and the plotted curves. It may be seen that 46 per cent of all the field data are within 25 per cent above or below the values shown in the graph, while a few cases may be 100 per cent above or below the graph. Of course, it will be the lengths that have more than average movement that will tend to have relatively short lives before cracking of the sheath in the manhole. A rough analysis indicates that some lengths will start to crack after a period equal to one fourth or one third of the average life of the cable on the line, and after a period equal to one half the average life about one sixth of the original lengths will have cracked. If each length is replaced as it cracks, the indications are that the rate of cracking will increase up to a period equal to about two thirds the average cable life, after which it will tend to level off or even decrease somewhat. If the sheath limits the life of the line to about 20 years, for example, then the annual rate of sheath cracks may become 50 or 75 per 1,000 lengths.

As indicated by the title of Figure 10, no significant difference has been found in the movement in service of cables of the sizes indicated operating at 4, 12, and 66 kv. This is in accordance with expectations, since the ratio of conductor cross section to total cable weight is about the same for all these cables (see Table IV), and the movement should, therefore, be about the same.

Cable of a given size is found to have about as much movement in 3.5-inch duct as in four-inch duct, and probably

also in three-inch and five-inch duct, although this latter is not well verified. Since lengths of cable in service are usually at least 250 feet long, limitation of the movement by anchoring is always a factor, and the negligible influence of duct size found to date indicates perhaps that anchoring occurs about as readily in large ducts as in small ones. Another way of looking at it is that the coefficient of either static or sliding friction is not much different for a cable in a large duct than in a small one, provided the cable can be installed in the smaller duct without actually jamming or tending to jam. The movement would therefore be expected to be about the same in both cases. Similarly, according to scanty data, the material of the duct does not seem to make much difference.

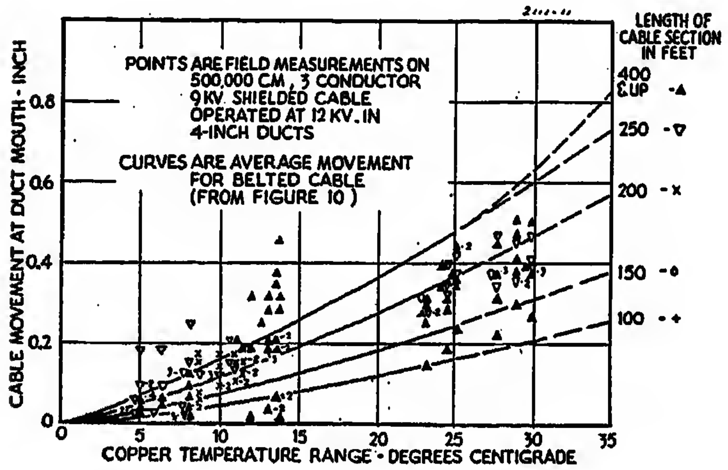

Figure 11. Comparison of movement of lengths of shielded cable with average movement of belted cable

It has been suggested that three-conductor cable constructed with a short lay should move substantially less than similar cable with a long lay. No significant difference has been detected based on field measurements on the usual run of belted cable and on some belted cable made some years ago with relatively short lay. These cables, of course, had the belt insulation and sheath tightly around the conductors. If, on the other hand, the three-conductor cable is of the shielded type, and the binder and sheath are not particularly tight, then the cable in ducts may move less with shortening of the lay. Even in this case there would still remain the thermal expansion of the lead sheath itself, which might produce substantial movement of the sheath at the duct mouth. Also, no significant difference has been found between cables having "compack" sector conductors and those having ordinary sector conductors.

It is not claimed that the factors discussed in the foregoing three paragraphs have no effect at all. What is meant is that their effects are not large enough to be detected individually in data on cable in service, because of the inherent variability of such data. For example, a single length of cable is often found to have considerable movement at one end and practically none at the other. The cause may be suspected to be variable friction along the duct, but it is not practicable to prove it. Similarly, the various other factors may be suspected, but no way has yet been found of isolating and proving them.

Considerable data have been obtained on cables not covered in the curves of Figure 10. Figure 11 shows data for 500,000-circular-mil three-conductor shielded cable operated at 12 kv (cable 5, Table IV). Such cable has about the same ratio of copper cross section to the total cable weight as the cables covered in Figure 10. However, for the larger temperature ranges the cable movement is somewhat less, and this characteristic tends to counterbalance the relatively smaller life to cracking in manholes for this cable as compared to belted type cable for a given movement at a duct mouth. Further field measurements are to be made. Other figures similar to Figure 11 could be plotted to show the data, for example, for field measurements on 350,000-circular-mil three-conductor 13-kv and 35-kv belted cables (cables 6 and 7, Table IV). These two cables have lower cross-section-to-weight ratios; and the field measurements at temperature ranges of about 10 or 20 or 30 or 42 degrees centigrade brought out that the movements were actually lower than on Figure 10. Similarly, cables 8, 10, and 11 of Table IV, that is, single-conductor 69-kv cables of the ordinary type, have lower cross-section-to-weight ratios than the cables of Figure 10, and their measured movement averages somewhat less. Figure 10 is used for predicting the probable movement of cables such as cables 6, 7, 8, 10 and 11 because of convenience and the assurance that the movement values will be conservatively high.

A direct relationship between cable movement and sheath life in service is not usually determinable except in special cases. As an example of the latter, the 69-kv cable in Chicago may be cited. There are over 4,000 lengths of 750,000- and 1,000,000-circular-mil single-conductor solid-type 69-kv cable on the system. Practically all of it has been in service about 14 years, and no sheath cracks due to movement have occurred. The daily temperature variation has been about 8 or 10 degrees centigrade throughout the life of the cables, and from Figure 10 the corresponding movement is found to be not more than about 0.15 inch at each duct. The manholes are all about $11^1/_2$ or 12 feet long, and the offset between the center of the cable at the duct mouth and center of joint is about 19 inches. On the basis of the usual distribution of measured cable movements for a given load, as shown on Figure 10, it has been computed that the average life of a cable line should be at least three times the period between installation and the occurrence of the first cracks. From this it may be concluded that the average life of the sheath on these cables will be at least 45 years. From this it is reasonable to conclude at once that any cable, excepting three-conductor shielded cable, having the same over-all diameter (2.8 inches—see Table IV) and ratio of copper cross section to total weight and installed in 12-foot manholes and subjected to not more than ten degrees centigrade daily temperature variation would have a life of at least 45 years.

If the expected daily temperature variations were to be larger, say 20 degrees centigrade, the probable life could be estimated as follows: From Figure 10 the daily movement would be about 0.37 inch. From Figure 8 the life under test conditions at 0.37-inch movement is roughly one third the life at 0.15 inch. From the estimates at the end of the previous paragraph, divided by three, it appears that the sheath life in service with a 20-degree range would be, perhaps, 15 years.

The big and outstanding point is that small increases in loading are reflected through the square law in sizable increases in temperature range; and these, in turn, cause large cable movements, because the cable movement increases faster than the first power of the temperature range. Furthermore, the sheath life decreases much faster than the first power of the increase in movement.

It has been found next to impossible to determine directly the numerical relation between cable movement and the actual sheath life of three-conductor cable in service. A rather unsatisfactory alternative which was perforce adopted, might be used by any utility in studying its own operating records for a given type of

cable. This method results in data such as shown in Figures 13 and 14 of the previous paper. Such data may be extrapolated for higher loads, using a relation such as in Figure 8.

Referring to Figure 8, detailed studies of over 300 sheath cracks and history in service of the cables involved indicate that the number of daily cycles to cracking for cable in service is less than the number of cycles to cracking in the dummy manhole for a given movement. The ratio may be roughly 50 per cent. The duration of each dummy manhole cycle is only 70 seconds as compared with 24 hours for cable in service. The longer time for one thing results in relatively more plastic flow of the sheath. Some field results indicate that vibration or special conditions in the manhole may in some cases lower the life in service considerably below the usual value. Another factor tending to decrease the sheath life in manholes as compared to life in test is that the sheaths in manholes on well-loaded lines are at higher temperatures than sheaths in the laboratory; this influence would become larger with wartime loading of cables at increased temperatures.

Table VI. Data on Movement of Long Lengths of Single-Conductor Cable in Cincinnati

Actual Cable Length—Feet	Total Movement for 38 C Temperature Variation—Inches	Calculated Length of Cable to Produce Same Movement as Measured—Feet
750	2.0	320
840	2.50	420
995	2.375	400
529	2.625	470
598	1.875	290
812	2.25	360
874	3.375	640
		Average 410

In estimating the effects of the higher loads due to the present emergency, it should be kept in mind that the cable has been in service for some time, and possibly one third or more of the sheath life, for example, has been spent. This should mean, for example, that with new daily loading, which would for a new cable give say ten years' life, one may obtain only five or seven more years' life for the cable in service, and a relatively high rate of sheath cracking may occur within a year or two.

On the other hand, the effect of emergency loads that may be carried for a day or two once a year is practically negligible, assuming movements up to about two inches. Some of the tests in the dummy manhole disclose no material effect on the life of the sheath when the movement was changed from the regular test value of 0.75 inch to 2.00 inches for one cycle every 170 cycles. The calculations based on data such as in Figure 8 indicate that the equivalent movement during emergencies should have no large effect on the sheath life. Of course, incidental to such a movement at the duct mouth, there should be room for the cable to move freely in the manhole without damage to the accessories or buckling of the cable.

Mitigation of Sheath-Crack Troubles

One result is certain to come from the heavier loads to be carried by existing cables in these days: sheath cracks will be much more numerous than in the past. The use of cable for repairs is going to be accelerated, unless means can be found to

(*a*). Lengthen the life of present sheaths.

(*b*). Repair them without the use of replacement cable, or both.

A direct line of attack now being tried in Chicago is to stop the cable from moving at the duct mouth. Specially designed grips of the woven basket type were laced to the cable at each duct mouth and anchored there with an adjustable tensioning device. The tension was brought up till the movement had been reduced to a negligible value. Incidentally, prior to making this installation, the force required to restrain the daily movement of three-fourth inch at the duct mouth was actually measured by dynamometer at the location of the test and was found to be around 1,000 to 1,500 pounds. After one year's trial no damage to the sheath because of the grips has been detected. One trouble is that the cable cools during the winter, and the grip is loosened, with the result that the cable can move back and forth at the duct mouth during the cooler part of the year unless extra trips are made to adjust the tension. The trial is being continued.

Another possible line of attack is to reduce the maximum strain in the lead. The strains have been measured at a few locations on cables in service and agree pretty well with the strains found in laboratory tests. The maximum strain occurs adjacent to the joint wipes for normal cable training with the joints mounted to slide freely toward the manhole wall and back. If the joint is blocked so that it cannot slide, two things seem to happen. The cable movement is reduced because of the increased resistance to it in the manhole, and the strain is distributed more uniformly throughout the bends in the cable, thus reducing the maximum strain. A discussion of this latter effect is given in the previous paper. In two dummy manhole tests, the average sheath life with the joint blocked was about 20 per cent more than with normal installation. The movement was three-fourths inch at each duct in both cases. In some field trials the joints were blocked in several manholes, and the movement decreased about 30 per cent. This suggests that the two factors together would double the life of the sheath, and so blocking of the joints should certainly be investigated further. One point not yet solved is the means for successfully taking care of effects of seasonal variations of conduit and cable temperatures.

A different line of attack is to develop some satisfactory method of repairing cracked sheaths. Experience in Chicago has been that solder patches and tight sleeves are quite unsatisfactory, mainly because, by the time a sheath crack is found in service, the entire length of sheath in the manhole is nearly worn out. After being patched, it cracks somewhere else in a year or two. From experimental work originated by W. B. Elmer, formerly of Boston Edison Company, and taken up in Chicago, it has been found that if a short section of sheath in each training bend is removed and replaced by a flexible insert, such as a Sylphon bellows, the strain on the remainder of the sheath

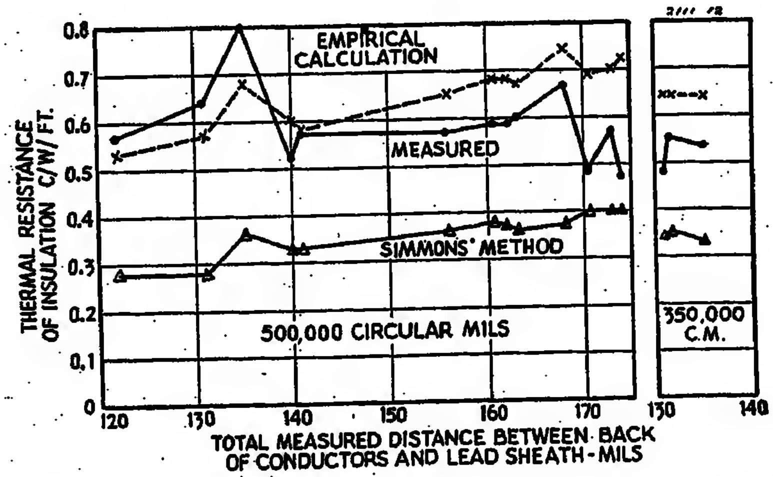

Figure 12. Thermal resistance of insulation of three-conductor sector-shielded cables.

becomes almost negligible. In one Chicago test a cable was run to failure with the joint blocked. The life was 8,417 cycles. At the end of the test, four six-inch Sylphons were installed in the bends near the joint and near the duct mouths, with the lead sheath removed under the Sylphons. The remaining sheath was clearly fatigued almost to failure. The cable was tested for an additional 16,805 cycles without any failure occurring. The deformations were measured and found to be concentrated in the Sylphons, being negligible in the remaining lead sheath. The question of mechanical problems and corrosion problems with the Sylphons, especially the latter problem, has not been completely solved so far as long life is concerned, but seems adequately solved for use at least during an emergency period of a couple of years.

One disadvantage of Sylphon repairs is that the line has to be taken out of service, the joint disassembled to install the Sylphons, and then rebuilt. The ideal repair from the standpoint of economy and speed would be to make a flexible insert out of some sort of hand-wrapped material in tape or strip form. Several of the most promising materials selected from the synthetic rubbers and plastics have been tried, with unsatisfactory results. The best results so far have been obtained with Glyptal 1,782 tape applied with Glyptal 1,276 cement. When tested on cable under water with pressure and vacuum cycles applied to the cable and moisture detectors under the hand-applied tape, lives of 28,000 cycles and over 43,000 cycles were obtained on two samples. The severity of manhole conditions, however, would substantially shorten the life of the material in actual service. Something better is desired, but it seems that Glyptal could probably be used if necessary with fairly satisfactory results.

Allowable Operating Temperatures

As a result of the studies discussed in parts I and II, the conditions for various types of cable in Chicago were reconsidered early in 1942, and new maximum allowable conductor temperatures were adopted as shown in Table VII. In addition special higher values were adopted for use during the war period. These wartime values are based on the assumptions that:

(*a*). The life of the cable system will be used up at a much higher rate than usual.

(*b*). The rate of troubles in cables in service will increase.

Table VII. Maximum Allowable Operating Temperatures for Impregnated-Paper-Insulated Lead-Covered Cables Adopted for Use in Chicago in 1942

Operating Voltage—Volts	Type of Cable	Maximum Allowable Conductor Temperature—Degrees Centigrade: Normal Operation	Emergency Operation
120–240	All	90 (100)	115 (135)
4,000	All	85 (95)	105 (120)
12,000	Belted made prior to 1931	78 (85)	90 (100)
12,000	Belted made in 1931 and later	78 (85)	95 (105)
12,000	Single-conductor and shielded three-conductor	78 (85)	105 (120)
33,000	Shielded, three-conductor cable with joints filled with "solid" compounds	71 (77)	84 (90)
66,000	Single-conductor, solid-type cable with joints filled with "solid" compounds	65 (68)	70 (75)
66,000	Oil-filled; single-conductor and three-conductor	78 (85)	105 (115)
132,000	Oil-filled; single-conductor	78 (85)	100 (110)

The values in parentheses are for use under wartime conditions only.

These temperatures for Chicago conditions are given only as an example of what one company is doing and are not considered to be necessarily applicable for other systems in which the installation and operating conditions are different. In general, the temperatures for normal operation of the higher-voltage cables were limited by the danger of excessive sheath cracking in manholes, while the temperatures for emergency operation of all cables and for normal operation of low-voltage cables were limited by danger of deterioration of the insulation or of excessive radial expansion of sheaths.

III. Heating Characteristics of Cables and Conduits

Three-Conductor Shielded Cable

Incidental to the accelerated aging tests on three-conductor shielded-type cable, mentioned in Part I, the thermal drop between the conductors and sheath was determined. The method was to average the results from at least four tests for each sample, the tests being made at the various temperatures from 60 to 115 degrees centigrade. The thermal drop was determined by the usual method of dividing the temperature difference between the conductor and sheath by the sum of the losses in the conductor and half the dielectric loss in the insulation.

Calculated values of thermal resistance were determined from the geometric dimensions of the cable using a thermal resistivity of 600 degrees centigrade per watt per centimeter cube. The values calculated by the D. M. Simmons[3] method are appreciably below the measured values, as indicated in Figure 12.

An empirical method of calculation was developed. It is based essentially on heat flow radially from only the backs of the sector conductors to the sheath. This method uses the usual formulas for one single-conductor cable with an empirical multiplier as follows:

$$R_t = \frac{\pi D_A}{\pi D_A - K} 0.00522 \rho \log_e \frac{D_0}{D_t} \tag{1}$$

R_t = the thermal resistance of insulation in ohms per foot
ρ = the thermal resistivity of insulation
D_0 = the inside diameter of the sheath
D_t = the diameter over the copper of the cabled conductors
D_A = the average of D_0 and D_t

K equals six times the insulation thickness for conductors with corners of small radius, such as 500,000-circular-mil "compack" conductors. For conductors with more rounded corners, K has been found to be greater up to about nine times the insulation thickness.

As indicated in Figure 12, this method gives a fair agreement with the measured results. The general idea is that the thermal resistance of air gaps and of contacts between the various materials in series between the conductor and sheath all add to the thermal drop to more or less counterbalance the low resistivity of the metal shielding tapes and binder tapes. The results in the figure apply to cables having a net measured insulation ranging from 89 to 140 mils. The total measured distance between conductor and sheath, however, was some 20 to 40 mils larger.

Apparently for three-conductor shielded cables with relatively small insulation, the effect of the regular three-mil copper shielding tape on carrying heat out from the inner portion of the cable is small. This point was checked further by tests on one sample of cable with wires in the center filler space. The results of measurements of resistance of these wires generally indicate that the rise in temperature of the wires above the sheath temperature was about ten per cent less than the rise of the temperature of the conductors above sheath temperature.

For thicker insulations, K in the above formula would probably be less than indi-

cated; that is, the copper shielding tape would be of relatively more benefit in keeping down the temperature rise.

Thermal Resistivity of the Sheath

During the aging tests of the three-conductor cables in the still air in the laboratory, sheath temperatures were determined. From these data the surface thermal resistivities were determined, and results are shown for four typical cables in Figure 13.

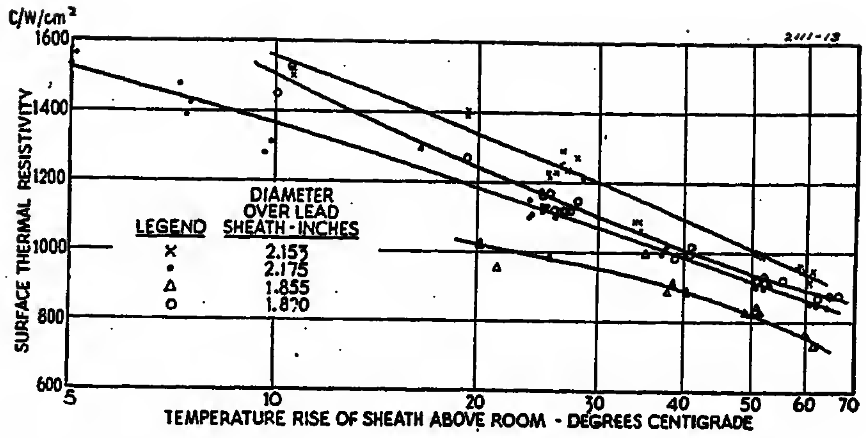

Figure 13. Surface thermal resistivity of lead cable sheaths (by tests in still air in laboratory)

1. One striking point is that for temperature rises of the sheath of 20 degrees or less, a cable of about two-inch diameter might have a surface thermal resistivity above the usual assumed value of 1,200.

2. There is considerable variation between the sheaths. The tests shown indicate a range of about 25 per cent for some cables of practically the same diameter.

3. The resistivity drops with temperature rise, as may be expected, the decrease between a 10-degree rise and a 40-degree rise being about 30 per cent.

Increasing Carrying Capacity of Conduits

In making a new design of conduit, it may be found from the standpoint of the desired loading of the cable that the originally proposed design of conduit would be inadequate. This situation may be remedied, for example, by spreading the ducts or by increasing the number of ducts and spreading out the cables by placing them in some of the outside ducts. Sometimes the problem arises as to whether for a given number of ducts the amount of heat that may be generated in them may be increased better

(*a*). By placing soil of low thermal resistance around the conduit instead of the soil found in the street.

(*b*). By simply having the conduit installed at a greater depth below the street surface.

This problem arises particularly where conduits are to be installed in soil consisting largely of slag or fine sand or miscellaneous backfill in the first two, four, or six feet of soil below the street level.

In the first method the special backfill material of low thermal resistivity is placed for a space of two feet on each side of the conduit and above the conduit for the distance from the street surface down to the bottom of the conduit. In such case the distance from the top of the conduit to the street surface may be the usual figure of about $2^1/_2$ feet. In the other method the cover over the conduit may become several feet, and the distance from the street surface to the bottom of the conduit may become, say, nine feet. There are two distinct technical advantages of this second method:

1. The conduit is brought closer to the ground water level.

2. The maximum temperature in the summer will be less for the base earth temperature than for conduit installed at the usual depth.

Sometimes soil conditions are such that even the replacement of so-called poor soil with a good soil will not solve the problem, because relatively little water is drawn into the so-called good soil to produce a low thermal resistance and good thermal dissipating characteristics for the conduit. The advantage of the lower value for maximum earth temperature for summer conditions is of particular interest, because the rating of the cable limits the loading more frequently in the summertime than in the wintertime.

One set of calculations on the economics involved showed that for installations of either a 6-duct conduit or a 12-duct conduit, the cost per kilovolt-amperes of allowable carrying capacity was appreciably less for the second scheme as compared with scheme (*a*). (Replacement of poor soil with soil of good thermal conductivity has been found very helpful in some cases for existing conduits.)

The method to be used for a new installation, however, depends to a large extent upon the conditions prevailing in the particular case. The gain obtained from increasing the depth of the conduit would be somewhat counterbalanced by the increase in required depth of the manholes and extra troubles that would accrue from water encountered in the manholes. Also, in some localities, rock is hit at relatively small depths.

Existing installations of other utilities may be of such a nature as to have a bearing on the method to be used. For installations in approaches to bridges, soil of poor conductivity may be very deep so that method (*b*) is not applicable. In this case method (*a*), with or without spreading out the cables by special duct formations, is effective. If further increase in current-carrying capacity of cables is desired for such locations, larger sizes of cables than are normally used along the remainder of the lines may be installed, thereby decreasing the losses in the conduit. For conduits under construction where poor soil is encountered in spots along a relatively small portion of the distance between manholes, replacement of soil has been found advisable.

Temperatures of Conduit

In the past usually most of the cables in a given conduit operated with daily maximum loads below the normal ratings. This phenomenon is recognized in establishing the ratings. If it were known that the several cables in a conduit were to operate part of each day throughout their lives at full normal rating, then the calculated normal ratings of each design of cable would be less than are usually established.

With wartime conditions, the maximum daily loading of cables usually increases. Also, the daily load factor usually increases. This means a substantial increase in the average amount of heat generated over each 24-hour period and a corresponding increase in conduit temperatures, even though *no* increase in normal ratings of the cables may have been established. The resulting copper temperatures may become much greater than occur in peacetimes, and even exceed the temperatures given in standards by several degrees or more.

In the previous paper an allowable limit of about 50 degrees centigrade was mentioned for the empty ducts of conduits in order to avoid

(*a*). Excessive drying out of the conduit and soil.

(*b*). An increase in heating constant.

(*c*). Resulting excessive conduit and cable temperatures.

Further field data have been studied. An analysis of heating characteristics of several conduits installed in soil of typical moisture content did not indicate an in-

Factors Which Influence the Behavior of Directional Relays

TROY D. GRAYBEAL
ASSOCIATE AIEE

Synopsis: Very little material dealing with the factors (such as network dissymmetries) which lead to incorrect operation of directional relays has appeared in the technical literature. Practical experience has been the guide as to the relative merits of the 12 possible connections which utilize either line-to-neutral or line-to-line voltages and line currents or the differences of line currents to actuate the relay elements. In this article a graphical method for analyzing directional-relay operation is developed, utilizing circle diagrams and symmetrical components, and the method is applied to general cases to ascertain the effects of network dissymmetries.

Since the relay volt-ampere expressions in terms of symmetrical components are too complicated to show the relative merits of the 12 connections, the expressions also are given in terms of the modified symmetrical components introduced by Edith Clarke and now widely used in network-analyzer studies of unbalanced faults. Circle diagrams based upon these modified components show conclusively that the ordinary 90-degree, 30-degree, and 60-degree connections are more free from disturbing influences than the other nine and therefore give more reliable operation in most practical applications of directional relays. The particular connection which will be most reliable at any given location can be determined by the methods given here when the constants of the power network are known.

Paper 42-90, recommended by the AIEE committee on protective devices for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted July 11, 1941; made available for printing April 20, 1942.

TROY D. GRAYBEAL is instructor in electrical engineering, University of California, Berkeley, Calif.

The author acknowledges his indebtedness to J. C. Balsbaugh of Massachusetts Institute of Technology, Robert L. Frank of the Bulldog Electric Products Company, and Paul Morton of the University of California, for important material and suggestions.

THE demand for reliable and continuous service from modern power systems has made it essential that short circuits and other faults cause as little disturbance as possible to the system as a whole. Ideal protection would consist of relays which would locate accurately the faulted equipment and cause only such equipment to be disconnected from the system when short circuits occur. Since overcurrent and distance relay elements as used in loop and parallel feeder networks cannot differentiate between faults on the incoming and outgoing sides of a breaker, directional elements or relays must be used for this purpose. To prevent unnecessary loss of load and undamaged apparatus, and to prevent undue damage to the faulted equipment, the directional relays must be designed and adjusted to operate correctly for as many conditions of operation as possible on all types of faults, and in particular for those conditions which are of most frequent occurrence. A comprehensive knowledge of the behavior of directional relays of a system is necessary in order that this result may be achieved.

Of the many types of directional relays which are manufactured, this paper is limited to those which operate on the wattmeter principle. Other types in which voltage restraint coils are used are closely related, from the standpoint of operating principle, to distance relays. These have been treated in detail by J. H. Neher[1] who has developed excellent methods for analyzing the performance of different forms of the distance relay.

The behavior of a wattmeter-type directional relay depends upon the vector volt-amperes supplied to the relay element. The magnitude and angle of this quantity is obtained from the product, in the vector sense, of the current and the conjugate of the voltage at the relay. The torque developed by the relay element is proportional to $|VI| \cos (\theta+\phi)$. The angle between the relay voltage and current is θ, and ϕ is the "relay angle," which is the angle between the current and voltage applied to the relay for which given magnitudes of these quantities cause maximum torque to be developed. The relay angle is positive if the current leads the voltage for this condition.

The vector volt-ampere product may be expressed in terms of symmetrical components. The different terms of the expression then are evaluated separately and combined to indicate the direction of the relay torque. The coefficients of the several volt-ampere terms are given in Table I for both single-phase and poly-

---

crease in heating constant for various temperatures up to 50 degrees.

A longitudinal duct temperature survey made in June 1941 along a conduit section showed temperatures along the portion of the length not affected by the presence of the manholes of 39 to 61 degrees centigrade. This conduit is located in miscellaneous fill consisting chiefly of cinders. This fill, being of a porous nature and well drained, normally holds very little moisture. The heating constant was found to be poor, but an analysis indicated no change from the previous year when the duct temperatures were much lower because of lighter loads on the cables. Other data, including experiences of over 20 years ago in Chicago, were also considered.

All of the data indicate that in many cases the allowable duct temperature limit of 50 degrees is too low, and at least for wartime conditions the maximum temperature for normal loading may be 55 or 60 degrees centigrade and five degrees higher for emergency loading.

Some factor of safety should be allowed for temperature variation between manholes, if duct temperatures are measured by the usual method at one spot along the conduit section. For the case where the idle duct temperatures were 39 to 61 degrees in the conduit section, the temperature 20 feet from the duct mouth was only 47 degrees, or 14 degrees lower than the maximum value. Such variation can be expected in conduit runs installed in soil of poor thermal conductivity when operating at temperatures of 50 degrees or more. Even in soil having good thermal characteristics, some variation, such as 15 or 25 per cent, in heating constant between two manholes may be expected, according to many field measurements. In this case, if the rise of the conduit temperature above base earth conditions is like a typical case in peacetime, that is, 16 degrees, then the variation is only four degrees; but, if the cable loading is up and the average conduit-temperature rise is 32 degrees, then the variation in duct temperatures may become about eight degrees—a large amount.

phase relays for all 12 possible connections which utilize either wye or delta voltages and either wye or delta currents to actuate the relay elements. "Line-to-neutral" voltages are referred to as *wye* voltages and "line-to-line" voltages as *delta* voltages. Likewise, "line" currents are *wye* currents and the "differences of line currents" are *delta* currents.

In order to study the effects of network dissymmetries, it is necessary to consider special network conditions beginning with the simpler cases. The general network representation illustrated in Figure 1 is used. In most cases, the impedance Z_Z is considered zero, since it has no effect whatever upon the distribution of the total fault current between sides M and N. The effect of Z_Z is to modify the voltage V_M which appears at the relay. Since the important consideration is the phase of V_M with respect to the relay current, Z_Z has no effect unless its angle is different from that of the impedance Z_M. In most actual power networks these angles will not differ greatly.

The simplest possible case is represented by $Z_Z=Z_{Rf}=0$, $Z_1=Z_2=Z_0$, and $Z_M=Z_N$ in all three sequence networks. When these conditions are substituted into the general relay volt-ampere expressions of Table I, four of the connections show inherent tendencies toward incorrect relay operation. If a particular connection will not give satisfactory performance in such a simplified system, it is of little use in a large complicated power network. Such connections, therefore, are not considered further and are omitted from Tables II and III.

Determination of Relay Behavior By Means of Circle Diagrams

Circle diagrams make possible visualization of the relations which must exist between the various sequence quantities as fault resistance or network constants vary. Thus, in Figure 3 drawn for the line-to-ground fault in terms of symmetrical components, the positive-sequence voltage vector is constrained to fall within the semicircle CEE_{f0} for any value of fault or network resistance; with a purely reactive network the vector falls on the circumference. Similarly, the sum of the negative- and zero-sequence voltages must always fall within the semicircle OAC, and the current within the semicircle OI_fF. The ranges of possible variation of the sequence voltages and currents are shown by the diagram to be confined to definite areas which are determined by the network reactances. This situation would be very difficult to visualize from the symmetrical-component equations alone.

(b)

(b). Equivalent circuit which represents either the positive-, negative-, or zero-sequence network of the actual system

Figure 1

The nature of the circle diagrams may be recognized from the circuits of Figure 2 in which the fault resistance is the variable parameter. These are series circuits in which E_{f0} (the positive-sequence voltage at the point of fault before the occurrence of the fault) is the driving voltage. In any circuit of this type, the current vector, as well as the vector voltage across any constant impedance portion of the circuit, describes a circle as the resistance varies.

For a line-to-ground fault, the voltage E_{f0} is laid off horizontally to scale and divided at point C (Figure 3) according to the ratio $CE_{f0}/OC=X_1/(X_2+X_0)$. If the magnitude of the fault current is known or assumed, the vector OI_f is constructed to scale so as to form a chord to the semicircular current locus. Then the lines OA perpendicular to I_f, AE parallel to I_f, and EE_{f0} perpendicular to I_f are drawn. The vector OB, which represents the voltage drop across both the negative- and zero-sequence networks, is constructed at an angle with I_f equal to the angle of the negative- and zero-sequence network impedances combined in series. The line DE_{f0} is drawn to intersect the line AE at the angle of the positive-sequence impedance to locate the end of the positive-sequence voltage vector V_1. The vector BD represents the voltage drop $3I_fR_f$ consumed by the fault resistance. The two voltage vectors $-V_2$ and $-V_0$ lead the total fault current by the angles θ_2 and θ_0 respectively, and the lengths are such as to complete the parallelogram $O(-V_2)B(-V_0)$. The division of current in either sequence network is such that I_M and I_N lag the corresponding sequence voltage drop by the angles of the corresponding sequence impedances Z_M and Z_N respectively. The location of all the circular loci in terms of the network impedances is given in detail in Figure 4, and the mathematical basis for the diagram in appendix A.

The two semicircles OAC and CEE_{f0} (Figure 3) are the loci of the two voltages $(-V_2-V_0)$ and V_1 respectively, when the resistances of the sequence networks are neglected. When resistances are considered, the ends of the two corresponding voltage vectors must lie somewhere *inside* the two semicircles. It is impossible for either of the two voltages $-V_2$, $-V_0$ or their vector sum, when laid off from O, to fall above the semicircular arc OAC. Likewise, the positive-sequence voltage V_1 cannot fall below the semicircular arc CEE_{f0} as long as the networks are inductive in nature.

The angles between the fault current I_f and the negative- and zero-sequence voltages are independent of the fault resistance. The angle between the positive-sequence voltage and the fault current varies with the fault resistance, but is restricted to the range zero to 90 degrees with the current lagging. If the impedance Z_M is more resistive than Z_N, the current coming to the fault from side M will lead the total fault current, and the current coming from side N will lag the total fault current. The vector sum of these two components must, of course, make up the total. The current I_{2-N} coming from side N cannot lag the voltage $-V_2$ by more than 90 degrees. It follows, therefore, that I_{2-N} can never lag E_{f0} by more than 90 degrees unless the zero-sequence network is more reactive than the negative-sequence network. In the same way, I_{0-M} can never lead the total fault current I_f by an angle greater than the angle of the zero-sequence network. As a limiting case, it may lag the voltage $-V_0$ by as much as 90 degrees and thus lie in the third quadrant. If the currents I_M and I_N are equal in all three sequence networks, the maximum angle between them is given by the expression $(90°-\theta_2+\theta_0)$. These limitations as to the possible ranges of the sequence quantities are of value in the determination of the direction of relay torque from the relay volt-ampere expressions, particularly when the expressions are used to judge the relative merits of the various relay connections.

Impedance between the relay and point of fault affects principally the magnitude

* To find the symmetrical-component expression for the total vector volt-ampere input to any relay, take the sum of all the column headings, each multiplied by the corresponding coefficient taken from the row opposite the relay considered. The voltage and current components in the network at the point where the relay is located must be used in these expressions.

of the voltages at the relay. As the impedance Z_{Rf} becomes larger and larger as compared with Z_M and Z_N, the negative- and zero-sequence voltages at M get smaller and smaller in magnitude. They are modified in phase only when the angle of Z_{Rf} is different from the angle of Z_M. In general, these angles will not differ greatly, and the predominate effect of impedance between the relay and fault point is to decrease the negative- and zero-sequence voltages and to increase the positive-sequence voltage. In an extreme case where all the resistance of side M is between the relay and fault point, and all the reactance beyond the relay, the negative-sequence voltage $-V_{2-M}$ would lie on a semicircle with $-V_2$ as the diameter. The relay voltage $-V_{2-M}$, therefore, may lie somewhat outside the semicircle OAC, but only in rare cases. The relative importance of Z_{Rf} is determined by how far back electrically from the fault point the relay is located. It becomes more important as the ratio Z_{Rf}/Z_M increases. This ratio is larger for a line connected into a large power-system network than for a line of the same constants connected into a small power-system network.

The diagram of Figure 3, together with others drawn for different network conditions, shows it is impossible to design a directional-relay scheme which will operate correctly for all possible faults on a normal power system. Erratic operation may be expected, if the angles of the impedances measured opposite ways from the fault point are greatly different, or if

the angle of the impedance between the relay and point of fault is considerably different from that of the total impedance Z_M. In general, the relay on the more reactive side of the fault is less liable to operate incorrectly.

When load currents are present, they must be added vectorially to the fault components in the positive-sequence network. Load currents increase one of the components I_{1-M} or I_{1-N} and decrease the other. In cases where the load current is comparable in magnitude with the fault current, the total positive-sequence current may be modified in phase sufficiently to cause incorrect relay operation. The relay most subject to this effect is the one at the receiving end of the line, since at this point the two components of positive-sequence current flow in opposite directions.

In order to obviate the effects of load current, some form of overcurrent device must be used in conjunction with the relay to prevent operation unless overcurrent or fault current exists in the system. The current balance scheme, which is commonly used for the protection of paralleled feeders, makes use of two current transformers, one in each feeder, with secondary windings connected so that the relay receives the difference of the two secondary currents. In this case, the relay current is given by the expression $I_f(1-f)$ which is independent of normal load current. I_f is the total fault current and f is the fractional length of the feeder from the relay to the point of fault. This scheme, however, is applicable only to feeders or other apparatus operating in parallel. In other cases where the load component of current may be comparable in magnitude with the fault components, the only workable scheme is the use of "ground relays" which operate on zero- or negative-sequence quantities only.

The ease with which directional-relay operation may be determined by use of the circle diagram is exemplified by Figure 5 which shows the behavior of an ordinary 90-degree-connected polyphase relay on a line-to-ground fault. The circle diagram is constructed from the network impedances in the manner outlined previously to give the magnitude and phase of the sequence voltages and currents at the relay. From Table I, the volt-ampere expression to be evaluated is $[(\text{conj } V_1)I_1\underline{|90}+(\text{conj } V_2)I_2\underline{|270}]$. The factor $3\sqrt{3}$ is omitted since the actual magnitude of the relay torque is unimportant. If the load current is small compared with the fault currents, I_1 is equal to I_2, and the expression may be written $(\text{conj } V_1-\text{conj } V_2)I_1\underline{|90}$. The relay torque then is proportional to the sum of the projections of the two voltages on the current vector I_1 rotated through the angle $(90°-\phi)$. Since both of these projections are positive for the conditions depicted in Figure 5, correct relay operation is indicated.

An alternative method which may be used to advantage when the volt-ampere expression consists of only two terms, makes use of the position of the current vector where the two voltage projections on the current are equal in magnitude but opposite in sign. A line in this position is designated an "equiprojection" line, and represents that phase position of the current for which the torque developed by an element having a relay angle of zero degrees is zero. If the relay angle ϕ is not zero, the zero-torque line is ϕ degrees leading the equiprojection line.

The equiprojection line is located by dropping a perpendicular from 0 to the line joining the ends of the two voltages $V_1\underline{|90}$ and $(-V_2\underline{|-90})$. Since the relay operates correctly if the current lags the zero-torque line by less than 180 degrees, correct operation is indicated in Figure 5, where the current is near the position for maximum torque for the two voltages concerned.

For the ordinary 90-degree-connected polyphase relay, the equiprojection line will coincide with E_{f0} if the positive- and negative-sequence networks are identical. Thus, disregarding the secondary effects of load currents, the direction of the relay torque is independent of the fault resistance for this connection.

When the volt-ampere expressions consist of more than two terms, or when the two terms do not involve the same current, the first method described must be used. An example of this character is given in detail in appendix B.

* To find the modified symmetrical-component expression for the total vector volt-ampere input to any relay, take the sum of all the column headings, each multiplied by the corresponding coefficient taken from the row opposite the relay considered. The voltage and current components in the network at the point where the relay is located must be used in these expressions.

ferently is indicated by the expressions of Table I. The cross-product terms (such as (conj V_1)I_2, (conj V_1)I_0, and so forth) are identical in all three expressions for a particular connection except that they are rotated through different angles before being combined with the other terms. Thus, negative torque may be produced in one relay even though the other two operate correctly. Since the polyphase relay consists of three single-phase elements mounted on a common shaft, the cross-product terms in the volt-ampere expressions cancel. The relay is governed completely by the three terms (conj V_1)I_1, (conj V_2)I_2, and (conj V_0)I_0. The latter term is zero in all cases except for ground faults, and then appears only in the expressions for the wye-voltage wye-current connections.

The wye-voltage delta-current connections give exactly the same relay operation as the corresponding delta-voltage wye-current connections. Therefore, neither set has any advantage over the other. Likewise, for faults not involving ground, the wye-voltage wye-current connections have no advantage over the delta-voltage delta-current connections. On ground faults the wye-voltage wye-current connections would give somewhat better performance. The angle of the (conj V_0)I_0 term usually is such that it represents positive torque, and the relay is somewhat more free from the disturbing influence of normal load current.

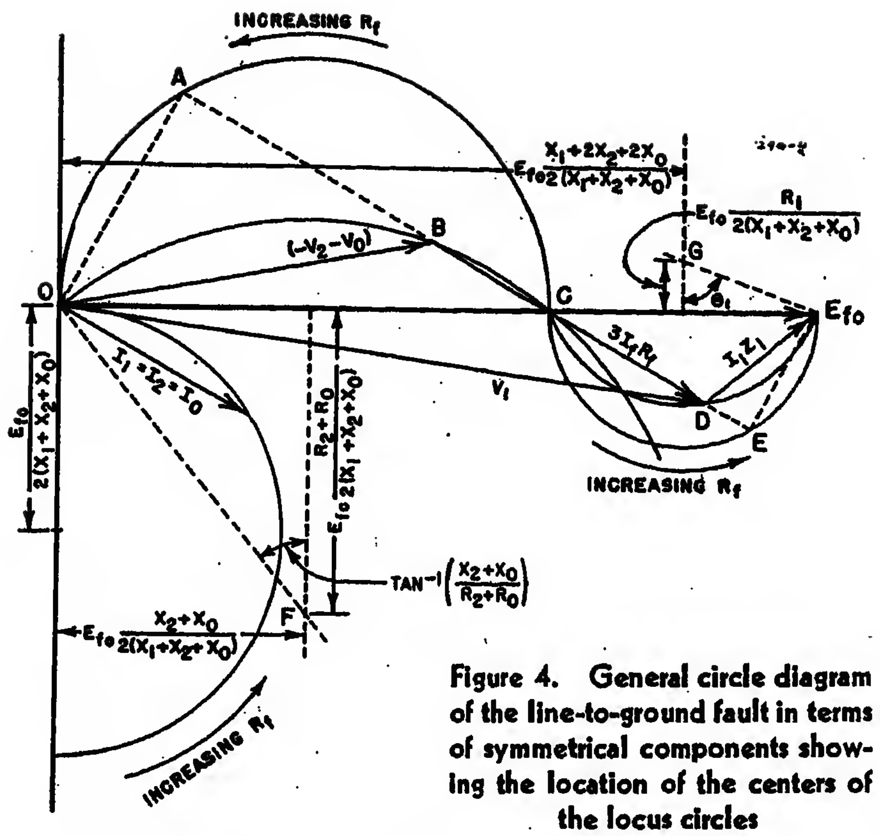

Figure 4. General circle diagram of the line-to-ground fault in terms of symmetrical components showing the location of the centers of the locus circles

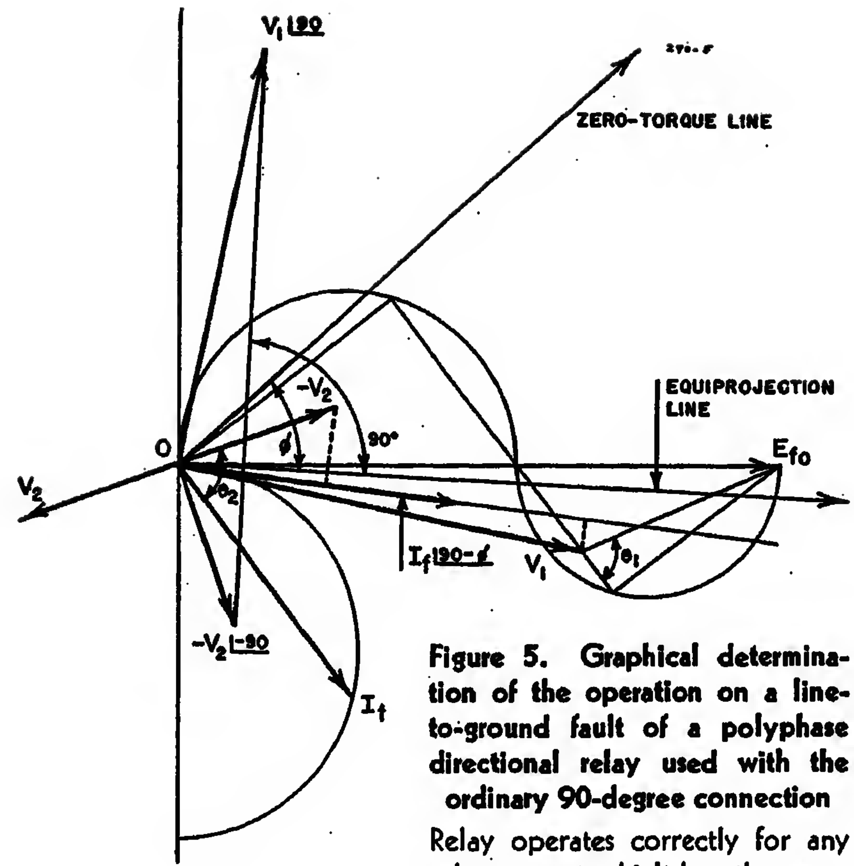

Figure 5. Graphical determination of the operation on a line-to-ground fault of a polyphase directional relay used with the ordinary 90-degree connection

Relay operates correctly for any relay current which lags the zero-torque line by less than 180 degrees

The relative merits of the 30-degree, 60-degree, and 90-degree connections may be studied by application of the circle diagram. The conditions existing during a line-to-ground fault are illustrated by the diagram of Figure 3. For the line-to-line fault, the diagram is similar, the essential difference being that point C is situated at or near the center of the line OE_{fo}, and V_0 does not appear at all.

Since the positive-sequence voltage can never be less in magnitude than the negative-sequence voltage, the zero-sequence voltage, or the vector sum, the term (conj V_1)I_1 usually will govern the relay behavior. A possible exception exists with the wye-wye connections. For a ground fault on a circuit which is grounded at one end only, the zero-sequence current at the relay might be considerably greater than either of the other two components, in which case the (conj V_0)I_0 term would take precedence. For this special condition the relay would be less subject to incorrect operation than in more general networks.

For the 90-degree connections, the volt-ampere input to the relay is $k[(\text{conj } V_1)I_1|\underline{90}+(\text{conj } V_2)I_2|\underline{-90}]$. Neglecting load current, I_1 is very nearly equal to I_2 in any actual power network. The expression therefore may be written $kI_1(\text{conj } V_1-\text{conj } V_2)|\underline{90}$. When only two terms are present in the volt-ampere expression, the relay torque may be obtained from the projections of the two voltages on the current vector rotated counterclockwise through the angle ϕ. For almost all conditions, V_1 will lag E_{fo} by an angle of from 0 to 45 degrees, and $-V_2$ will lie somewhere in the first quadrant as shown in Figure 3. Thus, the 90-degree connections will nearly always give correct operation if the relay angle ϕ is properly chosen.

The ordinary 30- and 60-degree connections give performance comparable with that of the 90-degree connections. The voltage V_1 will, in general, lag the voltage $-V_2$, so that rotation of V_1 counterclockwise and $-V_2$ clockwise tends to interchange their relative positions without appreciably affecting the torque produced. The relay angle ϕ should be zero or slightly positive for the 30-degree connection and positive for the 60- and 90-degree connections, perhaps 45 to 50 degrees for the latter, to insure correct relay operation for the greatest number of practical situations.

The 30- and 60-degree alternate connections are definitely inferior to the ordinary connections. To obtain the relay torque by means of the circle diagram, the two voltage vectors must be rotated in directions opposite to those for the ordinary connections. Thus, the voltages become widely separated in phase. One of the torque terms will usually be negative and the relay more subject to incorrect operation.

Modified Symmetrical Components and Relay Operation

In order that the relative merits of the several relay connections may be ascertained and compared when single-phase relay elements are considered, the system network impedances must be assigned different values, and the direction of the relay torque ascertained for each condition. The criterion as to the best connection is the range or allowable variation in both the magnitude and angle of the impedances that will not result in incorrect relay operation.

The direction of the relay torque is governed by the angle of the relay vector volt-ampere input for the particular relay and connection considered. The resultant torque is the algebraic sum of the separate components represented by the terms in the relay volt-ampere expression.

Values of network impedances which represent limiting cases from the standpoint of relay behavior are the only ones that need be considered critically when the effects of different forms of network dissymmetry are evident from the circle diagram. This is the case only when the relay volt-ampere expression contains very few terms. When symmetrical components are used for the determination of relay behavior in a generalized system network, the effects of dissymmetries are very obscure since many of the symmetrical component volt-ampere expressions contain as many as nine terms. Modified symmetrical components[2] not only provide a simpler circle diagram but also reduce considerably the number of terms in the relay volt-ampere expressions. For instance, the symmetrical-component expression for relay a of the ordinary 90-degree connection contains six terms as compared with two terms in the modified symmetrical-component expression. Thus, the use of modified symmetrical components makes possible a much more accurate evaluation of the relative merits of the several relay connections.

The circle diagram of the line-to-ground fault based upon the circuit of Figure 2b in terms of modified symmetrical components is illustrated in Figure 6. The

* To find the modified symmetrical-component expression for the total vector volt-ampere input to any relay, take the sum of the two column headings, each multiplied by the common factor and the corresponding coefficient taken from the row opposite the relay considered. The voltage and current components in the network at the point where the relay is located must be used in these expressions.

point C is determined by the ratio $OC/CE_{\alpha-f_o}=(X_0/2)/X_1$. Since the β-network is open, the voltage V_β is constant and equal to $-j(V_1-V_2)=-jE_{f_o}$ for any value of fault resistance. For completeness, this vector is superposed on the diagram.

The Ordinary 60-Degree Connection

The volt-ampere expression for relay c, the one principally affected by a line-to-ground fault, does not lend itself readily to general treatment, since it consists of six terms. However, a detailed study of the conditions existing in a large number of specific cases indicates that the 60-degree connection will give correct relay operation except for extreme conditions of network dissymmetry. As long as the vector sum of I_0 and I_α is a vector in the third or fourth quadrants, the V_β products yield positive torque. The V_0 and V_α products yield positive torque for most positions of the currents I_0 and I_α in the fourth quadrant, particularly those near $E_{\alpha-f_o}$. In most cases the currents will not fall outside the fourth quadrant and the relay will operate correctly.

The 60-Degree Alternate Connection

This connection is inferior to the ordinary 60-degree connection. Relay b, the one subject to operation on a line-to-ground fault, has exactly the same volt-ampere expression as relay c for the ordinary 60-degree connection, except for the sign of the two terms involving V_β. Thus, regardless of the value chosen for the relay angle, some of the torque terms will be negative, and the relay subject to incorrect operation.

The Ordinary 90-Degree Connection

On a line-to-ground fault, relay a is the one principally affected. The volt-ampere expression consists of two terms which involve V_β, I_α, and I_0. Since V_β is constant, the variations of I_α and I_0 are all that need be considered. If the power network is symmetrical so that the relay components of current are inphase with the fault components, incorrect relay operation can never occur, if the relay angle ϕ is between zero and 90 degrees. It can be shown that the current I_M must always lie inside a semicardioid along the vertical axis (Figure 7), and inside a semicircle in the third quadrant. In most instances the relay current will lie in the fourth quadrant, but, because of network dissymmetries, may fall outside. If the α network is mostly reactive, and the zero network resistive as viewed one way from the point of fault and reactive as viewed the other way, the zero-sequence current on the reactive side will lie in the fourth quadrant

For the 90-degree connection the impedance between the relay and point of fault has no effect on the relay performance except as a secondary effect arising from modifications in V_β at the relay due to the flow of normal load current in the β network. Since the relay is affected by load currents, the total component I_α at the relay must include the component due to loads as well as the fault component.

The Ordinary 30-Degree Connection

The terms of the volt-ampere expression for relay b which contain V_β are identical (except for the factor $1/2$) with those for the ordinary 90-degree connection. The additional two terms which must be considered involve V_α and will usually represent the greater portion of the relay torque.

In the general case for any network condition, the voltage V_α must lie within the two semicardioidal regions illustrated in Figure 7. Thus the maximum angular range of V_α is 270 degrees. This range is shifted by 90 degrees from the 270-degree current range and would seem to indicate that the relay angle should be approximately equal to +90 degrees. For the usual practical network conditions, however, the voltage V_α will lag slightly the voltage $E_{\alpha-f_o}$, and the current will lie in the fourth quadrant at an angle of perhaps 60 to 80 degrees lagging $E_{\alpha-f_o}$. Therefore, the relay angle should be only slightly positive or zero for most cases. The torque represented by the last two terms will, in general, be positive and add to that of the other two.

The Alternate 30-Degree Connection

The volt-ampere expression for the alternate 30-degree connection—relay c—is identical to that of the ordinary 30-degree connection—relay b—except for the sign of the two terms containing V_β. Thus, the torque represented by these terms will in most cases be of opposite sign from that represented by the other two. This connection is more subject to incorrect operation than the ordinary 30-degree connection.

The 90-Degree Wye-Voltage Delta-Current Connection

For this connection, relays b and c both operate on a line-to-ground fault, but in different ways as shown by the expressions of Table I. Except for the second term, one expression is the negative of the other. In many instances the second term would represent only a minor part of the total relay torque, and the two relays would function oppositely. This effect might occur even in a symmetrical network with the relay located near the fault point. This connection is definitely unreliable on ground faults. On other types of fault where the current I_β is present, the torque represented by the I_β

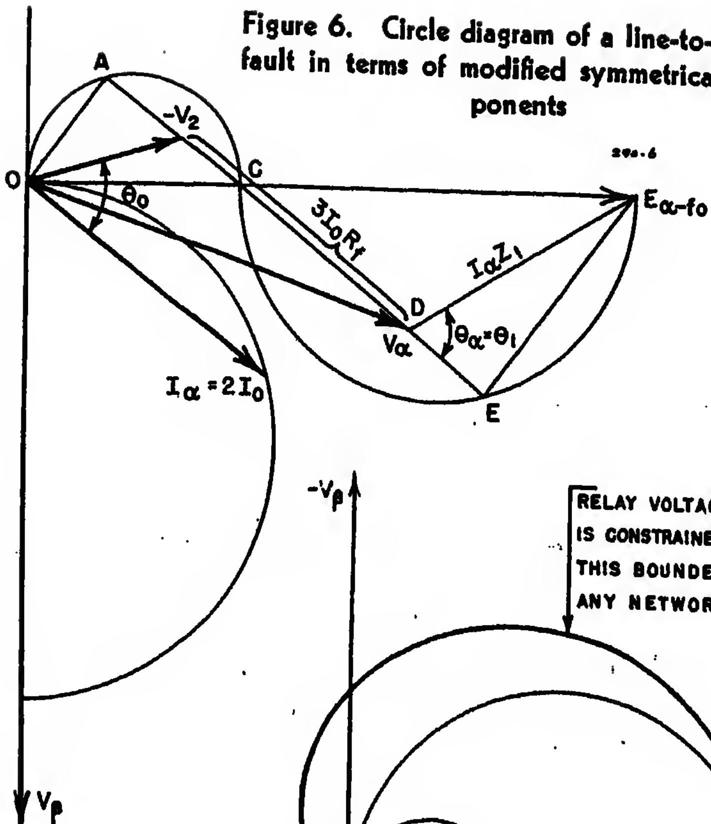

Figure 6. Circle diagram of a line-to-ground fault in terms of modified symmetrical components

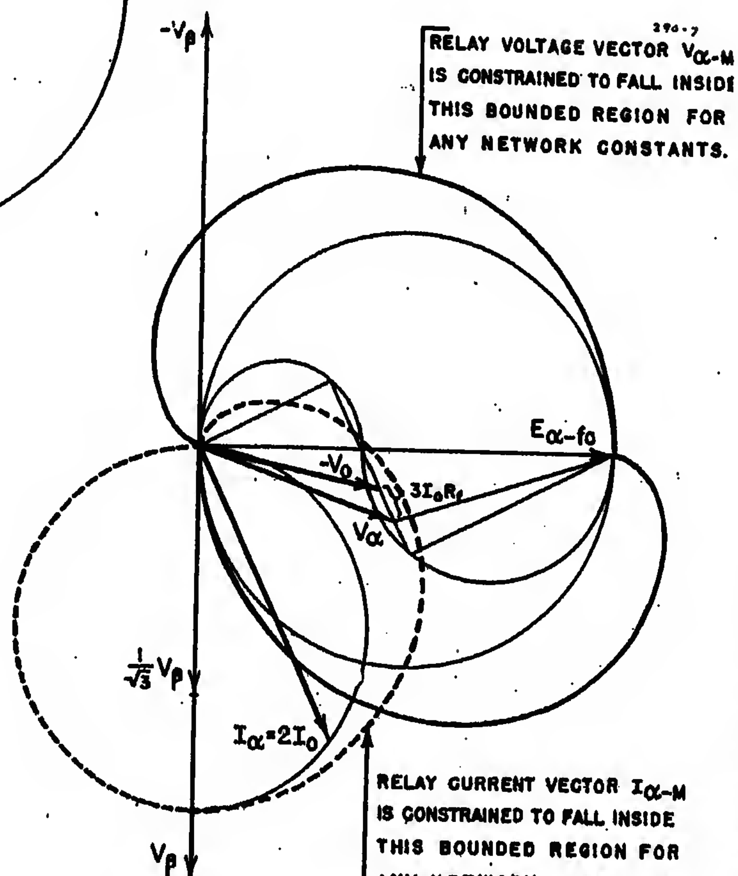

Figure 7 (left). Circle diagram showing the limits of variation of the relay current and voltage for either a line-to-ground or line-to-line fault expressed in modified symmetrical components

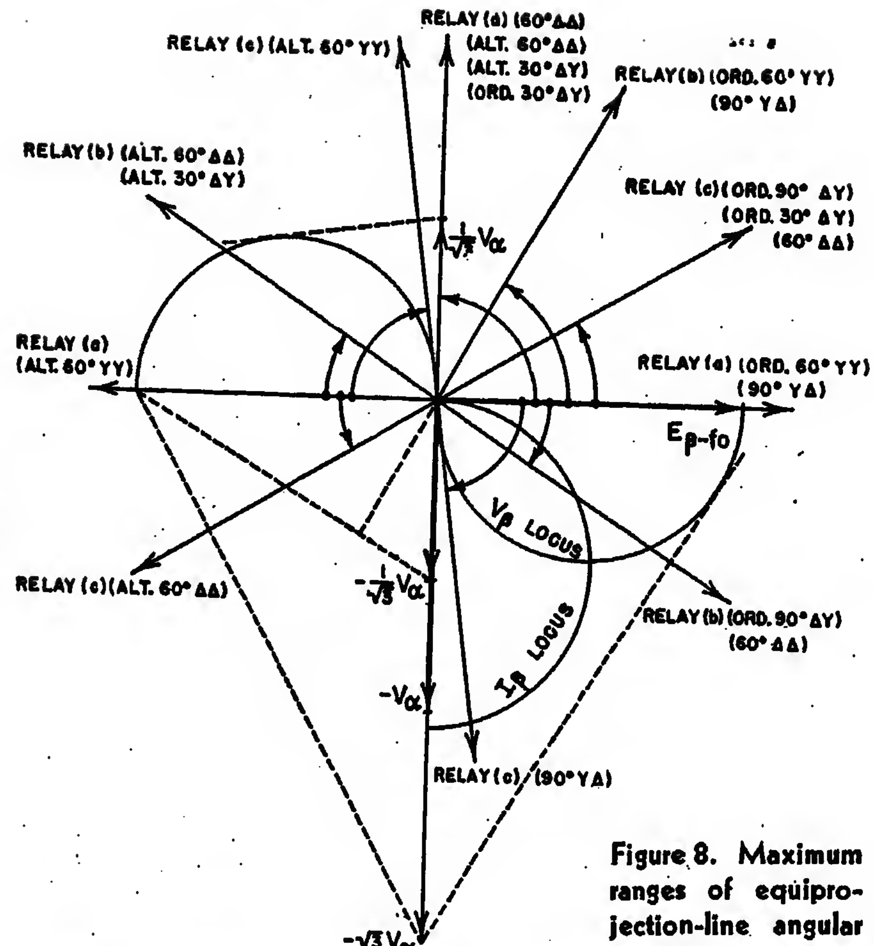

Figure 8. Maximum ranges of equiprojection-line angular variation on a line-to-line fault as influenced by fault or network resistances

The arcs with arrowheads indicate the maximum angular range of the equiprojection lines of each relay of the connections listed in Table III. Limitations as to the allowable variation of the network constants are $Z_Z=0$ and angle of Z_{Rf}=angle of Z_1

terms in the general expressions would not be zero and, since these components of torque are of the same sign for both relays, better behavior of the two relays would be obtained.

The 60-Degree Delta-Voltage Delta-Current Connection

Relay *a* for the delta-voltage delta-current connection behaves in much the same way as relay *a* for the ordinary 90-degree connection, the chief difference being that for the former there is no zero-sequence torque term. In some ways this is an advantage, because the operation of the relay is independent of the zero-sequence network, except as a secondary effect arising because of modifications in the current I_α. On the other hand, this relay connection would give operation more subject to the influence of normal load current, because it operates on V_β and I_α only. Normal load current reduces to equal components of I_α and I_β in time quadrature with each other.

Relay *b* behaves in much the same way as relay *a*. In general I_α and V_α will both lie in the fourth quadrant, and the torque represented by the first term will be positive and add to that of the second. For both relays the relay angle ϕ should be positive, perhaps about 45 degrees for usual network conditions.

The 60-Degree Alternate Delta-Voltage Delta-Current Connection

Comparing the volt-ampere expressions for this connection with those for the 60-degree delta-voltage delta-current connection, the signs are opposite for those terms involving the voltage V_β. Thus, the two relays tend to function oppositely on line-to-ground faults.

Relay *c* is actuated by two opposing torques, since the two terms will, in general, represent torque of opposite sign. The absolute values of the two vector volt-ampere components are of comparable magnitude, and incorrect operation of this relay is quite likely to occur. This connection is definitely inferior to the 60-degree delta-voltage delta-current connection.

Relay Operation on a Line-to-Line Fault

Circle diagrams for the line-to-line type of fault are quite similar to those for the line-to-ground fault, although somewhat simpler, because they do not involve the zero-sequence network. Since, in the equivalent representation of Figure 2*d*, the α network is open, the voltage V_α is constant. The voltage V_β follows the locus circle which has $E_{\beta-fo}$ as the diameter.

When the conditions for a line-to-line fault are substituted into the general volt-ampere expressions of Table II, each reduces to two terms. By factoring out the proper numerical factor, the coefficients of the terms nvolving V_β are reduced to unity, and the coefficients of the terms involving V_α to either $\sqrt{3}$ or $1/\sqrt{3}$. Since V_α is constant and equal to $E_{\alpha-fo}$ (except as influenced by normal load current), this procedure aids in the comparison of the various terms. The simplified expressions are given in Table III.

For the relay to operate correctly, the sum of the two torque components must be positive. Since the same current is involved in both components, it is necessary only that the algebraic sum of the projections of the two voltages on the current vector be positive to meet this condition.

To ascertain the effect of the possible current and voltage variations on the relay torque, the equiprojection-line method for the determination of relay behavior may be used to advantage. The equiprojection line represents that phase position of the current where the projections of the two voltages on the current vector are equal but of opposite sign. For any two given voltages, the equiprojection line is drawn from the origin perpendicular to the line which joins the ends of the two voltage vectors after one has been rotated through 180 degrees. Since the effect of the relay angle ϕ may be included by rotation of the equiprojection line through the angle ϕ, the maximum angular variations of the equiprojection lines may be studied independent of the relay angle. The proper value of the relay angle for any one of the different connections is such that the relay will yield positive torque for the range of currents most frequently encountered in actual power systems.

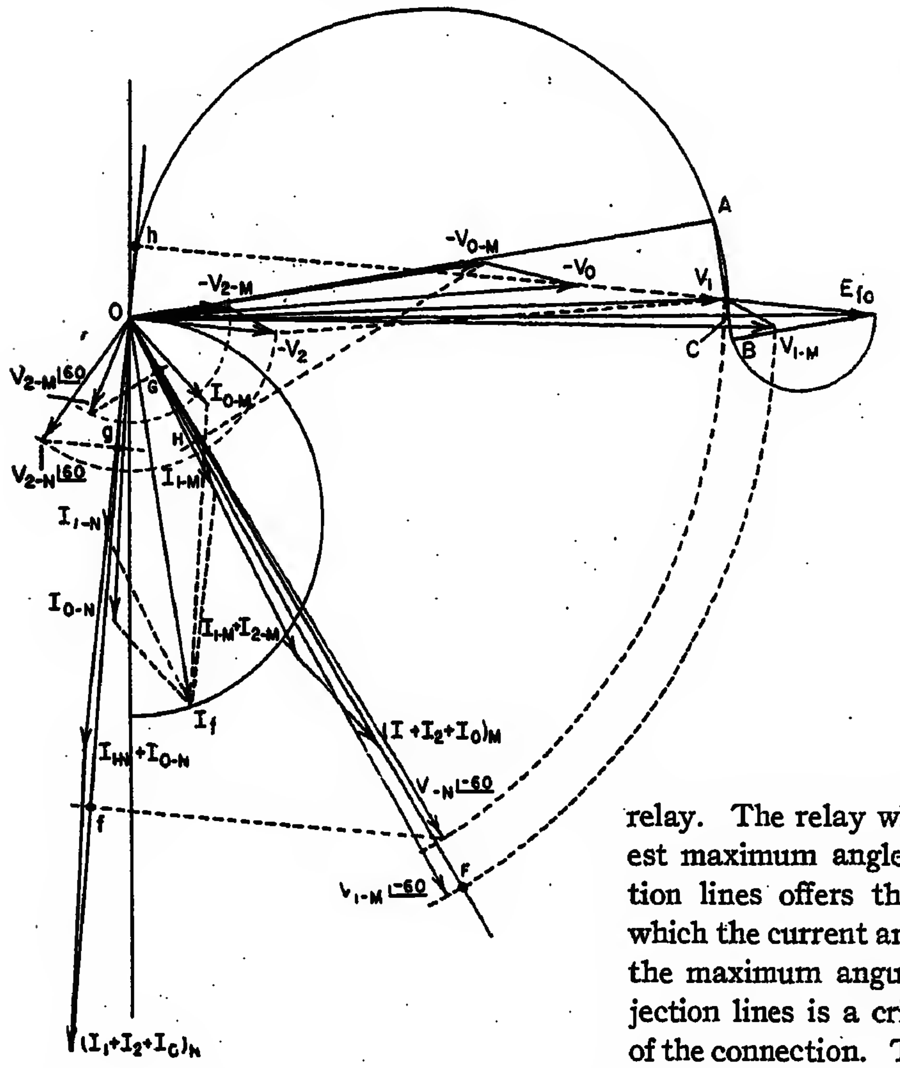

Figure 9. Illustrative example of the graphical determination of directional-relay behavior showing the operation of the ordinary 60-degree connection on a line-to-ground fault

For the case where the impedance Z_Z is zero and the impedances Z_{Rf} and Z_1 have the same angle, the maximum angular ranges of the equiprojection lines may be obtained from Figure 8. For this case, the current vector must lie either in the first or fourth quadrant, but usually in the fourth. The positions of the equiprojection lines indicated are the limiting positions, the angular ranges being indicated by arrows. The dotted construction lines show how the equiprojection lines were located. When just one voltage is involved in a relay volt-ampere expression, the equiprojection line is perpendicular to that voltage. The current angular range for correct relay operation is 180 degrees lagging the equiprojection line. Since the relay angle must be chosen such that the relay current will give positive torque, the angular range of the equiprojection line must be subtracted from 180 degrees to give the range of current variation for correct operation of the relay. The relay which yields the smallest maximum angle between equiprojection lines offers the largest range over which the current angle may vary. Thus, the maximum angular range of equiprojection lines is a criterion of the quality of the connection. The maximum angular ranges as determined from Figure 8 for the above-mentioned network conditions are given in the first column of Table A.

The figures of this table indicate that the three ordinary connections, the alternate 60-degree connection, and the 60-degree delta-voltage delta-current connection are the best. The latter connection gives very satisfactory operation on line-to-ground faults but is somewhat inferior on line-to-line faults. The converse is true for the alternate 60-degree connection.

When the restriction is removed that the impedances Z_{Rf} and Z_1 have the same angle, the voltage V_β may lie anywhere within a semicircle above $E_{\beta-fo}$ and a semicardioid below $E_{\beta-fo}$. When the other restriction, that the impedance Z_Z is zero, is removed, the maximum angular ranges are still further increased. The voltage V_β may then lie anywhere within a semicardioid below $E_{\beta-fo}$ in the fourth quadrant and a semicardioid above $E_{\beta-fo}$ in the first and second quadrants. The maximum angular ranges of the equiprojection lines are increased as shown in the table.

From the preceding considerations, the ordinary 90-degree connection is superior to any of the others. However, most of the connections are not so bad as they appear from the equiprojection-line angular variations, since these ranges are possible only for conditions of extreme dissymmetry which do not frequently occur in actual power networks.

Conclusions

Only three of the 12 relay connections which utilize wye or delta voltages and wye or delta currents seem to have definite merits for directional-relay applications. These three connections are the ordinary 60-degree (wye voltages and wye currents), the ordinary 90-degree (delta voltages and wye currents), and the ordinary 30-degree (delta voltages and wye currents). While it is not possible to state definitely which of these three connections is best for all possible faults, it would seem that the ordinary 90-degree connection is somewhat more free from disturbing influences than the other two. None of the twelve connections will give relay operation essentially independent of the type of fault as is the case with the 90-degree delta-voltage delta-current connection when applied to distance relaying.

For all the various connections, normal load current is the most disturbing influence with regard to correct relay operation. In many instances it may be impossible to obtain satisfactory results on ground faults without the use of "ground relays" which operate on negative- or zero-sequence quantities only. Some of the other factors besides the type of relay connection and normal load current in the system which influence directional relay operation are:

1. Type of fault.
2. Different angles in the positive-, negative-, and zero-sequence impedances as viewed from the fault point in the same direction from the fault.
3. Different angles in the impedances as viewed from the fault point in opposite directions in either sequence network.
4. Impedance between the relay and point of fault, particularly if the angle of this impedance is different from that of the total impedance as viewed from the point of fault.
5. Fault resistance.
6. Mutual impedance between the two parts of the system on opposite sides of the fault in networks of like sequence. Coupling of this nature is present in all except pure radial power networks.

Table A

Relay Connections	Maximum Angular Range of Equiprojection Lines (Degrees)		
	Network Conditions and Restrictions		
	$Z_2=0$ Angle of Z_{Rf} = Angle of Z_1	$Z_2=0$	None
Ordinary 60-degree	60	82	127
Alternate 60-degree	80	108	116
Ordinary 90-degree	60	66	74
Ordinary 30-degree	90	180	270
Alternate 30-degree	180	180	270
90-degree wye-voltage delta-current	120	130	130
60-degree delta-voltage delta-current	115	180	270
Alternate 60-degree delta-voltage delta-current	180	180	270

While most of the factors are not of sufficient importance to cause incorrect relay operation if only one influence were present, they are cumulative in the sense that several of these factors present at the same time may very easily result in incorrect directional relay operation.

Appendix A. Derivation of the Circle Diagram for the Line-to-Ground Fault in Terms of Symmetrical Components

From the conditions existing at the point of fault:

$$I_f=\frac{E_{fo}}{Z_1+Z_2+Z_0+3R_f}=\frac{E_{fo}}{R_1+R_2+R_0+3R_f+j(X_1+X_2+X_0)} \quad (1)$$

Letting the subscripts x and y indicate components of I_f in the X and Y directions respectively, one obtains by cross-multiplying and equating the reals and imaginaries

$$I_x(R_1+R_2+R_0+3R_f)-I_y(X_1+X_2+X_0)=E_{fo} \quad (2)$$

$$I_x(X_1+X_2+X_0)+I_y(R_1+R_2+R_0+3R_f)=0 \quad (3)$$

Elimination of R_f from these two equations gives the current-locus equation:

$$I_x^2+\left[I_y+\frac{E_{fo}}{2(X_1+X_2+X_0)}\right]^2=\left[\frac{E_{fo}}{2(X_1+X_2+X_0)}\right]^2 \quad (4)$$

This equation defines a circle which passes through the origin. The center is on the Y axis at the point

$$\left[0, \frac{-E_{fo}}{2(X_1+X_2+X_0)}\right]$$

The positive-sequence voltage V_1 is defined by the equation

$$V_1=E_{fo}-I_1Z_1 \quad (5)$$

or

$$(V_{1-x}+jV_{1-y})=E_{fo}-\frac{E_{fo}(R_1+jX_1)}{(R_1+R_2+R_0+3R_f)+j(X_1+X_2+X_0)} \quad (6)$$

Cross-multiplying, equating the reals and imaginaries, and eliminating R_f from the resultant two equations gives the locus equation of the positive-sequence voltage.

$$\left[V_{1-x}-E_{fo}\frac{X_1+2X_2+2X_0}{2(X_1+X_2+X_0)}\right]^2+\left[V_{1-y}-E_{fo}\frac{R_1}{2(X_1+X_2+X_0)}\right]^2=E_{fo}^2\left[\frac{R_1^2+X_1^2}{4(X_1+X_2+X_0)^2}\right]=\left[E_{fo}\frac{Z_1}{2(X_1+X_2+X_0)}\right]^2 \quad (7)$$

This equation defines a circle with center at the point

$$\left[\frac{E_{fo}(X_1+2X_2+2X_0)}{2(X_1+X_2+X_0)}, \frac{E_{fo}R_1}{2(X_1+X_2+X_0)}\right]$$

and of radius

$$\frac{E_{fo}Z_1}{2(X_1+X_2+X_0)}$$

It intersects the X axis at the two points

$[E_{fo}, 0]$

and

$$\left[\frac{E_{fo}(X_2+X_0)}{X_1+X_2+X_0}, 0\right]$$

These two intercepts, being independent of R_1, R_2, and R_0, depend only upon the *reactances* of the network.

It is more convenient to treat the vector sum of the negative- and zero-sequence voltages as a single voltage. The separate components may then be obtained easily after the diagram is thus constructed. For convenience, let

$$(-V_2-V_0)=V=I_f(Z_2+Z_0) \quad (8)$$

or

$$(V_x+jV_y)=\frac{E_{fo}[R_2+R_0+j(X_2+X_0)]}{R_1+R_2+R_0+3R_f+j(X_1+X_2+X_0)} \quad (9)$$

Cross-multiplying, equating the reals and imaginaries, and eliminating R_f from the resultant two equations gives the locus equation of the negative of the vector sum of the negative- and zero-sequence voltages.

$$\left[V_x-E_{fo}\frac{X_2+X_0}{2(X_1+X_2+X_0)}\right]^2+\left[V_y+E_{fo}\frac{R_2+R_0}{2(X_1+X_2+X_0)}\right]^2=E_{fo}^2\left[\frac{(R_2+R_0)^2+(X_2+X_0)^2}{4(X_1+X_2+X_0)^2}\right]=\left[E_{fo}\frac{|Z_2+Z_0|}{2(X_1+X_2+X_0)}\right]^2 \quad (10)$$

This equation defines a circle with center at the point

$$\left[\frac{E_{fo}(X_2+X_0)}{2(X_1+X_2+X_0)}, \frac{-E_{fo}(R_2+R_0)}{2(X_1+X_2+X_0)}\right]$$

and of radius $\dfrac{E_{fo}|Z_2+Z_0|}{2(X_1+X_2+X_0)}$

It intersects the X axis at the two points

[0, 0]

and

$$\left[\frac{E_{fo}(X_2+X_0)}{2(X_1+X_2+X_0)}, 0\right]$$

which, being independent of R_1, R_2, and R_0, depend only upon the *reactances* of the network.

Simultaneous solution of the two voltage locus equations—the equation of V_1 and the equation of $(-V_2-V_0)$—gives the points of intersection of the two circles

$$\left[\frac{E_{fo}[(X_1+X_2+X_0)(X_2+X_0)+(R_1+R_2+R_0)(R_2+R_0)]}{(R_1+R_2+R_0)^2+(X_1+X_2+X_0)^2}, \frac{E_{fo}[(R_1+R_2+R_0)(X_2+X_0)-(X_1+X_2+X_0)(R_2+R_0)]}{(R_1+R_2+R_0)^2+(X_1+X_2+X_0)^2}\right]$$

and

$$\left[\frac{E_{fo}(X_2+X_0)}{X_1+X_2+X_0}, 0\right]$$

The second point is the point of intersection of the two voltage locus equations with the X axis. Since this point is determined only by the reactances of the three sequence networks, it is independent of the resistances of the networks, as well as the fault resistance. As the resistances of the sequence networks approach zero, the two points of intersection approach each other, and the two locus circles approach tangency. The second point is always on the X axis, while the first may be either above or below the X axis depending upon the relative values of the sequence-network resistances and reactances. The first point represents conditions on the loci when the fault resistance is zero.

The derivation of the circle diagram for the line-to-line fault in terms of symmetrical components, and the derivation of circle diagrams for both types of faults in terms of modified symmetrical components follow closely the method used for the derivation of the circle diagram of the line-to-ground fault. All are based upon the circuit diagrams illustrated in Figure 2.

Appendix B. Illustrative Example of the Graphical Determination of Directional-Relay Behavior

To illustrate the use of circle diagrams and symmetrical components for the determination of directional-relay behavior, the following example is given in which the impedances of the equivalent-network representation of Figure 1 are per-unit values taken from an actual power network.

$Z_{1-Z} = Z_{2-Z} = 0.020\underline{|90.0}$ $Z_{0-Z} = 0.240\underline{|90.0}$

$Z_{1-X} = Z_{2-X} = 0.128\underline{|70.5}$ $Z_{0-X} = 0.214\underline{|52.6}$

$Z_{1-Rf} = Z_{2-Rf} = 0.097\underline{|34.0}$ $Z_{0-Rf} = 0.238\underline{|32.0}$

$Z_{1-M} = Z_{2-M} = 0.214\underline{|54.9}$ $Z_{0-M} = 0.489\underline{|40.8}$

$Z_{1-N} = Z_{2-N} = 0.188\underline{|88.5}$ $Z_{0-N} = 0.188\underline{|88.5}$

$Z_{1-y} = Z_{2-y} = 0.188\underline{|88.5}$ $Z_{0-y} = 0.188\underline{|88.5}$

$Z_1 = Z_2 = 0.124\underline{|75.5}$ $Z_0 = 0.383\underline{|84.6}$

$Z_1+Z_2+Z_0 = 0.629\underline{|81.0} = 0.098+j0.621$

$Z_2+Z_0 = 0.505\underline{|82.4} = 0.067+j0.501$

Type of fault: Line-to-ground
Relay connection: Ordinary 60-degree
Relay angle ϕ: 0 degrees

Construction of the Circle Diagram

The purpose of the circle diagram is to obtain the relative magnitude and phase of each of the sequence voltages and currents at the relay in the form of a vector diagram. The direction of the relay torque then is found by graphical evaluation of the torque components represented by the terms of the volt-ampere expressions of Table I.

In Figure 9, the vector E_{f0} is laid off horizontally to scale, and the point C located from the ratio $OC/OE_{f0} = (X_2+X_0)/(X_1+X_2+X_0) = 0.501/0.621 = 0.806$. The center of the fault current-locus circle is on the vertical axis below O by the amount $E_{f0}/[2\times(X_1+X_2+X_0)] = 0.805$. This point may be taken at any convenient distance below O, and the actual current scale left undetermined unless the current magnitude is required for other purposes.

The fault current vector I_f is drawn lagging E_{f0} by 81.0 degrees, the angle of the impedance of the three sequence networks in series. The lines OA and BE_{f0} are perpendicular to the fault current, and the line ACB is parallel to the fault current. The line $E_{f0}V_1$ is drawn at 75.5 degrees with AB to locate the end of the positive-sequence voltage vector V_1. Since the fault resistance is zero, this point also represents the terminus of the vector sum of the negative- and zero-sequence voltages $-V_2$ and $-V_0$.

The voltages $-V_2$ and $-V_0$ are drawn leading the fault current by 75.5, and 84.6 degrees respectively. The length of these vectors are such that they add vectorially to give the vector V_1.

The current components I_{2-M}, and I_{2-N} (equal to I_{1-M} and I_{1-N} respectively) are obtained most easily from the magnitude ratios $I_{2-M} = (0.188/0.385)I_f = 0.488I_f$ and $I_{2-N} = (0.214/0.385)I_f = 0.556I_f$ from which the corresponding current parallelogram is constructed. Likewise, the zero-sequence current components are obtained from the magnitude ratios $I_{0-M} = (0.188/0.632)I_f = 0.298I_f$ and $I_{0-N} = (0.489/0.632)I_f = 0.772I_f$.

The sequence voltages at M are found by adding the corresponding impedance drops to the sequence voltages at the point of fault. The positive-sequence voltage drop is $|I_{1-M}|(0.097)$. This drop is added to V_1 at the angle 34.0 degrees leading the current I_{1-M} to give the voltage V_{1-M}. Since I_{1-M} is equal to I_{2-M}, the same voltage drop in both magnitude and phase is subtracted from $-V_2$ to give the voltage $-V_{2-M}$. The zero-sequence voltage drop is $|I_{0-M}|(0.238)$. This drop is subtracted from $-V_0$ to give the voltage $-V_{0-M}$.

Graphical Determination of the Direction of Relay Torque

The method for the graphical determination of the direction of relay torque is applicable to any case whether the sequence voltages and currents are obtained from the circle diagram, by calculation, or by use of the network analyzer. Once the vector diagram of the sequence quantities is constructed to scale, the direction of relay torque is obtained by graphical evaluation of the torque represented by the terms of the volt-ampere expressions of Table I for the relay and type of connection considered.

For the ordinary 60-degree connection, the relay most affected by a line-to-ground fault is relay c. The volt-ampere expression for this relay (see Table I) may be written $(\text{conj } V_1)\,\underline{|60}(I_1+I_2+I_0) - (\text{conj } V_2)\,\underline{|120}(I_1+I_2+I_0) - (\text{conj} V_0)\underline{|0}\ (I_1+I_2+I_0)$. Thus, the three sequence currents at the relay may be combined and the resultant treated as a common reference current for the determination of the behavior of the relay. With reference to Figure 9, the voltage V_{1-M} is rotated clockwise through 60 degrees and then projected on the current vector $(I_1+I_2+I_0)_M$. Likewise, the voltage $-V_{2-M}$ rotated clockwise through 120 degrees, and the voltage $-V_{0-M}$ are projected on the same current vector. This process gives the three line segments OF, OG, and OH which are proportional in length to the components of relay torque represented respectively by the V_1, V_2, and V_0 terms of the volt-ampere expression. Since the three line segments extend downward from O, each represents positive torque. The sum of the three is, therefore, positive, and correct relay operation is indicated.

The behavior of the relay at N is obtained by a similar process in which the current vector $(I_1+I_2+I_0)_N$ and the voltages V_1, V_2, and V_0 are used. The three components of torque are represented by the line segments Of, Og, and Oh. In this case, Oh represents negative torque. The resultant of all three however is positive, so that correct operation of the relay at N also is indicated.

Notation

E_{f0}—Positive-sequence voltage at the point of fault before occurrence of the fault

$E_{\alpha-f0}$, $E_{\beta-f0}$—α and β components of the voltage at the point of fault before the occurrence of the fault

I_f—Total fault component of current at the fault

I_1, I_2, I_0—Positive-, negative-, and zero-sequence components of current at the relay, or in the fault if so specified

I_α, I_β, I_0—α, β, and zero components of current at the relay, or in the fault if so specified

R_1, R_2, R_0—Resistance components of Z_1, Z_2, and Z_0

V_1, V_2, V_0—Positive-, negative-, and zero-sequence components of voltage at the point of fault, or at the relay if so specified

conj V—Conjugate of the voltage vector V

X_1, X_2, X_0—Reactance components of Z_1, Z_2, and Z_0

Z_1, Z_2, Z_0—Total equivalent impedance of the positive-, negative-, and zero-sequence networks as measured at the point of fault

θ_1, θ_2, θ_0—Angles of the impedances Z_1, Z_2, and Z_0

ϕ—The "relay angle"; that is, the angle between the current and voltage applied to the relay for which given magnitudes of these quantities cause maximum torque to be developed. The angle is positive if the current leads the voltage for this condition

When necessary to distinguish between components of current or voltage at different points in the network, subscripts based upon Figure 1b are used. Thus, I_{1-M} is the positive-sequence component of current at point M and V_{1-M} is the corresponding component of voltage.

Impedances of the different parts of the network are designated by the subscripts indicated in Figure 1b. Thus, Z_{1-Rf} is the impedance between the relay and point of fault in the positive-sequence network.

Wye and Delta Currents and Voltages

I_A, I_B, I_C—*Delta* currents

I_a, I_b, I_c—Line or *wye* currents

V_A, V_B, V_C—Line-to-line or *delta* voltages

V_a, V_b, V_c—Line-to-neutral or *wye* voltages

$V_A = V_c - V_b$ $\quad I_A = I_c - I_b$

$V_B = V_a - V_c$ $\quad I_B = I_a - I_c$

$V_C = V_b - V_a$ $\quad I_C = I_b - I_a$

The Combination of Probability Curves in Engineering

ROGER I. WILKINSON
ASSOCIATE AIEE

1. Introduction

ENGINEERS are quite familiar with simple probability distributions showing the relative likelihoods of occurrence of the different values which a varying physical or electrical quantity may assume. As the complexities of machines and circuits in modern design increase, it becomes highly desirable to be able to estimate the probability distribution resulting from the joint presence of two or more sources of variation. This paper will undertake to present something of the theory of making such combinations, and its application to a number of practical examples.

2. Simple Probability Distributions

If a variable quantity x may take only values which are separated by finite intervals, it is known as a *discrete* variate. If there is no such restriction on the variable it is a *continuous* variate. We shall let p_x be the probability that the discrete variate takes the value x, and $\theta(r)dr$ be the probability that the continuous variate lies between r and $r+dr$.

To summarize in short compass the salient characteristics of any variate, discrete or continuous, it is convenient and customary to calculate the moments of its probability distribution. The ith moments taken about the zero of the variates are usually designated by μ_i', and are given by:

$$\left.\begin{aligned}&\textit{Discrete}\\ &\mu_i' = \sum_{x=\text{all values}} x^i p_x\\ &\textit{Continuous}\\ &\mu_i' = \int_{r=\text{all values}} r^i\theta(r)dr\end{aligned}\right\} \quad (1)$$

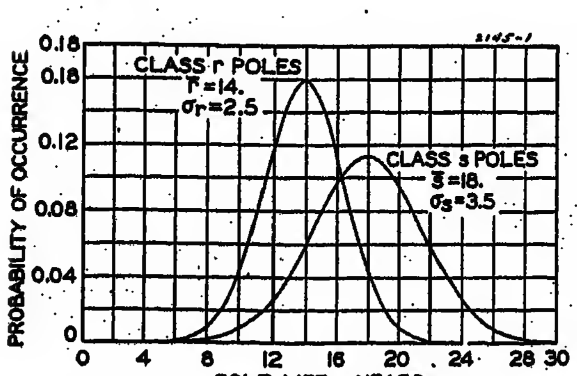

Figure 1. Two "mutually exclusive" universes

Likewise the ith moments taken about the average value ($\bar{x}$ or $\bar{r}$) of the variates are designated by μ_i, and are given by:

$$\left.\begin{aligned}\mu_i &= \sum_{x=\text{all values}} (x-\bar{x})^i p_x\\ \mu_i &= \int_{r=\text{all values}} (r-\bar{r})^i\theta(r)dr\end{aligned}\right\} \quad (2)$$

Certain transfer formulas are available relating the μ_i''s and the μ_i's of the first four moments; they are often of value since it may be more convenient first to calculate from data or theory the moments about one of the two reference points (0 or the mean), and then obtain the other if desired. These formulas are:

$$\left.\begin{aligned}\mu_0 &= \mu_0' = 1\\ \mu_1 &= 0\\ \mu_2 &= \mu_2' - (\mu_1')^2\\ \mu_3 &= \mu_3' - 3\mu_2'\mu_1' + 2(\mu_1')^3\\ \mu_4 &= \mu_4' - 4\mu_3'\mu_1' + 6\mu_2'(\mu_1')^2 - 3(\mu_1')^4\end{aligned}\right\} \quad (3)$$

A closely related set of descriptive functions which we shall want to use are known as semi-invariants. If the ith semi-invariant be designated λ_i, then

$$\left.\begin{aligned}\lambda_0 &= \mu_0' = \mu_0 = 1\\ \lambda_1 &= \mu_1'\\ \lambda_2 &= \mu_2\\ \lambda_3 &= \mu_3\\ \lambda_4 &= \mu_4 - 3\mu_2^2\end{aligned}\right\} \quad (4)$$

The 0th moment as seen by equations 1 is merely the sum of all values of the probability function and by definition must equal unity.

The first moment about zero, μ_1', of a variate is its *arithmetic mean* or average value $\bar{x}$ or $\bar{r}$; it thus indicates the general position of the variate along the scale of measurement.

The second moment μ_2 of a variate about its mean is a measure of the dispersion of the distribution. μ_2 is known as the *variance*, $\sigma=\sqrt{\mu_2}$ is called the *standard deviation*.

The third moment about the mean is a measure of the asymmetry of a variate's distribution; the asymmetry or *skewness* is defined as

$$k = \frac{\mu_3}{\mu_2^{3/2}} = \frac{\mu_3}{\sigma^3} \quad (5)$$

The fourth moment about the mean is a measure of the length of the tails and the peakedness of the mode of a distribution. This gives rise to the parameter known as the *excess* or *kurtosis* of a distribution; it is defined as

$$\beta_2 = \frac{\mu_4}{\mu_2^2} = \frac{\mu_4}{\sigma^4} \quad (6)$$

If the first few moments (or their associated parameters, mean, standard deviation, and so forth) serve to describe a probability distribution with considerable accuracy, then two distributions with a number of identical corresponding moments should closely resemble one another. To fit (or smooth) an observed probability distribution by an appropriate analytical curve form with unspecified constants, we first determine the lower moments of the analytical curve in terms of these constants. Then equating corresponding theoretical and observed moments gives relationships from which the constants of the fitting curve can be calculated. As many moments must be equated as there are unknown constants to be determined. For example, the value of the first moment or arithmetic mean a in the Poisson fitting distribution, $a^xe^{-a}/x!$ would be set equal to the observed mean of a set of data which this type of curve was appropriate to fit.

A variate's true distribution, if we could but determine it, would, except for rare instances, have a smooth unimodal form. Hence it will usually be desirable to smooth by the method of moments or in some other fashion a variate's rough observed distribution before entering upon its combination with other variates.

3. Laws of Combining Probabilities

Two or more events may occur independently, they may be mutually exclusive, or they may be correlated. If two events are independent, and the probability in favor of the first event is p_1, and in favor of the second is p_2, then the probability they will both occur is the *product* of their individual probabilities, p_1p_2. If either event a, or event b, or event c, and so forth, can happen, and the occurrence of one precludes the happening of another, they are known as mutually exclusive events. If events a, b, c, d... are mutually exclusive, the probability that *either a or b*, for instance, will occur is the *sum* of their individual probabilities,

Paper 42-145, recommended by the AIEE committee on communication for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 29, 1942; made available for printing June 10, 1942.

Roger I. Wilkinson is a member of the technical staff, probability research department, Bell Telephone Laboratories, Inc., New York, N. Y.

$p_a + p_b$. Correlated events lie between the limiting cases of independent and mutually exclusive events, and the laws of combining their probabilities are determined by the amount and kind of dependence between them.

4. Combining Variates With Mutually Exclusive Probabilities

When two or more mutually exclusive variates are combined, the result is a "mingled" universe made up of variate r (with probability distribution p_r or $\theta(r)dr$) h proportion of the time, and variate s (with probability distribution q_s or $\phi(s)ds$) j proportion of the time.... The distribution functions of the resultant z of such mutually exclusive variates are:

Discrete Variates

$$F(z) = hp_z + jq_z + \dots \tag{7}$$

Continuous Variates

$$F(z)dz = h\theta(z)dz + j\phi(z)dz + \dots$$

The moments of the resultant z taken about zero are readily expressed in terms of the moments of the component variates, as

$$\left.\begin{aligned}
\mu_{1z}' &= h\mu_{1r}' + j\mu_{1s}' + \dots \\
\mu_{2z}' &= h\mu_{2r}' + j\mu_{2s}' + \dots \\
&\dots\dots\dots\dots\dots\dots \\
\mu_{tz}' &= h\mu_{tr}' + j\mu_{ts}' + \dots
\end{aligned}\right\} \tag{8}$$

These equations permit us to express the parameters of z in terms of the parameters of its components as follows:

$$\left.\begin{aligned}
\bar{z} &= h\bar{r} + j\bar{s} + \dots \\
\sigma_z &= [h(\sigma_r^2 + \bar{r}^2) + j(\sigma_s^2 + \bar{s}^2) + \dots - \bar{z}^2]^{1/2} \\
k_z &= \frac{1}{\sigma_z^3}\,[h(k_r\sigma_r^3 + 3\sigma_r^2\bar{r} + \bar{r}^3) + j(k_s\sigma_s^3 + 3\sigma_s^2\bar{s} + \bar{s}^3) + \dots - (3\sigma_z^2\bar{z} + \bar{z}^3)] \\
\beta_{2z} &= \frac{1}{\sigma_z^4}\,[h(\beta_{2r}\sigma_r^4 + 4k_r\sigma_r^3\bar{r} + 6\sigma_r^2\bar{r}^2 + \bar{r}^4) + j(\beta_{2s}\sigma_s^4 + 4k_s\sigma_s^3\bar{s} + 6\sigma_s^2\bar{s}^2 + \bar{s}^4) + \dots - (4k_z\sigma_z^3\bar{z} + 6\sigma_z^2\bar{z}^2 + \bar{z}^4)]
\end{aligned}\right\} \tag{9}$$

Example—Length of Life of Outside Plant

A public utility serving a given area uses two kinds of poles in its outside plant. One kind, r, has an average life of 14 years with a standard deviation of 2.5 years, and the other, s, has an average life of 18 years with a standard deviation of 3.5 years. As shown in Figure 1 variations about the average life are substantially according to the normal law

$$f(x) = \frac{1}{\sigma_x\sqrt{2\pi}}\, e^{-\frac{(x-\bar{x})^2}{2\sigma_x^2}}$$

If approximately 20 per cent of the poles in the plant are of the r type, what is the distribution of life lengths on which the accounting department may base its pole depreciation rate?

Solution. The distribution of the overall life length will be, according to equation 7,

$$F(z) = 0.20\,\frac{1}{\sigma_r\sqrt{2\pi}}\, e^{-\frac{(z-\bar{r})^2}{2\sigma_r^2}} + 0.80\,\frac{1}{\sigma_s\sqrt{2\pi}}\, e^{-\frac{(z-\bar{s})^2}{2\sigma_s^2}}$$

$$= \frac{0.20}{2.5\sqrt{2\pi}}\, e^{-\frac{(z-14)^2}{2(2.5)^2}} + \frac{0.80}{3.5\sqrt{2\pi}}\, e^{-\frac{(z-18)^2}{2(3.5)^2}}$$

This distribution is shown in Figure 2 and is, of course, merely the weighted sum of the ordinates of the two mutually exclusive components. The parameters of this composite distribution are readily found from equations 9. For example, the average length of life of the whole pole plant is

$$\bar{z} = 0.20(14) + 0.80(18) = 17.2 \text{ years}$$

and the standard deviation of the universe of individual pole lives is

$$\sigma_z = [0.20(2.5^2 + 14^2) + 0.80(3.5^2 + 18^2) - 17.2^2]^{1/2} = 3.69 \text{ years}$$

5. Combining Independent Variates

In order to determine the resultant of any chosen values of two or more independent variates, the process by which they combine must be specified. This is expressed analytically by the *equation of relation;* it is written

$$z = \xi(r, s, t \dots) \tag{10}$$

For a particular choice of $r, s, t \dots$ (denoted by subscripts) we have $z_1 = \xi(r_1, s_1, t_1 \dots)$. The probability of their joint occurrence is then, by section 3, the product of their individual probabilities of occurrence:

Discrete Variates

$$F(z_1) = p_r p_s p_t \dots \tag{11}$$

Continuous Variates

$$F(z_1)dz = \theta(r_1)dr\,\phi(s_1)ds\,\psi(t_1)dt \dots$$

Equations 11 give the probability for obtaining z by just one particular selection from usually a number of mutually exclusive combinations of $r, s, t \dots$ which when substituted in equations 11 will produce the given value of $z = z_1$. Hence by the law of combining mutually exclusive events, the total probabilities of obtaining z_1 are

Discrete Variates

$$F(z_1) = \$ p_r p_s p_t \dots \tag{12}$$

Continuous Variates

$$F(z_1)dz = \$ \theta(r)dr\,\phi(s)ds\,\psi(t)dt \dots$$

where the symbol $\$$ indicates the summation of all eligible cases. Since z_1 is any value of z, equations 12 are the desired expressions for the probability distribution of z.

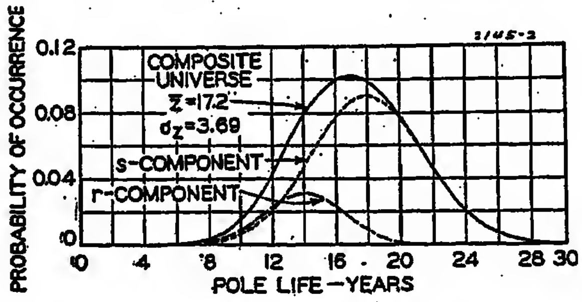

Figure 2. Composite universe formed from two "mutually exclusive" universes

5.1 Step-by-Step Combination of Independent Variates

It is clearly possible to obtain a distribution of the resultant $F(z)$, by writing out in tabular form all the ways of forming each value of z, then taking the products of the individual probabilities of occurrence for each way as in equations 11, and finally summing the probabilities according to equations 12. Such a procedure does not give the result in a general or analytical form for use in subsequent applications, but it does have the immediate advantage of providing the solution to a particular problem.

When more than two elemental variates are to be combined, it is nearly always possible first to combine two, then combine their resultant with the third elemental variate, and so on. The combination of any two variates is then done by means of a two-way or "square" table displaying the values of one variate (say s) with their corresponding probabilities of occurrence in the horizontal direction as column headings, and the values and probabilities of the other variate (say r) in the vertical direction, as line headings. An outline of this form is shown in Table I. There is no theoretical need that the range of the variate r represented by r_1 should equal the next range r_2, and the subsequent r ranges, or that the r ranges should be the same as the s ranges. Practically, however, such a selection is usually made.

For discrete variates the unit difference between successive r's and s's will generally be just one unit on the natural scale of measurement, such as one call, one object, one occurrence; otherwise the exactness of the solution will have been lost.

The step-by-step combination of continuous variates will seldom be wholly exact, because the variates' ranges must be broken down into a number of discrete intervals, each of which is represented by a single more or less typical value. However by taking these intervals smaller and

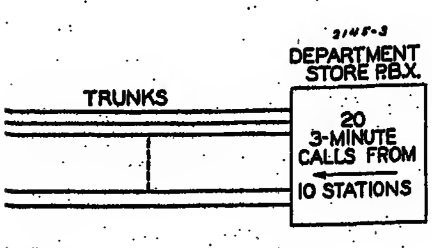
nall areas opposite each pair of s in Table I are shown two en- the upper left corner is the which results from substituting the equation of relation $z_{ij}=$ t is, of course, the value of z ıld occur if these particular r and s were present. In the corner is entered the product o probabilities shown at the d line headings, that is $\theta(r_i)\times$ ıs upon the completion of the alues of r have been combined :o the equation of relation with of s. If any restrictions are to d on the association of certain with those of s, the proper areas omitted from the table. If m r and n classes of s are made, all have mn z values each with ed probability of occurrence.
tribution $F(z)$ may now be a manner identical with that ouping observed data, that is, als are chosen, the proper val- assigned to each, and the prob- occurrence in each interval y adding the probabilities for 's falling therein. The cumu- ibution and the moments and of z may then be calculated in ay if desired.
mple sum or difference of the r tes is to be found, dividing each



Trunking arrangement between PBX and central office

into intervals of the same width as suggested above will expedite the working. In Table I all the values of a particular $z_w=r+s$ for the sum case (or $r-s$ for the difference case) will lie along one diagonal. The values of z_{w-1} will lie on the next diagonal above; the values of z_{w+1} on the next diagonal below and so on. Hence

1. There is no need to write in the z values in the body of the table.

2. The sum of the probabilities shown in any z diagonal is the total probability of occurrence of that value of z.

Each such sum may then be written conveniently at the edge of the square table opposite the end of its diagonal; this is the desired probability distribution.

Example—PBX Trunk Engineering

A group of trunks is to be provided for two-way use between a department store PBX (private branch exchange) as in Figure 3. There will be ten "outgoing" telephones at the store, originating on the average two three-minute trunk calls each in the busy hour. In addition, a sufficient number of stations will be provided at the store for incoming service only, to handle the 200 $1^1/_2$ minute customers' calls which are made in the average busy hour. How many trunks should be installed so that the customers may receive $P=0.01$ service?

Solution. Each of the 10 outgoing telephones will have a probability p of $\frac{2(3)}{60}=0.10$ of being in use at any random instant. The probability that exactly s will be so engaged is the binomial term

$$p_s=\phi(s)=\frac{n!}{s!(n-s)!}p^s(1-p)^{n-s}$$

where $n=10$ and $p=0.10$. Since a large number of sources will originate the incoming calls their distribution will be well represented by the Poisson expression

$$q_r=\theta(r)=\frac{a^r e^{-a}}{r!}$$

where

a = average simultaneous calls

$$=\frac{200(1^1/_2)}{60}=5.0$$

We now construct the square Table II, first calculating the various values of $\theta(r)$ and $\phi(s)$ from the above formulas to insert as column and line headings respectively. The s values have been reversed from the usual ascending tabular order so that the constant z diagonals will end at the right-hand edge of the table. The product of each pair of probabilities $\theta(r_i)\phi(s_j)$ is recorded in the body of the table and the diagonals summed as shown to give the desired $F(z)$ distribution. The cumulation of $F(z)$, designated $P(\geqq z)$, is also given.

From this last column we read the answer desired: To insure that the customers will not find the lines to the store busy oftener than 0.01 of the time, we must provide 13 trunks $[P(\geqq 13)=0.0083]$.

5.2 The Exact Analytical Combination of Independent Variates

If the probability distributions represented by the symbols p_r, p_s...and $\theta(r)dr$, $\phi(s)ds$ ..., in equations 12 are expressed as mathematic functions, it may well be that in numerous cases the summation operation indicated by $\mathfrak{S}$ can be performed analytically, thus giving the resultant $F(z)$ in similar analytical form. We must remember that $\mathfrak{S}$ represents a very special summation in which the relationships expressed by the equation of relation 10 are maintained. We may insure this by solving for one of the variates, say r, in equation 10, obtaining

$$\left.\begin{aligned} &r=f(z, s, t\ldots) \\ &\text{and} \\ &dr=\frac{df(z, s, t\ldots)}{dz}dz \end{aligned}\right\} \quad (13)$$

and substituting these in equations 12

Then the remaining independent variates may be summed over all ranges consistent with the value of z selected. Equations 12 then assume the completely definitized forms:

Discrete Variates

$$F(z) = \sum_s \sum_t \ldots \sum p_{f(z,\, s,\, t)} \ldots p_s p_t \ldots$$

Continuous Variates

$$\left.\begin{aligned} &F(z)dz = \\ &\quad dz \int_s \int_t \ldots \int \theta[f(z, s, t \ldots)] \times \\ &\quad \frac{d[f(z, s, t \ldots)]}{dz} \phi(s) ds \psi(t) dt \ldots \end{aligned}\right\} \quad (14)$$

5.21 Analytical Addition of Discrete Variates

The basic equation 14 for discrete variates can of course be applied whatever the equation of relation, and often its straightforward use is the simplest procedure. However for the addition, which is by far the commonest case, of discrete variates a method involving *frequency arrays* is found to be very powerful.

For our purpose, a frequency array is an expression containing the index A, which when *expanded in powers of A*, will give as the coefficient of A^r, the probability of occurrence of exactly r successes or events. Thus for the Poisson distribution the frequency array is $e^{m(A-1)}$, since, when expanded in powers of A, it yields the individual Poisson terms

$$e^{m(A-1)} = e^{-m}\left(1 + mA + \frac{m^2}{2!} A^2 + \frac{m^3}{3!} A^3 + \ldots + \frac{m^r}{r!} A^r + \ldots\right)$$

We note that the probability of finding exactly r events occurring with an average occurrence of m is the coefficient of A^r, that is $m^r e^{-m}/r!$

Secondly by substituting e^α for A, we obtain the "moment array" of the variate, which possesses the property that when it is expanded in *powers of* α, the successive moments of the distribution taken about zero are given as the coefficients of $\alpha, \frac{\alpha^2}{2!}, \frac{\alpha^3}{3!} \ldots$ Moreover the moment array *with respect to the mean* instead of the origin of the variate can be written by adding the factor $e^{-\alpha(\text{mean})}$. Thus the Poisson moment array with respect to the mean would be $e^{-\alpha m} \times e^{m(e^\alpha - 1)}$. Expanding we find

$$e^{m(e^\alpha - 1 - \alpha)} = 1 + m\frac{\alpha^2}{2!} + m\frac{\alpha^3}{3!} + (m + 3m^2)\frac{\alpha^4}{4!} + \ldots$$

18	0.000004									0.000001	0.000002	0.000001	18	0.000031	0.000045
19	0.000001									0.000000	0.000000	0.000000	19	0.000011	0.000014
													20	0.000003	0.000003

Hence the first, second, third, fourth ... moments of the Poisson variate about its mean are 0, m, m, $m+3m^2$ ... respectively. In Table III are given for four discrete variates common in engineering, the expressions for the frequency and moment arrays and the corresponding parameters.

The important characteristic of frequency arrays which we can make use of in adding discrete variates is that the array of their sum is the *product* of the individual arrays. Thus to add two Poisson variates r and s with distributions p_r and p_s, we multiply their frequency arrays giving

Array of $z=r+s$ is $[e^{a_r(A-1)}][e^{a_s(A-1)}]$.

This when expanded in powers of A gives

$$e^{-(a_r+a_s)}e^{A(a_r+a_s)}=e^{-(a_r+a_s)}\times\left(1+(a_r+a_s)A+\frac{(a_r+a_s)^2}{2!}A^2+\frac{(a_r+a_s)^3}{3!}A^3+\ldots\right)$$

But by definition the coefficient of A^z is the probability of exactly z occurrences. Hence

$$F(z)=\frac{(a_r+a_s)^z e^{-(a_r+a_s)}}{z!}$$

which demonstrates the truth of the familiar statement that the sum of two Poisson variates is a third Poisson variate whose average equals the sum of the components' averages. This same result could have been found by direct application of equation 14.

The sum distribution of the binomial and Poisson variates found step-by-step in Table II can readily be checked by the frequency array method. In a similar fashion the analytical expression for the sum and the moments of the sum of any two or more discrete variates can be obtained. The individual variates, whose frequency arrays are given in Table III will be found to simulate quite a number of the simple discrete distributions found in practice. The table could, of course, be extended indefinitely.

5.22 Analytical Combination of Continuous Variates

The application of equation 14 to the three most common equations of relation between two continuous variates yields

Linear Combination, $z=r\pm s$

$$F(z)dz=dz\int_s \theta(z\mp s)\phi(s)ds \tag{15}$$

Product Combination, $z=rs$

$$F(z)dz=dz\int_s \theta\left(\frac{z}{s}\right)\frac{1}{s}\phi(s)ds \tag{16}$$

Quotient Combination, $z=\frac{r}{s}$

$$F(z)dz=dz\int_s \theta(zs)s\phi(s)ds \tag{17}$$

The combinations of a great variety of continuous variates even in just the three type groups above can be imagined. We shall take up a few cases which illustrate the method of working.

5.22.11 Linear Combination of Distributions Limited in Both Directions—Square-Topped

If we have two square-topped variates r and s with distributions

$$\theta(r)dr=\frac{1}{b-a}dr$$

$$\phi(s)ds=\frac{1}{h-g}ds$$

what is the distribution of z, when $z=r+s$? Consider first the simple case of $a>h$ and $h-g>b-a$ (or $h+a>b+g$), as shown in Figure 4. From equation 15 we write immediately,

$$F(z)dz=\frac{dz}{b-a}\frac{1}{h-g}\int_{s=\text{all values}} ds$$

We need now to select carefully the limits of integration for s which include all the admissible values of s but no others. There will be three cases.

Case 1. When z lies between $a+g$ and $b+g$

$$F_1(z)=\frac{1}{b-a}\frac{1}{h-g}\int_{s=g}^{z-a}ds=\frac{1}{b-a}\frac{1}{h-g}(z-a-g)$$

Case 2. When z lies between $b+g$ and $a+h$

$$F_2(z)=\frac{1}{b-a}\frac{1}{h-g}\int_{s=z-b}^{z-a}ds=\frac{1}{b-a}\frac{1}{h-g}(b-a)=\frac{1}{h-g}$$

Case 3. When z lies between $a+h$ and $b+h$

$$F_3(z)=\frac{1}{b-a}\frac{1}{h-g}\int_{s=z-b}^{h}ds=\frac{1}{b-a}\frac{1}{h-g}(b+h-z)$$

The distribution of the resultant z is shown in Figure 4, and, as one might have expected, shows discontinuities at the points $b+g$ and $a+h$. Clearly the restriction of $a>h$ would make no change if it were lifted. We insure (although not absolutely) our selection of the proper limits for s by checking that the area under $F(z)$ is unity, that is

$$\text{Area}=\int_{a+g}^{b+g}F_1(z)dz+\int_{b+g}^{a+h}F_2(z)dz+\int_{a+h}^{b+h}F_3(z)dz=1$$

If instead of $h+a>b+g$ we had taken $h+a<b+g$, the equations for $F_1(z)$ and $F_3(z)$ would remain unchanged for the end intervals, while $F_2(z)$ for the central interval of z would become

$$F_2'(z)dz=\frac{1}{b-a}\frac{1}{h-g}\int_{s=g}^{h}ds=\frac{1}{b-a}\frac{1}{h-g}(h-g)=\frac{1}{b-a}$$

Finally it may be observed that when $a+h=b+g$, that is the two variates r and s have the same range, the central interval of z disappears entirely, leaving simply an isosceles triangular distribution whose average is $\bar{z}=\bar{r}+\bar{s}$, and whose range is the sum of the corresponding ranges of the r and s variates.

The distribution of the *difference* between two square-topped variates is obtained in a manner very similar to that used in determining their sum. Likewise, the distribution form resulting is very similar to the sum distribution; an example is shown as the lower diagram of Figure 4.

Example—Minimizing Noise in Telephone Circuits

Series capacitors are used in each side of the talking circuit at several points in local crossbar central office practice to isolate

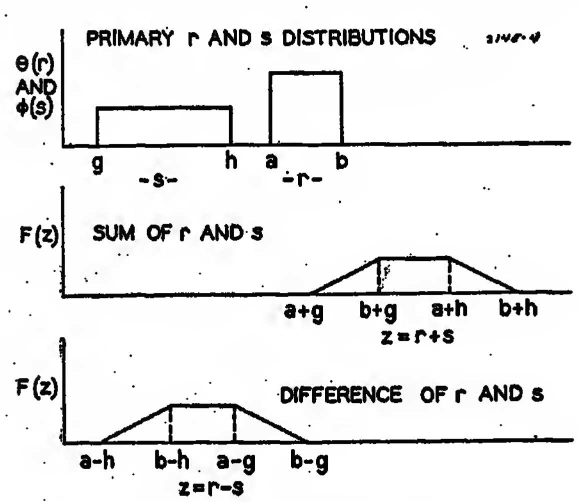

Figure 4. Linear combination of "square-topped" distributions

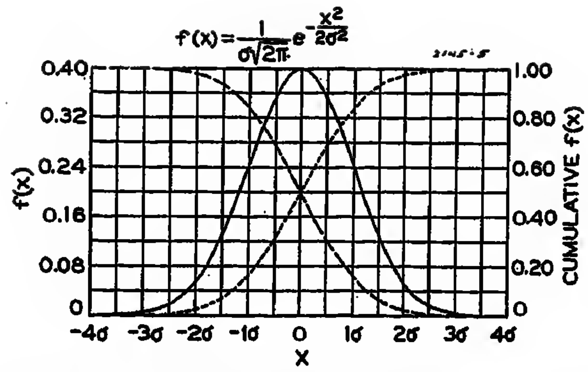

Figure 5. Individual and cumulative normal distribution

various d-c circuit elements. In order to insure satisfactory longitudinal unbalance characteristics (to mimimize noise) the two capacitors comprising a pair need to have very nearly identical capacitances. Suppose stock capacitors available for this purpose vary in capacitance with equal likelihood over the range 2.2 microfarads ±2.5 per cent. What will be the expected (or average) unbalance in the two sides of the circuit due to this cause? What is the probability the unbalance will exceed 0.08 microfarad?

Solution. Since the two capacitor capacitance distributions are identical, the $F(z)$ distribution will be an isosceles triangle, ranging about the mean $\bar{z}=0$, from $-2(0.025)(2.2)=-0.11$ microfarad to $+0.11$ microfarad. The expected unbalance will be found by determining the average of the absolute deviations from $\bar{z}=0$. In the notation used above and seen on Figure 4, this is

$$\overline{|z|}=2\int_0^{b-g}\frac{z}{(b-a)(h-g)}(b-g-z)dz$$

$$=0.0367 \text{ microfarad}$$

when $b=h=2.2+0.055=2.255$, and $a=g=2.2-0.055=2.145$. Similarly the probability that the unbalance z will exceed 0.08 microfarad is given by

$$P(>0.08)=\int_{0.08}^{0.11}F(|z|)dz=\frac{2}{(b-a)(h-g)}\times$$

$$\int_{0.08}^{0.11}(b-g-z)dz=0.0744$$

5.22.12 Linear Combination of Normal Variates

Of all continuous probability distributions the normal law shown plotted "individually" and cumulatively in Figure 5 is undoubtedly the one most frequently encountered in engineering work. Although the physical situation may but seldom meet the theoretical requirements of the normal distribution (such as that the variate has unlimited extent in both directions), nevertheless in many cases the normal curve provides a satisfactory fit over the major portion of the variate's range.

Let the variates r and s have the normal distributions

$$\theta(r)=\frac{1}{\sigma_r\sqrt{2\pi}}e^{-\frac{(r-\bar{r})^2}{2\sigma_r^2}} \tag{18}$$

and

$$\phi(s)=\frac{1}{\sigma_s\sqrt{2\pi}}e^{-\frac{(s-\bar{s})^2}{2\sigma_s^2}} \tag{19}$$

We desire the distribution of $z=r+s$. Substituting directly in equation 15 gives

$$F(z)dz=dz\int_{s=-\infty}^{+\infty}\theta(z-s)\phi(s)ds$$

$$=dz\int_{-\infty}^{\infty}\frac{1}{\sigma_r\sqrt{2\pi}}e^{-\frac{(z-s-\bar{r})^2}{2\sigma_r^2}}\times$$

$$\frac{1}{\sigma_s\sqrt{2\pi}}e^{-\frac{(s-\bar{s})^2}{2\sigma_s^2}}ds$$

$$=\frac{1}{\sqrt{\sigma_r^2+\sigma_s^2}\sqrt{2\pi}}e^{-\frac{[z-(\bar{r}+\bar{s})]^2}{2(\sigma_r^2+\sigma_s^2)}}dz \tag{20}$$

Quite obviously this resultant distribution is of the same normal form as were the two components, since if we set

$$\bar{z}=\bar{r}+\bar{s} \tag{21}$$

$$\sigma_z=\sqrt{\sigma_r^2+\sigma_s^2} \tag{22}$$

we obtain

$$F(z)dz=\frac{1}{\sigma_z\sqrt{2\pi}}e^{-\frac{(z-\bar{z})^2}{2\sigma_z^2}} \tag{23}$$

By an exactly similar analysis we should have found that the distribution of the *difference* $z=r-s$ of two normal variates has exactly the same distribution as given in equation 23, if instead of equation 21 we write

$$\bar{z}=\bar{r}-\bar{s} \tag{24}$$

It is thus quite obvious that *the sum (or difference) of two normal variates has a normal distribution whose mean equals the sum (or difference) of the means of the primary distributions, and whose standard deviation is the square root of the sum of the squares of the component standard deviations.*

Example—The Tractor Plant

In the assembly plant of a tractor company, one operation consists in bolting two connecting parts A and B end to end as in Figure 6. It is found by sampling the bins containing the two parts that eight per cent of the A parts exceed a variation of ±0.10 inch from the nominal or design value, and 14 per cent of the B parts exceed a variation of ±0.05 inch from their nominal value. What proportion of the bolted assemblies will exceed an error of 0.15 inch from the designed value?

Solution. Suppose past studies have shown that both parts A and B have manufacturing variations closely following the normal law. Then reading on Figure 5, we see that if eight per cent are to exceed a deviation from the mean of ±0.10 inch (that is four per cent exceed a +0.10-inch deviation and four per cent exceed a −0.10-inch deviation), the +0.10 deviation must correspond to $+1.75\ \sigma_A$ standard deviations, whence $\sigma_A=\frac{0.10}{1.75}=0.05714$ inch. Likewise with part B if we find that seven per cent of the samples exceed a deviation of +0.05 then 0.05 equals 1.48 standard deviations, or $\sigma_B=\frac{0.05}{1.48}=0.03378$ inch.

Now from equation 22 we calculate the standard deviation of the sum of the lengths of A and B, as

$$\sigma_z=\sqrt{(0.05714)^2+(0.03378)^2}=0.06638$$

We know from equation 23 that z is normal, so we have merely to find the probability of exceeding a deviation from the average of the specified 0.15 inch in a normal curve with $\sigma_z=0.06638$. This deviation when expressed in terms of σ_z is 2.26 standard deviations. Referring once more to Figure 5 we find the probability is approximately $2(0.012)=0.024$ that a random assembled unit will exceed the specified range. Or, conversely, we should expect $(1-0.024)100=97.6$ per cent of the assemblies to fall within the specified range.

5.22.2 Product Combinations of Variates

A single pair of variates will be chosen to illustrate the procedure followed to obtain the distribution of their product. Suppose we have a generalized exponential distribution (often designated as Pearson's type III) in r and a square-topped distribution in s, given by

$$\theta(r)=\frac{c^{n+1}}{\Gamma(n+1)}r^ne^{-cr}$$

$$\phi(s)=\frac{1}{h-g}$$

to find $F(z)$, when $z=rs$.

Substituting in equation 16 gives

$$F(z)dz=dz\int\theta\left(\frac{z}{s}\right)\frac{1}{s}\phi(s)ds$$

$$=dz\frac{c^{n+1}}{\Gamma(n+1)}\frac{1}{h-g}\int_{s=g}^{h}\left(\frac{z}{s}\right)^ne^{-c\frac{z}{s}}\frac{1}{s}ds$$

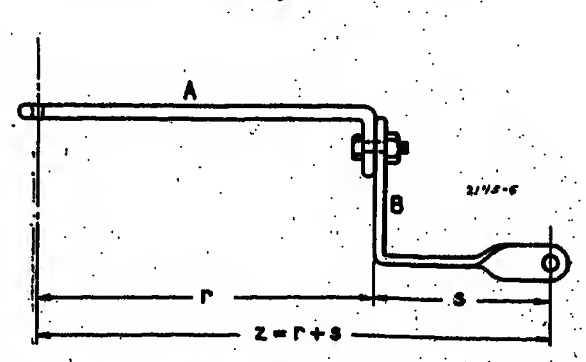

Figure 6. Assembly of tractor parts A and B

Table III. The Frequency and Moment Arrays, and Parameters of Several Common Discrete Distributions

Universe	Frequency Array	Moment Arrays: About Zero*	Moment Arrays: About Mean**	Parameters of the Universe: mean, $\bar{x}$	Standard Deviation, σ	Skewness, $k(=\sqrt{\beta_1})$	Kurtosis, β_2
Binomial:							
$f(x)=\binom{n}{x}p^x(1-p)^{n-x}$	$(q+pA)^n$	$(q+pe^{\alpha})^n$	$e^{-np\alpha}(q+pe^{\alpha})^n$	np	$\sqrt{npq}$	$\frac{1-2p}{\sqrt{npq}}$	$3\frac{n-2}{n}+\frac{1}{npq}$
Poisson:							
$f(x)=\frac{m^xe^{-m}}{x!}$	$e^{m(A-1)}$	$e^{m(e^{\alpha}-1)}$	$e^{-m\alpha}\cdot e^{m(e^{\alpha}-1)}$	m	$\sqrt{m}$	$\frac{1}{\sqrt{m}}$	$3+\frac{1}{m}$
Simple exponential:							
$f(x)=(1-e^{-c})e^{-cx}$	$\frac{1-e^{-c}}{1-Ae^{-c}}$	$\frac{1-e^{-c}}{1-e^{\alpha-c}}$	$e^{\frac{\alpha e^{-c}}{1-e^{-c}}}\frac{(1-e^{-c})}{(1-e^{\alpha-c})}$	$\frac{e^{-c}}{1-e^{-c}}$	$\frac{e^{-\frac{c}{2}}}{1-e^{-c}}$	$e^{\frac{c}{2}}+e^{-\frac{c}{2}}$	$e^c+e^{-c}+7$
Generalized exponential:							
$f(x)=\frac{(1-e^{-c})^2}{e^{-c}}xe^{-cx}$	$A\frac{(1-e^{-c})^2}{(1-Ae^{-c})}$	$e^{\alpha}\frac{(1-e^{-c})^2}{(1-e^{\alpha-c})}$	$e^{\frac{2\alpha}{1-e^{-c}}}\frac{(1-e^{-c})^2}{(1-e^{\alpha-c})}$	$\frac{1+e^{-c}}{1-e^{-c}}$	$\frac{\sqrt{2}e^{-\frac{c}{2}}}{1-e^{-c}}$	$\frac{e^{\frac{c}{2}}+e^{-\frac{c}{2}}}{\sqrt{2}}$	$\frac{e^c+e^{-c}+10}{2}$

* The moment array about zero is obtained by substituting $e\alpha$ for A in the frequency array.

** The moment array about the mean is obtained by multiplying the moment array about zero by $e^{-\alpha(\text{mean})}$.

Let $t=\frac{1}{s}$, so that $s=\frac{1}{t}$, $ds=-\frac{1}{t^2}dt$. This results in

$$F(z)dz=\frac{c^{n+1}}{\Gamma(n+1)}\frac{z^ndz}{h-g}\times\int_{1/h}^{1/g}t^{n-1}e^{-czt}dt \qquad (25)$$

The integration of this formula for n unspecified cannot be performed exactly. For low integral values of n, however, the expression can readily be written out by making a succession of n integrations, since

$$\int t^{n-1}e^{-ct}dt=\frac{t^{n-1}e^{-ct}}{-c}+\frac{n-1}{c}\int t^{n-2}e^{-ct}dt$$

until the last integral is of the form

$$\int e^{-ct}dt=-\frac{1}{c}e^{-ct}$$

Thus when $n=1$, equation 25 becomes simply

$$F(z)dz=\frac{c}{\Gamma(2)}\frac{dz}{h-g}\left[e^{-\frac{cz}{h}}-e^{-\frac{cz}{g}}\right]$$

If n is any positive integer, it can be shown that

$$F(z)dz=\frac{c}{n}\frac{dz}{h-g}\left[P\left(n,\frac{cz}{g}\right)-P\left(n,\frac{cz}{h}\right)\right]$$

where $P(n, m)=\sum_{x=n}^{\infty}\frac{m^xe^{-m}}{x!}$, the Poisson summation which is tabled for wide ranges.

5.22.3 Quotient Combination of Variates

To illustrate the exact analytical determination of the distribution of the quotient of two independent variates, we choose the case of $z=r/s$ in which r and s are of the generalized exponential form. Their distributions are

$$\theta(r)=\frac{c^{n+1}}{\Gamma(n+1)}r^ne^{-cr}$$

$$\phi(s)=\frac{q^{m+1}}{\Gamma(m+1)}s^me^{-qs}$$

From equation 17

$$F(z)dz=dz\int\theta(zs)s\phi(s)ds$$

$$=dz\frac{c^{n+1}}{\Gamma(n+1)}\frac{q^{m+1}}{\Gamma(m+1)}\times\int_{s=0}^{\infty}(zs)^ne^{-czs}s^{m+1}e^{-qs}ds$$

$$=\frac{c^{n+1}}{\Gamma(n+1)}\frac{q^{m+1}}{\Gamma(m+1)}z^ndz\times\int_{s=0}^{\infty}s^{m+n+1}e^{-(cz+q)s}ds \qquad (26)$$

Apparently equation 26 is of the same form as equation 25 just considered under "Products," except that here the limits of s are 0 and ∞. This last condition produces the complete gamma function, since

$$\int_0^{\infty}x^ne^{-ax}dx=\frac{\Gamma(n+1)}{a^{n+1}}$$

in which $\Gamma(n+1)=n!$ for n integral. Hence equation 26 reduces to

$$F(z)dz=c^{n+1}q^{m+1}\frac{\Gamma(m+n+2)}{\Gamma(n+1)\Gamma(m+1)}\times\frac{z^ndz}{(cz+q)^{m+n+2}} \qquad (26\text{-a})$$

Tables of logarithms of the Γ function are available as well as factorials of numbers which may be used in their place when m and n are integers.

Since the rth moment of z in equation 26 is

$$\mu_r'=\frac{q^r}{c^r}\frac{\Gamma(n+r+1)}{\Gamma(n+1)}\frac{\Gamma(m-r+1)}{\Gamma(m+1)}$$

we readily find

$$\bar{z}=\frac{q}{c}\frac{n+1}{m}$$

and

$$\sigma_z=\frac{q}{cm}\sqrt{\frac{(m+n+1)(n+1)}{m-1}}$$

It is to be particularly noted that $\bar{z}$ does *not* equal the ratio of $\bar{r}$ and $\bar{s}$, which here would give $\frac{q}{c}\frac{n+1}{m+1}$ instead of $\frac{q}{c}\frac{n+1}{m}$.

5.3 Approximate Analytical Combinations of Independent Variates

Very often it becomes highly desirable to find an estimate of the resultant of two or more independent variates when it is impossible or inexpedient to combine them either by the step-by-step or the completely analytical method. Some-

times, for instance, raw data depicting the behavior of one of the elements are widely scattered or are not easily fitted by the usual methods; a fitting curve may have too complex an equation to permit analytical manipulation; complete information on one or more primary variates may be lacking; or again only estimates of the resultant parameters may be needed for one's purpose.

In this event satisfactory resort may usually be made to various schemes for combining the parameters of the distribution functions to obtain the corresponding parameters of the resultant curve. From these, in turn, a frequency distribution may be constructed if desired, using one

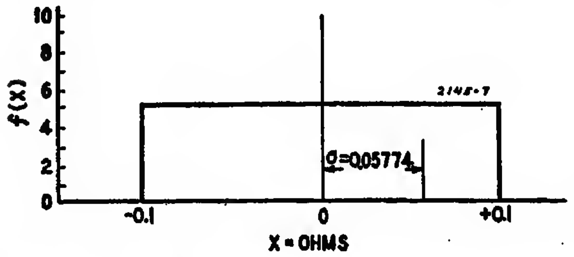

Figure 7. Resistance variation in coils of wire

of the systems of generalized frequency curves (such as the Pearson types or the Gram-Charlier series). The more powerful of these combination methods will now be considered for the three common operations, those having linear, product, and quotient equations of relation.

5.31 Approximate Linear Combinations

The parameters which lend themselves best to the approximate linear combination of variates are the semi-invariants defined by equations 4. Thiele has demonstrated the following relationship for every linear function of uncorrelated observations, the extreme simplicity of which he says "renders the semi-invariants unrivalled as the most suitable symmetrical functions and the most powerful instrument of the theory of observations."

If the equation of relation is $z=a+bx+cy+\ldots+dt$ then the semi-invariants L_r of the resultant z distribution are

$$\left.\begin{aligned} &L_1=a+b\,{}_x\lambda_1+c\,{}_y\lambda_1+\ldots+d\,{}_t\lambda_1\\ &L_2=b^2\,{}_x\lambda_2+c^2\,{}_y\lambda_2+\ldots+d^2\,{}_t\lambda_2\\ &\cdots\cdots\cdots\cdots\cdots\cdots\\ &\text{and, generally}\\ &L_r=b^r\,{}_x\lambda_r+c^r\,{}_y\lambda_r+\ldots+d^r\,{}_t\lambda_r \end{aligned}\right\} \qquad (27)$$

for $r \geqq 2$.

Having found the semi-invariants of the combined distributions, we may if we like, retransfer them to moments by equations 4, and then determine the mean standard deviation, skewness, and kurtosis of the resultant. Following through these operations we can express these latter parameters in terms of those of the component distributions:

$$\bar{z}=a+b\bar{x}+c\bar{y}+\ldots+d\bar{t} \qquad (28)$$

$$\sigma_z=\sqrt{b^2\sigma_x^2+c^2\sigma_y^2+\ldots+d^2\sigma_t^2} \qquad (29)$$

$$k_z=\frac{b^3\sigma_x^3k_x+c^3\sigma_y^3k_y+\ldots+d^3\sigma_t^3k_t}{[b^2\sigma_x^2+c^2\sigma_y^2+\ldots+d^2\sigma_t^2]^{3/2}} \qquad (30)$$

$$\beta_{2z}=\frac{b^4\sigma_x^4(\beta_{2x}-3)+c^4\sigma_y^4(\beta_{2y}-3)+\ldots+d^4\sigma_t^4(\beta_{2t}-3)}{[b^2\sigma_x^2+c^2\sigma_y^2+\ldots+d^2\sigma_t^2]^2}+3 \qquad (31)$$

Equations 28 and 29 of course include the familiar relations:

1. The mean of the sum (or difference) of independent variates is the sum (or difference) of the means of the individual variates.

2. The standard deviation of the sum (or difference) of independent variates is the square root of the sum of the squares of the individual standard deviations.

It is perhaps not universally appreciated that these relations are true whatever the distribution forms of the component variates.

When n identical variates are to be added, which is a common case, equations 28 to 31 reduce to

$$\left.\begin{aligned} &\bar{z}=n\bar{x}\\ &\sigma_z=\sqrt{n}\,\sigma_x\\ &k=\frac{1}{\sqrt{n}}k_x\\ &\beta_2=\frac{1}{n}\,[\beta_{2x}-3]+3 \end{aligned}\right\} \qquad (32)$$

Thus the resultant's average is just n times an individual average, the standard deviation has increased at the rate of $\sqrt{n}$, while the skewness has diminished as $1/\sqrt{n}$, and the kurtosis is approaching 3 as a limit at a rate dependent on $1/n$. It will be seen that these last two limits, $k=0$ and $\beta_2=3$ are characteristic of the normal law. Likewise it can be shown that the same limits are approached for any linear equation of relation as n increases; moreover the primary variates need not all be alike. Hence we conclude that, if a large number of variates are combined linearly, their resultant will tend to approach the normal distribution with mean and standard deviation calculated from equations 28 and 29. As a practical matter, if no one distribution has a standard deviation substantially larger than the others to be combined linearly, the resultant of as few as six or eight components will nearly always be so closely normal that it may be considered normal for most engineering purposes.

Example—Resistance Unbalance in Wires

Two copper wires of 50 miles length are to be built from 120-pound coils (173 pounds to the mile, approximately), and the electrical resistances per coil vary with an equal likelihood over all values ± 0.1 ohm from the average as shown in Figure 7. What is the probability that the completed wires will differ in resistance more than 1.5 ohms?

Solution. The number of coils n in each wire will be $n=\frac{50(173)}{120}\approx 72$. Hence the probability distribution for single wires will be closely normal about a mean value $\bar{r}$ equal to the average resistance per coil times the number of coils in the 50-mile length. The standard deviation of a single coil's resistance, by application of equation 2, is

$$\sigma_x^2=\mu_2=\frac{K\int_{-0.1}^{+0.1}x^2dx}{K\int_{-0.1}^{+0.1}dx}=\frac{\frac{2(0.001)}{3}}{0.2}=0.0033333$$

and $\sigma_x=0.05774$ ohm. Similarly we find $k_x=0$, and $\beta_{2x}=1.80$. Then by equation 32 the standard deviation for a single wire of 72 coils is $\sigma_{72}=\sqrt{72}\,\sigma_x=0.4899$ ohm. Likewise $k_{72}=\frac{1}{\sqrt{72}}0=0$, and $\beta_{2n}=\frac{1}{27}\,[1.80-3.0]+3=2.9833$. The single-wire resistance distribution will then be closely normal, with the equation

$$\theta(r)=\frac{1}{0.4899\sqrt{2\pi}}e^{-\frac{(r-\bar{r})^2}{2(0.4899)^2}}$$

The distribution of the difference $z=r_1-r_2$ in two such wires will likewise be normal (from section 5.22.12) and will have the parameters, from equations 24 and 22

$$\bar{z}=\bar{r}_1-\bar{r}_2=0$$

$$\sigma_z=\sqrt{\sigma_{r1}^2+\sigma_{r2}^2}=\sqrt{2(0.4899)^2}$$
$$=0.6918 \text{ ohm}$$

This distribution of z is shown in Figure 8. The probability that the two wires will differ in resistance more than 1.5 ohms, that is in excess of $2.168\sigma_z$, is read from a normal probability table or from Figure 5 to be 0.0302. The corresponding areas are indicated in Figure 8.

5.31.1 Distributions of Means

The reliability of the observed mean of a sample of n items is often desired.

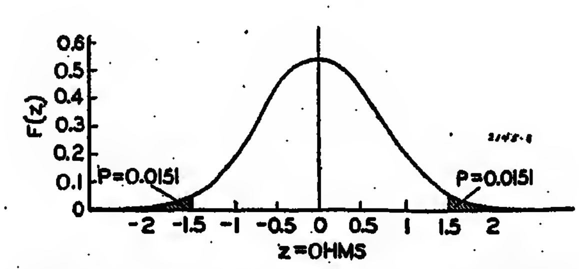

Figure 8. Difference between single-wire resistances

The true answer involves an application of *a posteriori* probability theory. However if n is large, say 100 or more, it is usually satisfactory to substitute the following *a priori* problem: If n items are drawn at random from a hypothetical universe with assumed parameters, what is the probability that a sample differing from this universe as far as that actually drawn could have resulted? This probability is then taken as a satisfactory approximation to the probability that the unknown true universe differs from the observed sample as far as did the hypothetical universe. The best estimate of the standard deviation of the unknown universe is the observed sample's standard deviation.

The distribution of the *means* of samples of n items is identical with that of the *totals* of n items when the latter's variate scale is reduced by $1/n$th. It is easy to see that the parameters of the means of successive samples of n items are

$$\bar{x}=\frac{1}{n}[\text{mean of the totals distribution}]=\bar{x} \tag{33}$$

$$\sigma_{\bar{x}}=\frac{1}{n}[\text{standard deviation of the totals distribution}]=\frac{\sqrt{n}\sigma}{n}=\frac{\sigma}{\sqrt{n}} \tag{34}$$

$$k_{\bar{x}}=k_{\text{totals}} \tag{35}$$

$$\beta_{2_{\bar{x}}}=\beta_{2\text{totals}} \tag{36}$$

Hence as n increases, the distribution of the means of successive samples of size n rapidly approaches the normal law, while the expected average is the universe average, and the standard deviation (or standard error) of the means decreases inversely as the square root of the number of observations n. This last, of course, agrees with the common sense conclusion that the larger the sample the more reliable its mean should be.

EXAMPLE—SAMPLING OF MANUFACTURED PRODUCT

A sample of 225 rough castings is taken at random from a shipment of about 10,000 and weighed individually. The average weight is found to be 11.72 pounds with a standard deviation of 0.804 pound. What is the probability that the average weight for the whole shipment is less than 11.60 pounds?

Solution. We solve the allied *a priori* sampling problem: If the true average is 11.60 pounds with standard deviation of 0.804 pound, what is the probability that a sample of the size drawn could have a mean of 11.72 *or higher?* The standard deviation of averages of samples with 225 items is estimated from equation 34 as $\sigma_{\text{avg}}=\frac{0.804}{\sqrt{225}}=0.0536$. The discrepancy between the hypothetical universe mean and the observed sample mean is $11.72-11.60=0.12$, which in terms of σ_{avg} is $\frac{0.12}{0.0536}=2.24$ standard deviations. From the cumulative curve of Figure 5 the probability of exceeding a deviation of 2.24 standard deviations is about 0.0125. We take this as the probability that the unknown true average in the shipment could lie below 11.60 pounds.

5.32 Approximate Product Combinations

In the formation of products the characterizing *moments* rather than the semi-invariants (which are so powerful in linear combinations) are found to be particularly useful. From equations 14 we can immediately write the moments of the product distribution (for discrete variates) as

$$\begin{aligned}\mu_i' &= \Sigma\Sigma\ldots\Sigma z^i p_r p_s\ldots p_t\\ &= \Sigma\Sigma\ldots\Sigma(rs\ldots t)^i p_r p_s\ldots p_t\end{aligned}$$

Since we are dealing with independent variates, this last expression may be rewritten as

$$\mu_i'=\Sigma r^i p_r \Sigma s^i p_s\ldots\Sigma t^i p_t$$

which in moment notation is

$$\mu_i'=\mu_{i_r}'\cdot\mu_{i_s}'\ldots\mu_{i_t}' \tag{37}$$

The same relationship can as readily be developed using continuous variates with integral signs replacing the summation signs. We conclude that *the ith moment about zero of the product is equal to the product of the individual ith moments about zero of the components.*

From equation 37 expressions showing the relationship between the parameters of the resultant and of the components are easily written. We find

$$\bar{z}=\mu_1'=\bar{r}\bar{s}\ldots\bar{t} \tag{38}$$

$$\sigma_z^2=[(\sigma_r^2+\bar{r}^2)(\sigma_s^2+\bar{s}^2)\ldots(\sigma^2+\bar{t}^2)]-(\bar{r}\bar{s}\ldots\bar{t})^2 \tag{39}$$

The values of the "higher" parameters can more readily be found in any specific case by numerical substitution in the basic equation 37, except perhaps in the case of just two variates.

Just as it was found that a linear combination of n independent variates tended toward the normal form as n increases, it may be shown by an analogous reasoning that the *product* of n independent variates tends toward the log-normal form. The log-normal distribution is a positively skewed unimodal curve whose lower limit is zero and upper limit is infinite and whose logarithms form a normal distribution. The chief restriction to this general conclusion on the trend of product distributions is that no one of the components should have the ratio of its standard deviation to its mean value very much larger than all of the other components' standard deviation-to-mean ratios.

5.33 Approximate Quotient Combinations

The problem of determining the parameters of a quotient distribution, given the corresponding parameters of the components, is complicated by the fact that values of the divisor variate must not ordinarily be permitted to occur at zero with any except a negligible likelihood. Approximate solutions must usually then be guarded by various restrictions regarding the distribution s in the quotient equation of relation $z=\frac{r}{s}$. If, however, we have a quotient distribution of the form $z=\frac{r+\bar{r}}{s+\bar{s}}$ in which $\bar{s}$ is several times the standard deviation of s, a satisfactory parameter solution can usually be found.

The most obvious, and oftentimes the easiest, procedure is to transform the equation of relation from a quotient type to the product type by merely changing the distribution of the variable in the denominator to its reciprocal's distribution. That is, if the equation of relation is given as $z=\frac{r}{s}$, then by setting $s=\frac{1}{w}$ we obtain $z=rw$ which is now a product of two independent variates. The subsequent analysis can then be handled as described in section 5.32 by taking products of the corresponding moments of r and w. Thus

$$\mu_i'{}_{z(=r/s)}=\mu_{i_r}'\cdot\mu_i'{}_{w(=1/s)}$$

This procedure will work in all cases to give the true moments of the final quotient distribution $F(z)$, except where the form of the w distribution is such that the moments cannot readily be determined. Even then a practical solution can sometimes be found, as suggested by Karl Pearson, by tabulating the reciprocals of the observations if the information on s is given in this form, and then calculating the moments of the reciprocal distribution. Likewise if the analytical expression for the probability distribution of the s variate is given, and this defies handling, the area under the probability curve may be divided into an appropriate number of class intervals, the area (observations) in each determined, and the procedure just outlined then carried through.

Fieller has given an exact expression for the distribution of $F(z)$ when the two variates r and s are normal. It is quite complex and for most engineering problems would be highly laborious to calcu-

late. If the normal divisor variate s has a mean such that $\bar{s} \geqq 3\sigma_s$, then Geary has found that although z itself is not normal, a second variable dependent on z which we will call t *is* nearly normal. The variable t corresponding to any selected z is found from

$$t=\frac{\bar{s}z-\bar{r}}{\sqrt{\sigma_r^2+\sigma_s^2z^2}}$$

Then

$$F(z_1<z<z_2)\approx\frac{1}{\sqrt{2\pi}}\int_{t_1}^{t_2} e^{-\frac{t^2}{2}}dt$$

in which the value of the definite integral is readily read from a normal probability table or from the cumulative normal curve on Figure 5.

Craig and others have studied the general quotient problem and have established relationships between the final distribution's semi-invariants and those of the r and s components. If r and s are substantially normal and uncorrelated, and the s values occur with negligible likelihood at $s=0$, that is $\bar{s}>hs$ where h is say 5 or more, the quotient semi-invariants are given approximately by

$$\left.\begin{aligned}
L_1&=\mu_{1z}'=\bar{z}\approx\frac{\bar{r}}{\bar{s}}\left[1+\left(\frac{\sigma_s}{\bar{s}}\right)^2+3\left(\frac{\sigma_s}{\bar{s}}\right)^4+15\left(\frac{\sigma_s}{\bar{s}}\right)^6\right]\\
L_2&=\mu_{2z}=\sigma_z^2\approx\left(\frac{\bar{r}}{\bar{s}}\right)^2\left[\left(\frac{\sigma_s}{\bar{s}}\right)^2+8\left(\frac{\sigma_s}{\bar{s}}\right)^4+69\left(\frac{\sigma_s}{\bar{s}}\right)^6\right]+\left[\left(\frac{\sigma_r}{\bar{s}}\right)^2+3\left(\frac{\sigma_s}{\bar{s}}\right)^2\left(\frac{\sigma_r}{\bar{s}}\right)^2+15\left(\frac{\sigma_s}{\bar{s}}\right)^4\left(\frac{\sigma_r}{\bar{s}}\right)^2\right]\\
L_3&=\mu_{3z}\approx\left(\frac{\bar{r}}{\bar{s}}\right)^3\left[6\left(\frac{\sigma_s}{\bar{s}}\right)^4+116\left(\frac{\sigma_s}{\bar{s}}\right)^6\right]+3\left(\frac{\bar{r}}{\bar{s}}\right)\left[2\left(\frac{\sigma_s}{\bar{s}}\right)^2\left(\frac{\sigma_r}{\bar{r}}\right)^2+24\left(\frac{\sigma_s}{\bar{s}}\right)^4\left(\frac{\sigma_r}{\bar{s}}\right)^2\right]\\
L_4&=\mu_{4z}-3\mu_{2z}^2\approx72\left(\frac{\bar{r}}{\bar{s}}\right)^4\left(\frac{\sigma_s}{\bar{s}}\right)^6+84\left(\frac{\bar{r}}{\bar{s}}\right)^2\left(\frac{\sigma_s}{\bar{s}}\right)^4\left(\frac{\sigma_r}{\bar{s}}\right)^2+12\left(\frac{\sigma_s}{\bar{s}}\right)^2\left(\frac{\sigma_r}{\bar{s}}\right)^4
\end{aligned}\right\}\quad(40)$$

Naturally, the further either of the two component distributions deviates from the conditions stated above under which these equations have been derived, the more approximate they become.

Summary of Fundamentals

Probability or Frequency Curve Description of Variates

1. The majority of the essential information contained in a batch of data taken on a variate x can be summarized in a small number of statistical constants or parameters called the mean $\bar{x}$, standard deviation σ_x, skewness k_x, and kurtosis β_{2x}. These parameters are usually found by calculating the moments (or the semi-invariants) either of the observations or of the theoretical distribution describing the variate x.

Laws of Combining Simple Probabilities

2. When two events are mutually exclusive, the probability of one or the other occurring is the sum of their individual probabilities of occurrence.

3. When two events are independent the probability of their joint occurrence is the product of their individual probabilities of occurrence.

Combining Variates With Mutually Exclusive Probabilities

4. The parameters of the distribution z composed h proportion of the time by variate r, j proportion of the time by variate s, . . . , are given by

$$\bar{z}=h\bar{r}+j\bar{s}+\ldots$$

$$\sigma_z=[h(\sigma_r^2+\bar{r}^2)+j(\sigma_s^2+\bar{s}^2)+\ldots-\bar{z}^2]^{1/2}$$

$$k_z=\frac{1}{\sigma_z^3}[h(k_r\sigma_r^3+3\sigma_r^2\bar{r}+\bar{r}^3)+j(k_s\sigma_s^3+3\sigma_s^2\bar{s}+\bar{s}^3)+\ldots-(3\sigma_z^2\bar{z}+\bar{z}^3)]$$

$$\beta_{2z}=\frac{1}{\sigma_z^4}[h(\beta_{2r}\sigma_r^4+4k_r\sigma_r^3\bar{r}+6\sigma_r^2\bar{r}^2+\bar{r}^4)+j(\beta_{2s}\sigma_s^4+4k_s^3\bar{s}+6\sigma_s^2\bar{s}^2+\bar{s}^4)+\ldots-(4k_z\sigma_z^3\bar{z}+6\sigma_z^2\bar{z}^2+\bar{z}^4)]$$

Combining Independent Variates According to the Equation of Relation, $z = \xi(r, s, t\ldots)$

5. The total probability of $F(z)$ is found from $F(z)=\text{\$}p_rp_sp_t\ldots$ or $F(z)dz=\text{\$}\theta(r)dr\times\phi(s)ds\psi(t)dt$ . . . in which \$ means the summation of the probability products for all possible ways of forming z according to the equation of relation.

6. $F(z)$ may sometimes be evaluated most conveniently for particular problems by a step-by-step method of combining probabilities.

7. If the probability distributions for the variates are known analytically, it is often possible to perform the $F(z)$ summations, obtaining an exact analytical expression for $F(z)$. Results typical of this method are:

(*a*). The sum of two Poisson variates is a third Poisson variate whose average equals the sum of its components' averages.

(*b*). The sum (or difference) of two normal variates has likewise a normal distribution whose mean equals the sum (or difference) of the means of the components, and whose standard deviation equals the square root of the sum of the squares of the components' standard deviations.

(*c*). The product of a square-topped and a simple type III Pearson variate yields the form

$$F(z)=\frac{c}{h-g}\left[e^{-\frac{cz}{h}}-e^{-\frac{cz}{g}}\right]$$

(*d*). The quotient of two generalized exponential (Pearson type III) variates has the form

$$F(z)=c^{n+1}q^{m+1}\frac{\Gamma(m+n+2)}{\Gamma(n+1)\Gamma(m+1)}\times\frac{z^n}{(cz+q)^{m+n+2}}$$

8. Approximate distributions of the resultant variate can be constructed if its parameters can be found. These can be expressed in terms of the components' parameters as follows:

(*a*). *Linear Equations of Relation.* $z=a+bx+cy+\ldots+dt$

$$\bar{z}=a+b\bar{x}+c\bar{y}+\ldots+d\bar{t}$$

$$\sigma_z=\sqrt{b^2\sigma_x^2+c^2\sigma_y^2+\ldots+d^2\sigma_t^2}$$

Expressions for k_z and β_{2z} are given by equations 30 and 31. From these we conclude that the sum of a large number of independent variates, no one of which has a predominant variation, tends rapidly toward the normal form with the parameters $\bar{z}$ and σ_z just given. Likewise, the standard deviation of the means of successive samples of size n is $1/\sqrt{n}$ times the standard deviation of the universe.

(*b*). *Product Combinations.* The mean and standard deviation of the product of variates r, s, . . . t, is given by

$$\bar{z}=\bar{r}\bar{s}\ldots\bar{t}$$

$$\sigma_z^2=[(\sigma_r^2+\bar{r}^2)(\sigma_s^2+\bar{s}^2)\ldots(\sigma_t^2+\bar{t}^2)]-(\bar{r}\bar{s}\ldots\bar{t})^2$$

As the number of variates combined according to a product equation of relation increases, the resultant tends toward the log-normal form.

(*c*). *Quotient Distributions.* No rigorous method exists for obtaining the parameters of the quotient distribution in terms of the components' parameters. A number of estimates involving certain restrictions are given in section 5.33.

Series Capacitors for Transmission Circuits

E. C. STARR
FELLOW AIEE

R. D. EVANS
FELLOW AIEE

Synopsis: This paper presents the results of an analytical and experimental investigation of the use of series capacitors to increase the permissible loadings of long high-voltage a-c transmission lines. Because of limitations imposed by synchronous stability and reactive kilovolt-ampere requirements, conventional lines, when extended to the higher voltages and greater lengths, cannot be loaded to values of power sufficiently high to develop maximum over-all economy. It is shown that, when suitably applied, series capacitors will make possible the desired optimum loadings and will very materially reduce transmission costs.

The theoretical possibilities of using series capacitors to compensate the excessive inductive reactance of long lines have received consideration for many years. Practical series capacitors require protective equipment, but shunting of the capacitors in the earlier schemes resulted in a decrease instead of an increase in the transient-stability limits.

The authors propose series capacitors of the limited-voltage type in combination with auxiliary equipment which not only protects the insulation but quickly restores the capacitors to the circuit after the faulted conductors are isolated, thus preventing a decrease in system power limit at the time of need. The application requirements of necessary apparatus are also briefly outlined.

Results of analytical studies and miniature-system tests in connection with a typical application of series capacitors to one of the major lines of a typical transmission system are included. This work deals with relative transmission costs, transient stability, spontaneous hunting, and the subsynchronous operation in the induction starting of machines. The conclusion is reached that the proposed series-capacitor scheme appears practicable for long transmission lines.

Paper 42-112, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 10, 1942; made available for printing May 18, 1942.

The authors acknowledge the assistance of A. C. Monteith and C. F. Wagner with the general problem, and of R. E. Marbury with capacitor design and protection, of J. D. Pierce for conducting the miniature-system tests, and of E. J. Harrington, H. M. Smith, and J. D. Curtin for analytical calculations.

THE necessity for long-distance transmission of large blocks of power has grown rapidly during the last few years. Some of the large-scale hydroelectric developments in the western states are located in relatively remote districts and have given rise to transmission problems involving distances of the order of 250 miles and blocks of power of the order of 300,000 kw. Proposed developments in other locations involve similar or longer transmission distances and equal or greater blocks of power. The three most important considerations in each of these major power developments are:

1. The conservation and most effective utilization of important natural resources.

2. The delivery of large blocks of power to natural load centers at minimum annual costs. With all factors given due consideration, these costs should not exceed those of other available power sources.

3. The delivery of large blocks of power to natural load centers with a high degree of reliability.

Due to basic circuit considerations, as transmission distances are increased, the voltages indicated become progressively higher, and the line costs increase at an accelerated rate. For the longer distances, power-limit or stability considerations, together with load and line reactive-kilovolt-ampere requirements, cause the unit power costs to rise rapidly. A basic analysis of the fundamental circuit properties involved indicates that, although a number of methods can be employed to improve the operating characteristics of long transmission circuits, the most promising expedient at the present time is line-reactance compensation by means of series capacitors. In the following sections, the theory and application of these devices as they relate to the costs and performance of major transmission circuits will be discussed in their essential details.

Modified Basic Analysis of Transmission Problem

Reduced to its fundamental elements, an a-c transmission line and its associated transformers constitute a connecting link of finite impedance between a generating station and its load, or between two electric systems. It has been shown that the power delivered over a circuit containing lumped impedance Z of angle θ, with voltages E_s and E_r maintained at the sending and receiving ends respectively, when these voltages are separated in phase position by the angle δ, is expressed by the following equation:

$$P_r=\frac{E_sE_r}{Z}[\cos(\delta-\theta)]-\frac{E_r}{E_s}\cos\theta] \qquad (1)$$

Resistance effects are ordinarily small in practical transmission circuits, and a close approach to the actual performance, when a reasonable stability margin is allowed, can be obtained by neglecting resistance in the preceding equation. The result is the simple expression as follows:

$$P_r=\frac{E_sE_r}{X}\sin\delta \qquad (2)$$

The power transfer is then a function of the product of the sending and receiving voltages, is a function of the angular displacement between these voltages, and is an inverse function of the circuit equivalent reactance interposed between the above voltages.

Control of Circuit Impedance

The most convenient and economic voltage of generation is approximately

13.8 kv. Similarly, the best voltage for primary distribution in moderately heavy load areas and also for large individual loads is approximately 13.8 kv. If a transmission circuit must be employed between the generating station and load center, the above two voltages referred to a common base and maintained by regulating devices, are the quantities appearing as E_s and E_r in the preceding equations. The equivalent reactance X of the transmission circuit between the generating and receiving busses then determines in a large measure the amount of power than can be transmitted over this circuit.

If overhead transmission circuits are employed, the reactance of the conductors themselves will approach 0.8 ohm per mile at 60 cycles for any practical conductor and for all types of construction. It is evident that, as the transmission distance increases, the circuit reactance increases rapidly, and the power transmitting ability may thereby be reduced below the required value. Resistance effects, as controlled by conductor size, can be reduced from values giving transmission losses of the order of 15 per cent to practically zero without materially altering the power limit, although they do have a definite influence on the economic problem.

An approximate expression for maximum power, assuming 13.8 kv for sending and receiving voltages, and assuming 35 degrees between these voltages to allow for the reactance of terminal equipment and margin in stability, is as follows:

$$P_{rm} = \frac{110}{X}\,10^3\,\text{kw} \qquad (3)$$

The maximum power capacity is thus an inverse function of the equivalent reactance between the 13.8-kv generating and load busses of the transmission circuit.

If overhead line construction is to be retained, four different alternatives are available for reducing this equivalent reactance to the required value. These are:

1. Line-impedance conversion.
2. Multiple-circuit operation.
3. Reduction of system frequency.
4. Line-reactance compensation.

These items will be discussed in the indicated order in the following paragraphs.

High-Voltage Operation

For the reduction of equivalent series impedance, the first and most commonly employed expedient is impedance con-

version which is accomplished by transformation to higher voltage. The well-known relationship between the high-side and the low-side equivalent impedance of a transformer, namely, that the equivalent low-side impedance of the high-side circuit is equal to the actual impedance of the high-side circuit divided by turn ratio squared, makes it possible to reduce the equivalent impedance between the low-voltage busses to a marked degree.

As an example of the effectiveness of a high-voltage transformation in reducing the equivalent impedance of a circuit, it can be observed that the reactance of an overhead line 100 miles long is approximately 80 ohms at 60 cycles. If line resistance were totally absent, if infinite busses were available at each end of the line, and if voltages of 13.8 kv were maintained at the terminals, the maximum synchronous capacity of the circuit would be approximately only 2,390 kw. A ten-to-one transformation on each end of the line, resulting in a line voltage of 138-kv, neglecting the reactance introduced by the transformers, would reduce the circuit reactance as it affects the low-voltage busses to 0.01 × 80 ohms or 0.80 ohm. This change, neglecting transformer impedances and line resistance and assuming infinite terminating busses, would result in a synchronous power limit 100 times that obtained originally, or 239,000 kw.

This particular expedient, namely, raising the line voltage by transformation to reduce the equivalent impedance between generator and load busses, has been followed to the practical exclusion of all other methods available for reducing this impedance. Voltages as high as 287.5 kv have been employed in gaining this end, and it will be observed that the equivalent impedance of a line of that voltage referred to a 13.8-kv bus is approximately 0.0023 times the actual line impedance.

It is evident that the only essential purpose of going to high transmission voltages is to reduce the equivalent impedance between the low-voltage busses at the terminals of the circuit. This one benefit, together with reduced equivalent surge impedance, which has been shown to be essential to the transfer of large blocks of power at high efficiencies, can be gained through high-voltage operation only at considerable expense. When voltages are increased, transmission structures become larger, conductor diameters, separations, and clearances become necessarily greater, and line insulation becomes more costly. Transformer and other high-voltage substation equipment costs increase much more rapidly than the voltages in the higher ranges, and transformer reactances, which add directly to the reactances of other elements of the circuit, increase more rapidly than the voltage rating.

Conductor diameters and desirable cross-sectionable areas are thrown so far out of balance at the higher voltages by corona loss, permissible line efficiencies, and mechanical considerations that, considering the necessarily great investment in the high-voltage system, electrical loadings approaching the values required to develop maximum transmission economies cannot be attained in the longer high-voltage lines. Most of the existing long, high-voltage circuits, because of stability limitations and reactive-kilovolt-amperes requirements, cannot be loaded to values exceeding approximately 50 to 75 per cent of the magnitude required to develop minimum annual costs per kilowatt transmitted. As an example of this limitation, it can be observed that the ratio of line loading for maximum economy to line loading for maximum power established by stability is approximately 2.5 in the case of a typical two-circuit 230-kv line somewhat less than 250 miles long and equipped with a mid-point sectionalizing station and normal low-reactance terminals. Even greater discrepancies exist in other more costly circuits of comparable length.

From the preceding discussion it is apparent that the expedient of ever

higher transmission voltages, which are employed only for the purpose of reducing the equivalent system reactances, has reached and perhaps passed its justifiable limit until other steps are taken to strike a better balance among all factors concerned. The line-charging kilovolt-amperes of long high-voltage circuits is useful in most cases but detrimental in some. In those cases for which it is of benefit, it is obtained at relatively high cost.

It seems evident then that serious consideration should be given to other available means for decreasing the equivalent reactance between generator and load busses where long-distance transmission is necessary, and for increasing the electrical loading of these circuits to their points of maximum economy.

Multiple Circuits

The use of two or more transmission circuits in multiple results in a proportional decrease in the system transfer impedance, and when terminal ratings are increased in proportion, results in a similar increase in power capacity. Considerable improvement in operating characteristics and transient-stability limits can be obtained when such multiple circuits are sectionalized at one or more points proportionally distributed throughout their length. Individual line sections on which faults have occurred can then be isolated in only a few cycles after the initiation of the fault with a minimum of increase in total circuit reactance. The costs of multiple circuits with sectionalizing facilities go up in approximate proportion to the power capacities and consequently little is gained toward improving the economic loading status of long high-voltage circuits.

Reduction of System Frequency

Since inductive reactance is a direct function of frequency, the loading of simple systems with given transformation ratios should, over the narrow practical range available, attain synchronous limits in approximate inverse proportion to the frequency employed. This expedient as a supplement to high-voltage transformation, or impedance conversion, has been employed in a number of foreign countries. However, because of the relatively small over-all benefit to be obtained, due to incandescent-lamp flicker at the lower frequencies, increased size and cost of induction equipment, and the necessity for numerous frequency changers, this method of gaining low reactance is not advisable and is being looked upon with disfavor in some localities where it is now practiced. The stability problem may not be avoided unless a considerable part of the load can be utilized at the transmission frequency.

D-C Operation

If the frequency is reduced to zero, that is, if direct current at high voltage is employed, power transfer is accomplished by difference of magnitude between terminal voltages instead of by difference between angular positions. It can be shown that the basic gain for direct current, when the same maximum insulation stresses are allowed, is produced by the 41 per cent higher effective voltage. This results in twice the power delivered over a given circuit having the same conductors and insulation and permitting the same transmission efficiency. Further advantages, however, are indicated. No synchronous stability limitations exist, and, if adequate terminal equipment can be made available, lines can be loaded to their economic limits. Moderately long a-c lines have synchronous load limits approximating their surge-impedance values. The economic limit employing direct current with the same conductors and insulation, in the average case, is approximately three times the a-c limit. If lines as long as 500 miles are required, this ratio would become larger than four. If it becomes necessary to transmit large blocks of power to points as remote as 500 miles, the d-c system will be particularly attractive. In that case the large saving in line costs over a-c requirements would make available very considerable sums for the necessary d-c terminal equipment. If this equipment can be made available at a figure that will increase the total terminal cost to a value approximately two times present a-c terminal cost, 500-mile transmission of large blocks of power can be made as economically feasible as some of the present systems of much shorter lengths. D-c transmission is not suited for supplying power to the intervening area, as there is no d-c equivalent for the a-c transformer. The major problem hinges upon the successful development of adequate terminal equipment.

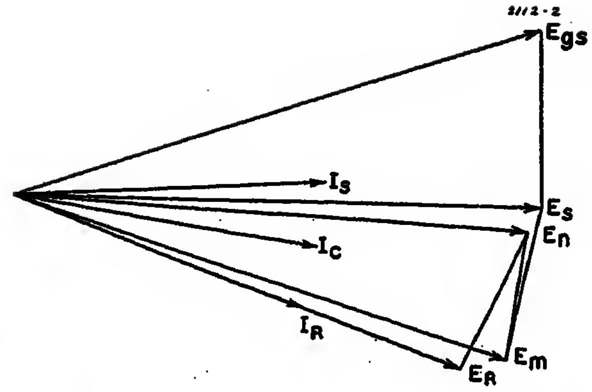

Figure 2. Vector diagram for series-capacitor transmission system shown in Figure 1

Line-Reactance Compensation

The most important alternative or supplement to high-voltage transformation for reducing the equivalent impedance between generator and load low-voltage busses is the use of line-reactance compensation. Such compensation can best be obtained through the use of static capacitors operating in series with the

transmission line conductors. After considering all these methods in the light of recent developments, it was concluded that line-reactance compensation deserved a special study, the results of which have led to the series-capacitor scheme described in the next section.

Proposed Series-Capacitor Scheme

The general arrangement proposed for using series capacitors for the compensation of the inductive series reactance of transmission circuits is shown schematically in Figure 1. This figure shows a protected or limited-voltage type of series capacitor located in a common-bus connection in a two-circuit line. The proposed arrangement would increase the permissible transmission-circuit loading, which is normally based on the system riding through a double line-to-ground fault and the subsequent circuit-isolating operation. Such an arrangement with series capacitors can be used to increase by 50 per cent or more the rating of the circuit, assuming that generating and receiving equipment are increased in proportion. Previous series-capacitor schemes actually reduce transient stability limits,[3] because they lack the quick restoration feature of the present proposal. Vector diagrams for a particular load condition on the system of Figure 1 are given in Figure 2 which shows the large negative phase-angle shift introduced by the series capacitor.

The series-capacitor system, just described, is based on an analysis of factors which include: the type of capacitor, whether of nonlimited- or limited-voltage design; location of the capacitor in the circuit, whether in the individual lines or in a common-bus connection; the method of using the capacitor, whether

1. Normally in the circuit, shunted during the fault and restored after fault isolation.
2. Normally not in the circuit but switched into the circuit after the fault is isolated.

The factors also include the application problems of single-circuit and multiple-circuit lines.

Types of Capacitors

When systems with series capacitors are subjected to faults, high-voltage drops across the capacitors are produced by the increased line currents, and measures against overvoltage must be provided. Two types of capacitors may be used:

1. The nonlimited-voltage type in which sufficient insulation is provided in the capacitor to meet the fault condition.
2. The limited-voltage type which has insulation sufficient for all normal-circuit conditions and protective equipment to limit the excess voltages.

The nonlimited-voltage type of series capacitor has the desirable feature of always being available to provide reactive compensation, even during system faults. Unfortunately, the cost of the nonlimited-voltage type of capacitor is prohibitive, at least in comparison with the limited-voltage type. This results from the fact that, when high-speed fault clearing is employed, the capacitor cost is determined principally by the maximum voltage condition and the capacitive reactance desired at 60 cycles.

The limited-voltage scheme uses

1. Capacitors that are much smaller and less expensive than those of the nonlimited type.
2. Protective equipment that not only limits overvoltages by providing a shunting path of negligible or low impedance but also opens this path promptly upon fault removal, incidentally reducing fault currents to the noncompensated value during the shunting operation.

Protective apparatus and the basis for selecting capacitor voltage ratings cannot be discussed here because of space limitations. Tests, however, have shown that suitable protective apparatus can be built. In the studies of system performance to determine the application requirements of series capacitors for transmission circuits, it is assumed that the protective equipment

1. Limits voltage on the first half cycle of overvoltage.
2. Restores series capacitor to the circuit within two cycles after the fault is isolated.

Location in the Circuit

Series capacitors can be located at any point in a single-circuit line, but preferably near the reactance center of the system, as this limits the duty on the capacitor protective equipment, reduces the voltages to ground, and minimizes the problems of exciting inrush currents. For multiple-circuit lines the series capacitor can be located in the individual line sections or in the common-bus connection, as shown in Figure 1. Multiple-circuit lines are normally laid out so that the circuit load can be carried with one line section out of service. For such conditions there is a decided advantage in using the series capacitor in a common-bus connection not only because the capacitor kilovolt-amperes is not reduced by the switching out of a line section, but also because fewer units are required. Several series capacitors may be used, but there is little advantage in using more than the number of intermediate switching stations.

Switching Arrangements for Series Capacitors

The condition of highest circuit reactance in a multiple-circuit line occurs as a result of switching operations that isolate a line section. Series capacitance may be required for the condition of highest circuit reactance but may not be needed for the normal condition with all lines in service. Hence, series capacitance can be used in two ways:

1. Series capacitor normally in the circuit, shunted for the fault condition, and quickly restored to the circuit after fault isolation.
2. Series capacitor not normally in the circuit, but switched into the circuit after a line section is switched out of service.

A combination of these arrangements so as to vary the amount of capacitance compensation according to the load or circuit arrangement is also possible. Both of these arrangements can be used with the layout of Figure 1. However, in the second arrangement the control equipment should be similar to that for the first arrangement in order to meet the condition for a second fault in the remaining sections of the two parallel lines. The choice between these arrangements depends upon the relative advantages from the stability standpoint in starting from a condition of lower or higher system angle, as discussed in the section on stability.

Amount of Compensation

Stability and economic conditions control the amount of capacitive reactance to be used in any particular case. Assuming that generating and receiving systems are adjusted in proportion to the load transmitted, and that equal margins of stability are to be obtained, the relative stability limits can be estimated approximately from the inverse ratio of the 60-cycle transient reactances of lines including the series capacitor. Table I lists for several circuit arrangements and amounts of capacitance compensation the relative power limits calculated for the lines including capacitors but not terminal equipment. The amount of compensation is the ratio in per cent of the capacitive reactance to the total reactance with all line sections in service. The tabulated power limits are for one line section out of the circuit and are compared to that of a two-circuit line with one intermediate station but without series capacitors. Table I shows that,

neglecting resistance, 67 per cent capacitive-reactance compensation is required with a two-line system and one intermediate station to give the same power limit as a system with three lines and one intermediate station and no series capacitors, assuming in both cases a transient disturbance requiring the isolation of a faulted line section. Similarly, considering the same two-circuit line carrying a given load, Table I shows for the same system and for the same stability margin that 50 per cent capacitance compensation is required for a 50 per cent increase in power limit.

Power-System Stability With Series Capacitors

Series capacitors increase the stability limits of systems by reducing the series or transfer reactance between internal voltages of machines, and thereby increasing the synchronizing power. Thus, series capacitors increase both the steady-state and transient stability of systems. Usually the transient-stability limits are well below the steady-state limits, so that a considerable increase in the former is possible before the latter condition becomes controlling. Nevertheless, it is desirable when considering series capacitors to investigate steady-state as well as transient limits.

The stability problem with series-capacitor systems can be viewed in the same manner as that of other systems by considering only the 60-cycle reactances of the circuit. It is, of course, necessary to take into account the changes in circuit reactance produced by the inclusion of the series capacitors in the circuit, and for the shunting of the capacitors during the fault and possibly for a brief interval thereafter.

A physical picture of the system phenomena during a fault and the resulting transient can be obtained from Figure 3. The system is assumed to consist of a hydroelectric generator feeding through a series-capacitor transmission system to an infinite bus, subjected to a fault at the point F which is cleared by the isolation of the faulted line section. The circuit is assumed to be without loss so that the power-angle diagrams are simple sine curves. Parts of four power-angle curves are plotted for the four conditions that arise as a result of the application of a fault and the subsequent circuit-isolating operation. These include:

1. The initial condition with all lines and series capacitors in service, curve I.

2. Condition 1 plus the application of the fault and the shunting of the series capacitors, curve II.

3. Normal condition but with one line section and series capacitor out of service, curve III.

4. The system normal with series capacitors in circuit but with one line section out of service, curve IV.

Consider the system of Figure 3 to be operating at the load and angle corresponding to the point a on curve I. Upon the application of the fault, the output of the generator drops to the point b on curve II. The difference in power ab accelerates the generator and increases the angle by which it leads the receiver. At the point c the fault is to be isolated by the action of high-spread breakers and relays, thus changing the operating point to e on curve III. Power corresponding to de decelerates the generator, but because of the accumulated velocity it swings forward along curve III. At the point h the series capacitor is restored to the circuit by the opening of the shunting path in the protective equipment, and operation proceeds from the point g on curve IV. Because the energy stored during the accelerating period has not been completely absorbed, the system continues to swing forward ultimately reaching point k, such that the decelerating area [area $(edih)$ + area $(gijk)$] equals the accelerating area $(abcd)$. The system is stable for the conditions shown and will oscillate about the point o and ultimately come to rest at that point. The system would be unstable for the conditions shown unless the series capacitors were restored to the circuit promptly after the isolation of the faulted line section.

If series capacitors of the nonlimited-voltage type are used, the curves of Figure 3 still apply; but upon the isolation of the fault at point c, the operating point changes instantly to the point f on curve IV. In this case the total area under the power-angle curve available for deceleration is increased by the area $(efgh)$. There is, therefore, some advantage in reducing the interval required for the restoration of the series capacitor to the circuit after the fault has been removed.

Examination of Figure 3 shows the great importance of using high-speed breakers and relays for circuit isolation when series capacitors are used. The duration of the fault is of greater importance than the duration of the period in which the series capacitor is shunted by protective equipment. Fortunately, high-speed breakers and relays operating in four to six cycles are available. When these are used, the energy of acceleration is greatly reduced and is easily offset by relatively small increases in the power-angle curve above the transmitted load.

The power-angle curve II of Figure 3 is based on faults of the low-resistance type. If the system faults are of the high-resistance type, such as may occur on lines without ground wires, the resultant load on the generating station may be greater than the normal output. Under such conditions radically different transient conditions obtain, as illustrated in Figure 4a. For this case, upon the application of the fault the output of the generator immediately increases from a' to b' on curve IIa. The power corresponding to $a'b'$ decelerates the generator and reduces the angle by which it leads the receiver. At the point c' the faulted line section is cleared, and, assuming self-clearing protective equipment, the operation point changes at once to point f' on curve IV corresponding to the final circuit condition, with the series capacitor in the circuit, but with one line section out of service. Under this condition the power corresponding to f' produces a large accelerating action. However, the system, because of the accumulated velocity, continues to swing back and ultimately reaches the point

k' such that the accelerating area ($d'f'k'j'$) equals the decelerating area ($a'b'c'd'$). The power system now swings forward with increasing velocity corresponding to the accelerating area ($k'oj'$). For the power-angle relations shown in Figure 4a, the decelerating area (*omn*) is insufficient to absorb the resultant transient and instability results.

In connection with Figure 4a, it is pertinent to consider the condition that results if all or part of the series capacitor were not introduced into the circuit until after the faulted line section is cleared. This would result in a higher circuit reactance for the initial condition and a larger initial angle at the beginning of the transient disturbance. A little consideration will show that starting with a larger initial angle, say at the point *o*, the system will swing back through an angle slightly greater than before, but the maximum point reached on the backward swing will occur at an angle larger than that corresponding to the point k'. Consequently, the system will swing through a small angle, and for the conditions shown in the figure stable operation will obtain. Thus for some system conditions there is a gain from the stability standpoint in starting from a relatively large initial angle and switching the capacitors into the circuit only when they are needed because of the switching out of a line section.

For a different case shown in Figure 4b, the presence of a large series capacitor in the circuit initially is disadvantageous. The fault is assumed to be of very short duration, and the capacitance compensation to be quite large for the initial condition. Assuming again that the protective equipment is of the self-clearing type, the transition is made at once from the fault condition of curve II to the final circuit condition of curve IV. For the case without capacitors initially in the circuit and the transient starting from the point *a*, the accelerating area is *abcd*, and the area available for deceleration is *demn*. For the case with capacitance normally in the circuit and the transient starting from a smaller initial angle at a', the accelerating area is $a'b'c'e'o$, and the area available for deceleration is *omn*. A comparison of these two cases shows that the system is more stable when starting from the larger initial angle; that is, from the circuit condition with the higher circuit reactance or smaller capacitance compensation.

The conditions illustrated in Figures 4a and 4b have been introduced to show the various factors involved in the problem. However, if appreciable angular swing occurs during the fault so that the transition to the final circuit condition occurs in the vicinity of the point *o*, then there is usually an advantage in having the series capacitor in the circuit for the initial as well as the final circuit condition. This result will vary with the number of tie points in the system and the amount of change in circuit reactance. For the usual case, however, there is sufficient movement of the machines on the system to justify the inclusion of the series capacitor normally in the circuit.

Reclosing Breakers

The advantage of reclosing breakers for improving system stability can be increased by the use of series capacitors in combination. This results from the fact that the power limit for the normal circuit conditions is large in comparison with the power limit with a line section out of service. This is illustrated by the large decelerating area under curve I in Figure 3, as compared with curve IV.

Single-Circuit Lines

Series capacitors can be used on single-circuit lines to increase the power limits, substantially in inverse proportion to the change in 60-cycle reactances. Such power systems are normally laid out to withstand disturbances that result from the loss of any transmission-line section, such as may result from the dropping of a line conductor. Accordingly, such systems are normally designed for operation close to the steady-state stability limit with the knowledge that faults on the circuit will normally result in circuit outage. Series capacitors can be used on such single-circuit lines to increase the stability limit, both for steady-state conditions and for transient disturbances resulting from faults on other line sections.

Single-pole switching with quick reclosing[2] is being used to improve the performance of single-circuit lines, particularly tie lines, from the standpoint of single line-to-ground faults. If series capacitors are added to such systems they will increase the power limit for the initial and final circuit conditions and on sound phases during fault condition. Such systems with series capacitors are, of course, subject to the limitations of other single-pole switching systems. Thus the length of line section must be limited or other measures used for insuring suppression of the arc to the faulted conductor when isolated at both ends. The system layout must be such that the time permissible from the stability standpoint is long enough to permit the reclosing cycle.

Special Application Problems

Actual transmission systems differ in a number of respects from the simplified conventional systems which have been considered hitherto in the discussion of the stability problem. For example, the preceding discussion has been based on

Table II. Characteristics of Motor-Generator Sets

Rating / Damper Winding / Reactance (Per Unit)	Motor Generator1 100 Kva—Copper	Motor Generator2 100 Kva—None

T_{do}'	1.20	1.20
Inertia Constant H Kw-Sec per Kva	8.60	2.68

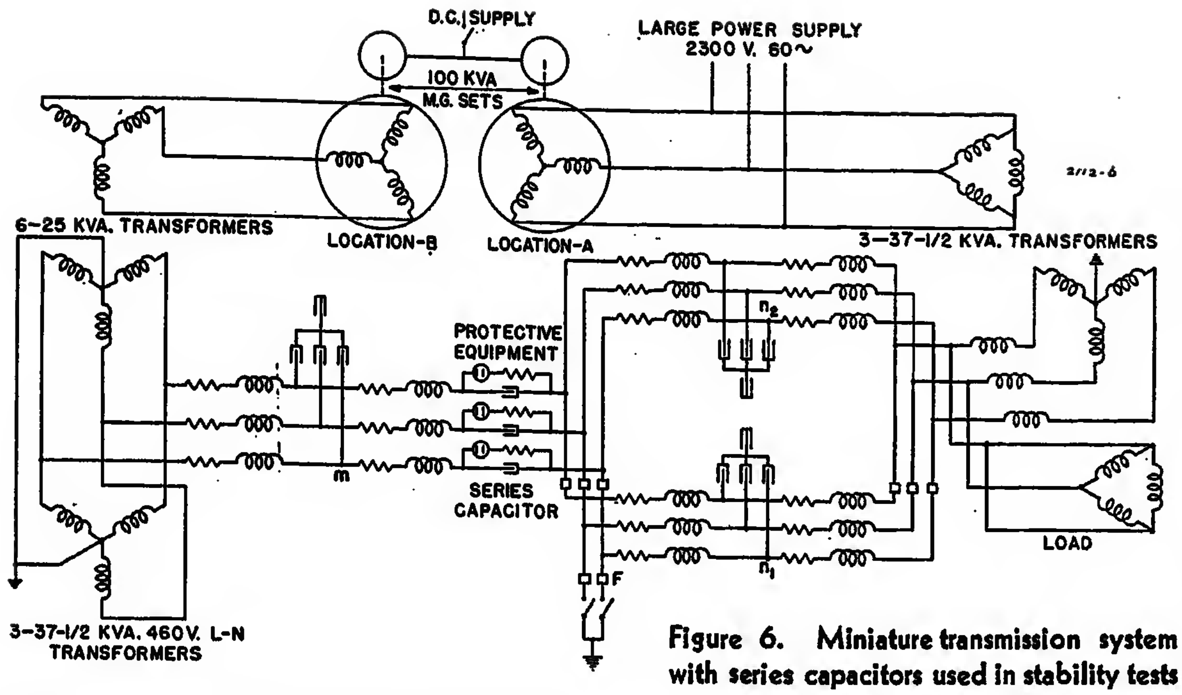

Figure 6. Miniature transmission system with series capacitors used in stability tests—simplified schematic diagram

resistanceless circuits supplied by hydrogenerators feeding into an infinite bus. The actual system includes loss and the receiver includes a shunt load with local generators also feeding into it. For the investigation of stability and similar problems, such as spontaneous hunting and subsynchronous operation in the induction starting of machines, it is advantageous to consider a typical transmission system suitable for series-capacitor application.

Typical Transmission System for Series-Capacitor Application

In order to develop further the characteristics of series-capacitor systems, a typical transmission circuit in a system undergoing considerable expansion was selected for theoretical analysis and subsequently for miniature-system tests. For these purposes simplified layouts approximating certain stages of the transmission development were selected. The principal features of these are shown schematically in Figure 5. In these layouts the output of two or three Station I generators is assumed to be transmitted over two or three 220-kv circuits for a distance of 234 miles. Three particular layouts selected for study are:

Figure 5a—Two 220-kv circuits.
Three 108 megavolt-ampere generators.
With series capacitors.

Figure 5b—Two 220-kv circuits.
Two 108 megavolt-ampere generators.
No series capacitors.

Figure 5c—Three 220-kv circuits.
Three 108 megavolt-ampere generators.
No series capacitors.

Miniature-System Tests

To complement the analytical work, miniature-system tests were made in the Westinghouse stability laboratory in order to examine further the operating characteristics of a system with series capacitors. The miniature-system tests included:

1. Stability.
2. Spontaneous hunting.
3. Subsynchronous effects in the induction starting of induction motors or synchronous machines.

The layout shown schematically in Figure 6 was used for the miniature-system stability tests. Two motor-generator sets, designated as M-G 1 and M-G 2, were used in set locations *A* and *B* respectively. These sets are identical, except for inertia and damper windings, and the characteristics affected by these features are given in Table II. Dampers are of the connected type in open slots.

The miniature-transmission system was adjusted to have circuit constants corresponding to the layout of Figure 5a, choosing for the generator the direct-axis transient reactance, X_d'. These constants and the miniature-system voltages were chosen so as to load the generator to the same proportion of its rating as the generators of the actual transmission system. The excitation for the generator was controlled by an exciter-rheostatic voltage regulator maintaining constant voltage on the transmission line. The receiver system was represented by transformers and impedance to the power supply corresponding to the transient reactance of the Station II generators and transformers, and by a shunt-impedance load.

Table III. Stability Limits of Various Systems for Double Line-to-Ground Fault

Layout	Series Capacitor	Station I Generator (Megavolt-Amperes)	220-Kv Lines	Miniature-System Stability Limit (Kw)
Figure 5a	61 per cent	324	2	104
Figure 5a	42 per cent	324	2	94
Figure 5b	None	216	2	61
Figure 5c	None	324	3	113

The series capacitors were connected between the two busses at the intermediate sectionalizing station. Tests were made principally with capacitive-reactance values of 61 per cent and 42 per cent of the total inductive reactance for two lines for both sections, although in a few hunting tests still other values were used. Each capacitor was provided with shunt protective gaps which included a low resistance in series to limit the discharge current through the protectors. A special self-clearing type of protective gap was used.

The layout to simulate the system of Figure 5b was obtained by correspondingly increasing the impedance of the generators, transformers, and loads in the ratio of 3 to 2. The layout corresponding to Figure 5c was obtained by reducing in the ratio of 3 to 2 the impedances of the series branches of the

two-lines section between Station 1 and the intermediate station and halving the series impedance of the unfaulted line section between the intermediate station and the receiver.

The stability tests were run by adjusting the system to deliver the desired amount of power under specified voltage conditions. A fault was applied to one transmission line section by means of the fault breaker. Faults were of the zero impedance, double line-to-ground type. The results of the stability tests are given in Table III.

Figure 7 shows an oscillogram for a stable condition corresponding to Figure 5a. The oscillogram shows a double line-to-ground fault of about seven cycles duration. Both protective gaps functioned during the fault condition and at the end of the fault were self-clearing. It will be noted that the voltages across the capacitors were limited by protective-gap breakdown during each half-cycle.

Observations with the aid of a stroboscopic device on the relative phase relation of the rotor of the set in the B location to the voltage of the power supply at receiver showed that the stability limits occurred for the three layouts of Figures 5a, 5b, and 5c at about the same phase displacements. The three systems, however, delivered different amounts of power for the same phase angle, the amounts of power being approximately in inverse proportion to the total 60-cycle transfer reactance between internal voltages.

Results of the tests given in Table III correspond to faults applied only at the intermediate station in the section between it and the receiver. This location required operation of protective gaps on the series capacitor, a circumstance unfavorable to the series-capacitor system in comparison with the layouts without series capacitors. The two sections of transmission circuit were interchanged, and the faults were applied at the sending end of the first section. The results of stability tests for this condition gave approximately the same ratio of stability limit for the layouts corresponding to Figures 5a and 5b as for faults at F.

Hunting Tests

Spontaneous hunting of synchronous machines is an infrequently encountered phenomenon on operating power systems.[3,4] Such hunting occurs only on systems having a high ratio of resistance to reactance, and on lightly-loaded machines and on machines which are not equipped with suitable damper windings. The use of series capacitors, by decreasing the effective 60-cycle circuit reactance would be expected to increase the tendency toward spontaneous hunting. For this reason tests were made on the miniature system using machines both with and without damper windings.

The first step in the experimental investigation of hunting was the determination of whether the miniature system of Figure 6 adequately simulated the electromechanical conditions in regard to hunting. The obvious difference between the actual system and the miniature system is in the representation of the prime mover. In the miniature system the prime mover is represented by a motor supplied by another motor-generator set obtaining power from an infinite bus. Tests under conditions for simulating hunting showed that motor-generator set A tended to follow the oscillation of motor-generator set B, introducing a damping action on it. Accordingly, a relatively high resistance was introduced in the supply to the d-c motor of set B. Under this condition, the ratio of power oscillations in output of generator B to motor input was over 50 to 1. This is shown in the oscillogram of Figure 8 by the single-phase watt element recording the output of the generator without dampers and the fluctuation in the direct current to the motor. It will be noted that the power oscillations in the two sets are substantially in quadrature. In order to increase the power output of set B, the voltage of the motor circuit was increased by adding a 250-volt shop supply in series.

A physical explanation for spontaneous hunting has been given by C. F. Wagner.[3] He showed that the tendency toward hunting depends upon the operating point on the power circle diagram of the system, and that the oscillations have positive damping for loads beyond a given value and negative damping for loads less than this value. As stated previously, the tendency toward spontaneous hunting is increased as additional resistance and capacitive reactance are introduced into a circuit. Accordingly, the tests for spontaneous hunting were made with different values of line resistance introduced symmetrically into each equivalent π section and with different values of series capacitance. The tests were carried out so as to determine the critical load at which the tendency toward spontaneous hunting would be encountered. This was done by setting up the system for the desired operating condition and introducing an oscillation produced by a switching operation. The conditions were carefully examined to determine whether the oscillations corresponded to positive or negative damping. By observing the switching oscillations at several different loads it was possible to determine the critical point. Tests were carried out with both the sets, thus giving tests on

1. A generator without dampers
2. A generator with copper dampers

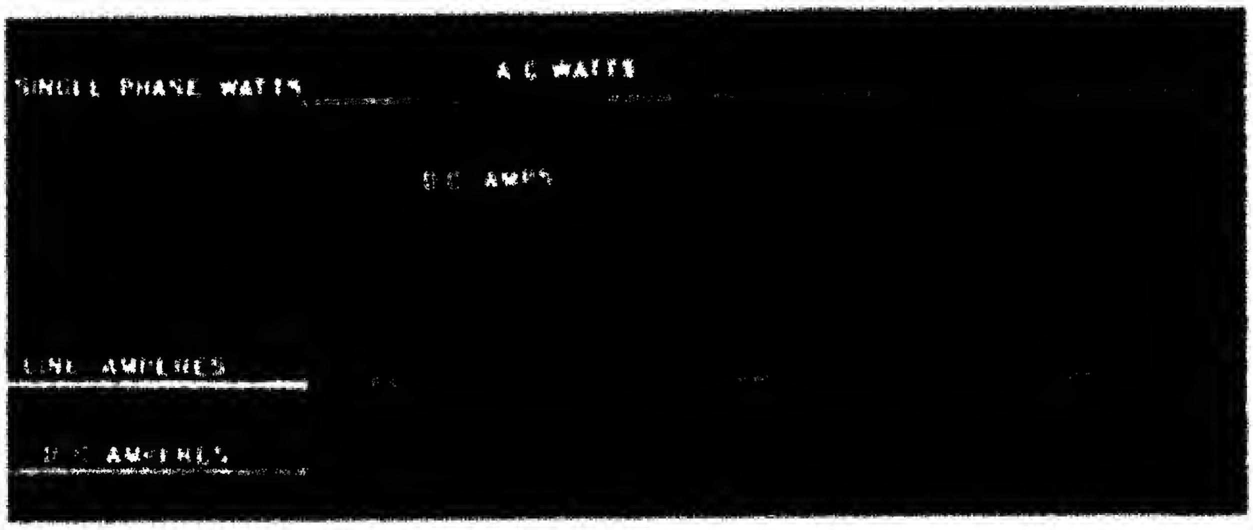

Figure 8. Oscillogram from hunting tests showing the oscillation-damping action of motor-generator set at location A of the miniature-transmission system of Figure 6

The results of the tests on spontaneous hunting are summarized in the curves of Figures 9 and 10. In Figure 9 the conditions in regard to line resistance and amount of series capacitive reactance are plotted in per cent of the normal line reactance for two circuits and two sections, not considering the reduction due to the series capacitor. In these curves the critical load is expressed as a per cent of the transient stability limit for the corresponding case as listed in Table III using the values corresponding to normal line resistance for all cases. Figure 10 gives the same data as Figure 9 but is plotted in terms of the total resistance and total transient reactance at 60 cycles between internal voltages, taking into

X_C—Series-capacitor reactance

P/P_L—Ratio of transmitted power to stability limit

ccount the reactance of the series capacitor. The miniature system using the enerator with dampers when laid out to epresent the layout of the typical transmission system was stable for normal alues of line resistance, even when series apacitors were used of higher reactance nan contemplated for the amount of ower to be transmitted. The miniature ystem using machine without dampers as stable when transmitting a reasonable amount of power in comparison to ie stability limit. Hunting under light ad is not considered important as the pacitors can be switched out of the rcuit because they are not needed under is condition for stability.

A special hunting test was made to ow whether series capacitors affected ie hunting conditions except by changg the 60-cycle reactance of circuit. For is purpose two circuits of equal resistce and equal 60-cycle reactance were mpared using

A circuit with only inductive branches.

A circuit with additional inductive retance offset by equal capacitive reactance.

sing the generator without damper ndings, no hunting was found with the ductive circuit but there was hunting th the series capacitors, although e critical load was only $2^1/_2$ per cent of e transient stability limit.

Since the spontaneous hunting has eived but relatively little attention in ent years, there are little data to show w the damping on a miniature system mpared with that of actual power systns. Accordingly, tests were made on the miniature-system setup for the layout of Figure 5a with a 60 per cent series capacitor, but with the system carrying half load. A line section was switched out of service and then restored, the latter transient being recorded on oscillograms, both for the machine without damper windings and for the machine with copper dampers. For the machine without dampers the natural frequency was 43 cycles, while for the machine with copper dampers the natural frequency was 80 cycles. The oscillations for these cases were reduced by about 7 and 30 per cent respectively per cycle of electromechanical oscillation. It is proposed that tests be made on the actual power system, and the results compared with those obtained from similar tests on the miniature system.

Induction Starting of Machines

An interesting test was made to simulate the induction starting of induction motors or synchronous machines. This test was made with the layout of Figure 5a with a 60 per cent capacitor but with the load and receiver system disconnected at the end of the second transmission section of Figure 6. A 10 horsepower squirrel-cage induction motor was connected at the receiving end of the transmission system. Under normal voltage conditions the motor started without any difficulty. The generator voltage was reduced to about 20 per cent of normal in order to simulate the starting of an induction motor with a heavy inertia load, and under this condition, the motor operated at a subsynchronous speed. This phenomenon of subsynchronous operation[5] is caused by resonance at a frequency below 60 cycles. At normal voltages on the system the induction motor has sufficient torque to overrun the subsynchronous speed before the torque caused by low-frequency resonance can build up. At low system voltages, the motor acceleration is slower and the torque caused by low-frequency resonance builds up to a higher value. In spite of this the motor accelerated beyond the subsynchronous speed but was unable to reach normal speed and dropped back to the subsynchronous speed. As was expected, a load of high power factor, about 95 per cent, drawing as much current as the accelerating current of the motor was sufficient to avoid operation at a subsynchronous speed and to permit acceleration to normal speed. This peculiar condition is considered of little importance from a practical standpoint, since no normal operating condition is visualized in which the difficulty would be encountered. The nearest approach is the condition of starting up a system with the series capacitor in the circuit followed by the induction starting of a large synchronous condenser at the receiver. Under these conditions diffi-

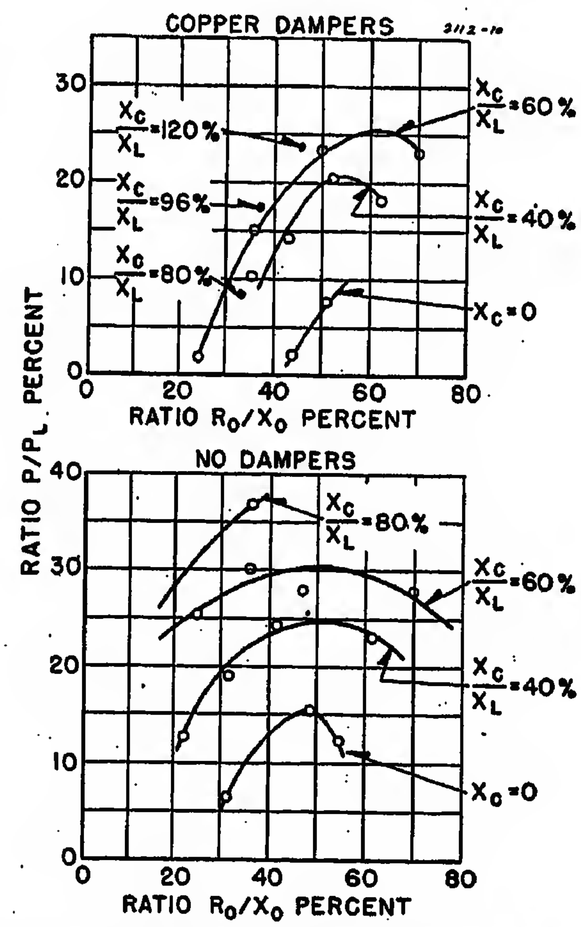

Figure 10. Critical conditions for spontaneous hunting from miniature-system tests—no hunting for points above curves

culty may be encountered in accelerating the condenser to normal speed. The difficulty can, of course, be overcome by switching the capacitor out of service until the condenser is in synchronism. If considerable generating capacity or considerable shunt load is connected in parallel with the condenser, no difficulty in starting is to be expected.

Economic Advantages of Series Capacitors

An example of the substantial economies that can be effected by the judicious use of series compensation in appropriate circuits will now be given. In this example the two-circuit, 230-kv line between the Station I and the Station II developments is assumed to be compensated to bring it more nearly in line with the load capacity required to develop maximum transmission economy. An additional generator at Station I and a corresponding increase in generator and load capacity at the Station II end are assumed. Series capacitors giving $66\frac{2}{3}$ per cent compensation are to be located at the mid-point of the transmission line, as in Figure 5a. This series capacitor will give with three Station I generators and two lines a greater margin of stability than will be obtained for the case of Figure 5b with two Station I generators, two transmission lines, and no series capacitors, and closely the same margin of stability as obtained in the case of Figure 5c with three Station I generators, three transmission lines, and no series capacitors. The calculated results of the economic study are as follows:

Transient stability limit of uncompensated two-circuit line with normal margin (load reduced 20 per cent for same machines)	175,000 kw
Transient stability limit of compensated two-circuit line with proportionally increased terminals with corresponding stability margin	290,000 kw
Line-reactance compensation required on complete two-circuit line base	66.7 per cent
Series capacitor required	108,000 kva total
Series capacitor installed cost at $11.00 per kilovolt-ampere	$1,190,000
Cost of one additional circuit with sectionalizing facilities (based on minimum construction cost)	$4,500,000
Saving in capital outlay through use of series compensation, or 73.5 per cent of cost of third circuit	$3,310,000
Transmission efficiency:	
Three-circuit line, full-load	95.0 per cent
Two-circuit line, compensated, full-load	92.4 per cent
Increased losses, two-circuit line as compared to three-circuit line, all sections operating	8,560 kw at max. load
Incremental loss chargeable to compensated two-circuit line at 85 per cent loss factor (equals approximately 82 per cent load factor)	6,180 kw
Cost of generating incremental loss chargeable to compensated two-circuit line at $125.00 per kilowatt generation cost	$772,000
Incremental short-time synchronous-condenser capacity required by the two-circuit compensated line at full load with one section out over that required by three-circuit line at full load and one section out	42,800 kvar
Incremental cost of synchronous-condenser capacity at $4.00 per reactive kilovolt-ampere (over-load rating)	$171,500
Total cost of compensation, or 47.4 per cent of the cost of the equivalent third circuit	$2,133,500

The above conservative example illustrates clearly the very considerable economy that can be effected by the proper use of series compensation. If high emergency-load capacity is the primary consideration, the aggregate increase in losses is negligible, and the comparison is even more favorable.

In the case of heavy impedance loads, or of lines materially shorter than the one chosen in the above example, the loadings of maximum economy may be attainable without compensation and without giving rise to any synchronous stability problem. In such cases, excessive voltage regulation instead of instability will be the major controlling factor. The circuit loadings will be considerably in excess of the normal surge-impedance values, and series-reactance compensation can be employed to improve the voltage regulation and the power factor at the generator end of the line.

A further study of the particular application, however, may in certain cases disclose that the same kilovolt-ampere rating in shunt capacitors applied to the low-voltage bus at the receiving-end of the transmission circuit would result in slightly better voltage regulation and efficiency conditions than when that capacitor is used as a series device. This difference in favor of shunt application will be particularly evident when the load power factor is near unity or slightly lagging. The application of shunt capacitors in this case results in improved power factor and decreased transformer and line currents with decreased voltage regulation and reactive kilovolt-amperes generated in the line and in the transformer leakage reactance. If such a circuit were operating independently of other systems, and if the load were of a relatively steady character, the shunt application might prove to be the more economic. However, if the load is supplied by a multiple transmission system, or is of fluctuating character, series compensation can result in considerably improved performance over that obtained when the necessary capacitive kilovolt-amperes are used in shunt on the load bus. In such cases the problems require individual analysis to determine the most economic expedient to obtain the desired end, both as regards economy of operation and system performance.

When synchronous stability limitations prevent the most economic loadings, series compensation, up to a certain degree, will in general be found to give better economies than other alternatives. If increased equivalent surge-impedance load ratings are required, the line capacitive susceptance can in effect be increased by shunt capacitors on the low-voltage receiving bus by the same factor that the line equivalent reactance is decreased by series compensation.

Requirements of Series Capacitors and Protective Equipment

Results of the analytical studies and miniature-system tests lead to the following conclusions as to the requirements of series capacitors and their protective equipment.

Series capacitors should be of the limited-voltage type and provided with protective equipment which

1. Operates on the first cycle of overvoltage to limit the voltage stress on the insulation.
2. Restores the capacitor to the circuit in the shortest practical time after the faulted line section is cleared, preferably within not more than two cycles.

Provision will be desired in some cases to switch the capacitor into the circuit only after a line section is switched out of service. Additional protective features

should be provided to prevent sustained high currents which would produce important heating effects. The protective equipment should include means for switching the capacitor into the circuit and out of the circuit as may be desired locally for inspection or repair, or by remote control as may be found advantageous from the standpoint of system operations. A small impedance in the shunting circuit is advantageous in limiting condenser discharge current; in addition, resistance tends to damp transient currents and improve stability.

Conclusions

Analytical studies, including the economic problem, have shown that long high-voltage transmission circuits can be operated at their optimum loadings only when their equivalent impedances, or effective lengths, are reduced by a sizable factor. This reduction in transfer impedance can be accomplished most economically through the use of series compensation. Such applications on appropriate systems would result in considerable over-all economic gains. Although in the shorter lines of lower voltage, independent economic gains may not be possible through the application of series compensation, these circuits can be increased in emergency capacity and electrical stiffness to a marked degree by the application of appropriate reactance compensation.

The analytical work and the miniature-system tests have shown that the stability of transmission systems with series capacitors can be estimated from consideration of the 60-cycle constants of the circuit in the conventional manner. Such estimates or calculations of stability should take into account the decreased circuit impedances that result when series capacitors are in the circuit and also the transient changes that result from the operation of protective equipment.

Transmission systems with series capacitors are not subject to spontaneous hunting, providing machines are equipped with suitable damper windings, or provided the system is not operated at too low a percentage of its normal rating. By observing practical operating restrictions at light load, it is possible to avoid problems of hunting and subsynchronous operation in the induction starting of machines.

The proposed scheme of using series capacitors of the limited-voltage type, in combination with protective equipment that quickly restores the capacitor to the circuit after fault isolation, is viewed as providing attractive possibilities for increasing the permissible and economic loading of long transmission circuits. Series-capacitor schemes have inherent advantages for increasing the permissible short-time loads or for increasing the emergency loads of existing systems. The scheme is viewed as sufficiently promising as to justify a large-scale experimental installation.

Lightning Investigation on 132-Kv Transmission System of the American Gas and Electric Company

Discussion and authors' closure of paper 42-18 by I. W. Gross and G. D. Lippert, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 178–85; previous discussions published in AIEE TRANSACTIONS, 1942, pages 450–3.

R. H. Golde (British Electric and Allied Industries Research Association, London, England): The maximum values of lightning currents which may flow in the various parts of a transmission system are of great interest to all engineers concerned with the protection of overhead lines, and the authors' continued collection and latest presentation of statistical data are a most valuable addition to our knowledge of this subject. In their discussion, however, the authors draw attention to two features in their results which they suggest are in conflict with the present knowledge of surge phenomena and, in particular, that relating to the effective surge impedance of line conductors. The probable explanation of these results is as follows:

Table A gives the maximum voltage values which would be obtained if the maximum line currents plotted in Figure 5 of the authors' paper were multiplied by a surge impedance of 400 ohms. The resulting products, if regarded as voltage surges on the line conductors, are rightly described as fantastic. I should therefore like to suggest that the relatively few high current values given in Figure 5 were actually measured in cases in which a direct stroke occurred to a line conductor somewhere in mid-span with immediate flashover to earth at the first tower or towers encountered. In this case the short length of line wire between the point struck and the first tower carries practically the whole lightning current, but as its length is small compared with the equivalent length of the front of the average lightning current, it is misleading to attribute to it any surge-impedance value. The discharge phenomenon is simply that of a charged condenser—the lightning channel—discharging to earth through a short path with its inherent capacitance and inductance values, the conditions being very different from those obtaining for a long line conductor. The resulting surge voltages which are propagated along the line would then be given by the line currents measured beyond the region where discharge to earth takes place multiplied by the correct surge impedance of the line.

The second point which, according to the authors, "requires some further study or interpretation" concerns the line surge impedance values derived in Table II. These values are much too small to be explained by any known effect, including that of corona. Now it appears that the current and voltage values quoted in Table II were measured when discharge of the arresters protecting the stations in question took place. Under these conditions reflection phenomena invalidate the calculation of the line surge impedance as the quotient of the bus voltage and line current. An accurate calculation could be carried out only if the discharge characteristic of the arrester, the shape of the incident surge, and the distance between the recording points and the discharging arrester were known. If, in the absence of these data, it be assumed, as a first approximation, that the measured line currents and bus voltages reach their crest values at the same instant and that the incident surge has a very short front and long tail, then

$$E=e\frac{2R}{Z+R}$$

and

$$I=i\frac{2Z}{Z+R}$$

where

E = busbar voltage
e = voltage of incident surge
I = resulting line current during operation of arrester
i = current of incident surge
Z = line surge impedance
R = equivalent discharge resistance of arrester

Since e/i is equal to Z, it follows that the quotient E/I is independent of the line surge impedance and is in fact equal to the equivalent discharge resistance of the arrester at the instant when both bus voltage and line current reach their maximum. The resistance values quoted in Table II are quite reasonable if thus explained, and there is no need to invoke any change in the accepted value for the line surge impedance.

There are several items on which further comments might be made but only the most important may be mentioned. Returning to Figure 5, it has been indicated that the highest current values recorded are probably not line currents in the sense of surges which are propagated along the line. Assuming that currents of the order of 3,000 amperes are the highest which can travel along the line conductors without causing flashover, it is seen from the two curves in Figure 5 that some 75 per cent and 90 per cent respectively of the currents recorded fall within that range. These currents may therefore be due to cases of back flashover, though it would also be interesting to get the authors' information as to the maximum possible earth fault currents on these systems, since it may be feasible to explain at least some results by normal frequency earth fault currents following a flashover at one or more towers. It follows that Figure 5 consists of two parts, that is, effects of direct strokes to line wires and cases of back flashover, which are not strictly comparable.

The beneficial effect of bonding the tower legs below the ground surface is convincingly shown by the currents discharged through these connections. The authors regard this effect to be due to "an even, uniform, and quick distribution of current to the various tower structural members." It is difficult to see why the lowest cross members of lattice towers should not be equally effective, and I should suggest that the effect described is primarily due to these additional connections acting as earth electrodes.

The good result to be obtained by the use of long earthing tubes, particularly in soil with a top layer of high resistivity, has long been recognized by practical experience. The authors' current measurements provide, therefore, interesting direct confirmation. On the other hand, the meager effect of a ten-foot tube (Table III, case 2), installed as shown in Figure 2, is hardly surprising, since this tube which is placed between tower legs of equal length to itself cannot be expected to contribute materially to the combined earthing resistance of the tower. It would be interesting if the authors could install some earthing tubes at the ends of the 40-foot counterpoise wires and determine the current distribution for that case.

I. W. Gross and G. D. Lippert: The discussion of the paper by Mr. Golde is most welcome, and we are gratified to note that the data are helpful in furthering the study of lightning phenomenon. Some of the items discussed by Mr. Golde have been previously discussed by Mr. Hagenguth and others and have been commented upon by the authors. Further comment on these items by the authors at this time does not appear necessary.

The surge crest ammeter links on the line conductors were so adjusted and calibrated that the maximum possible 60-cycle fault currents (in the order of 2,500 amperes) would not materially affect the results.

The beneficial effect of bonding the four tower legs together below ground is apparently not obtained by the diagonal bracing of the tower above ground. Lightning-current measurements (not reported in the paper) made on four leg towers above the point of connection of the first lattice braces indicated the lightning current was concentrated in the two legs directly connected to the counterpoise where the underground bonding was not in use.

The 10-foot ground rods reported in the paper were not installed with any expectancy of obtaining an appreciable decrease in the over-all tower-footing resistance. These short rods were installed for the sole purpose of studying their performance in combination with longer rods. It was believed that the effect of these short rods would be largely obscured by the longer rods and the 250-foot counterpoise connections, and the observed results to date have indicated that this is precisely what happens.

Rectifier Terminology and Circuit Analysis

Discussion and authors' closure of paper 42-83 by C. H. Willis and C. C. Herskind, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section, pages 496–9.

I. K. Dortort (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): A uniform system of terminology for the circuit

elements of rectifier systems is highly desirable, and any attempt to bring some order out of the present confusion deserves everyone's co-operation. To that end, it is suggested that we retain certain terms of the present terminology.

The greatest disagreement probably exists concerning the terms half-wave, full-wave and single-phase rectifiers. The true single-phase rectifier is recognized as a half-wave rectifier by all. It is nothing more than a simple check valve seldom used in power circuits. If we dispose of it by giving it some such name as "simple half-wave" or "valve," the problem of naming the other types of circuits is very much simplified. We could then go back to the terms half-wave and full-wave rectifiers, terms which are generally acceptable and understood by the majority of people using rectifiers. The terms would apply strictly to the conductively connected transformer windings or circuit elements.

The terms suggested by the authors are similar to the German "one-way" and "full-way" connections. Hermann in *Elektrotechnische Zeitschrift*, December 1938, does not indicate that the use of these terms has improved the situation in Europe over our own.

It is believed that it would be better to remove the full-wave or "double-way" rectifier from under the heading of "simple rectifier." The full-wave rectifier partakes of the properties of both the "multiple" and "cascade" rectifiers in that the d-c voltages are added, but the ripple voltages do not coincide, producing a ripple of higher order. This applies quite generally to any cascaded half-wave or full-wave rectifiers whose phases do not coincide.

More thought should be given to the problem of properly naming rectifying devices or valves which may be used for purposes other than rectification. They may perform the function of inversion, frequency changing, commutation for "commutatorless motors." The function of inversion and rectification may be embodied in one device. In all of the functions listed here the rectifiers act as commutators. Some years ago Brown Boveri adopted the generic term of "mutator."

An easily evaluated factor providing a common denominator for a large number of rectifier circuits will certainly prove useful. To a very limited extent, the percentage reactance of the transformer has been used that way in the past. The reactance factor given in the paper can be readily modified to make it universally applicable at least to the commonly known and used power rectifier circuits.

The commutating reactance is the total lumped reactance between two anodes which undergo commutation, divided by two. In other words, it is the reactance attributed to each anode in a balanced system. This quantity is called x_c in the paper. In the same way we can call the commutating voltage, E_c, one-half the voltage appearing between the two anodes. This is, of course, the anode to neutral voltage, $E_s \times \sin(\pi/p)$. The peak value of the current which would flow in a short circuit between these two anodes is, $(\sqrt{2}E_c)/X_c$. Let us call this value I_c'. The shape of the anode current during commutation is a segment of a sine wave of this amplitude.

The ratio $(I_cX_c)/(\sqrt{2}E_c)$, where I_c is the total direct current to be commutated by an anode, is akin to the so-called percentage reactance of the transformer and might be called the per unit reactance drop. Actually it is equal to I_c/I_c' and could also be called the per unit load based on the peak short-circuit current.

If one uses $(I_cX_c)/(\sqrt{2}E_c)$ as the reactance factor and calls it F_x for convenience, the equation for the overlap becomes $\cos(u + oc) = \cos\alpha - F_x$. This relationship holds for any number of phases.

Another interesting property of this modified reactance factor can be demonstrated very easily. The theoretical no-load voltage of the rectifier is $\dfrac{\left(\sqrt{2}E_s \sin\frac{\pi}{p}\right)}{\frac{\pi}{p}}$. This can be converted to or derived directly[1] from Goodhue's relationship to $\dfrac{\sqrt{2}E_c}{\frac{\pi}{p}}$. The drop in voltage on the d-c side due to reactance is $\dfrac{I_cX_d}{\frac{2\pi}{p}}$ as shown in the paper. The per unit d-c voltage drop is therefore $\frac{1}{2}[(I_cX_c)/(\sqrt{2}E_c)]$ or $\frac{1}{2}F_x$, regardless of the number of phases or the types of windings! And this ratio holds true whether it is a half-wave or full-wave rectifier! Should the need ever arise, this relationship can be applied to unsymmetrical circuits by readily means of Goodhue's rectifier calculus.

The curves given for the a-c current harmonics and d-c voltage ripple harmonics apply only to a restricted number of systems. Since F_x is a common parameter for more systems than $(I_cX_c)/E_s$, curves plotted against F_x should have more general application.

1. Self-Regulated Compound Rectifiers, W. Melvin Goodhue and R. Burton Power. AIEE Transactions, volume 55, 1936, pages 1200–5.

C. H. Willis and C. C. Herskind: The modification of the reactance factor as suggested by Mr. Dortort so as to make it universally applicable to the different types of rectifier circuits has been considered by the authors. Such modification would be desirable if it provides the simplest and most convenient procedure for describing and calculating rectifier characteristics. However, a careful consideration of the number and form of the characteristic curves required to describe the more commonly used rectifier circuits and a study of the procedures involved in the use of these curves by the rectifier designer, indicate that the reactance factor as defined in the paper has a number of advantages over the other definitions which are possible.

If the reactance factor is defined by the quantity I_cX_c/E_s, a complete set of curve sheets will be required for each type of circuit, classifying the circuits in accordance with the value of P. While the angle of overlap can be shown on a single curve sheet for all types of circuits, if the reactance factor is defined by the full third term of the overlap equation, most of the other characteristics such as overlap factor, power factor, harmonic voltages and currents, interphase transformer voltage, and so forth, have values which are functions of both the angle of overlap and the number of phases P. Therefore, these characteristics require different curve sheets for the different values of P, regardless of the manner in which the reactance factor is defined. Furthermore, the reactance factor I_cX_c/E_s represents the simplest form in which the essential factors may be combined in a single quantity and should be easiest to use.

Thermal Co-ordination of Motors, Control, and Their Branch Circuits on Power Supplies of 600 Volts and Less

Discussion of paper 42-79 by B. W. Jones, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section, pages 483–7.

Jerome J. Taylor (The Detroit Edison Company, Detroit, Mich.): The approach to the subject of generalized protection of motors and lines is interesting and direct; the subject is a live one now, because many people do not realize how explosive a low-voltage fault can be when source capacity is large. In the latter respect ordinary cartridge fuses, properly constructed and installed, are remarkable both as to current-interrupting and current-limiting capabilities, with the result that in many cases they will clear the circuit with no disturbance whatever, regardless of prospective short-circuit current. This is somewhat more than can be said for most breakers in spite of the comparatively high cost of other types. The combination of such fuses with overload relays of the type described in the paper, appears to give complete protection to the equipment involved, and to the flexible in its application to individual requirements.

Selenium Rectifiers and Their Design

Discussion and author's closure of paper 42-86 by J. E. Yarmack, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section, pages 488–95.

C. G. Howard (Fansteel Metallurgical Corporation, North Chicago, Ill.): This paper is timely and one I consider highly beneficial to the members of AIEE engaged in the application or use of rectifiers.

The subject has been very well handled by Mr. Yarmack, who has been associated with the manufacture and application of the selenium rectifier since its introduction in the United States about four years ago.

I have closely followed the application and growth of the selenium rectifier in the electrical industry since its development in Europe about 1932. Having been associated with the manufacture of rectifiers since 1924 for various branches of the railway, electrical, and radio industries, I have been highly interested in basic developments of rectifiers of the electrolytic and dry disc types.

Our company's first application of the selenium rectifier was in the railway signal field, where it has been accepted by a large number of the railroads as a highly reliable means of charging signal batteries, and supplying d-c power for various signal and communication purposes.

Having studied and tested the selenium rectifier for about ten years, I am well acquainted with its characteristics and limits. To my knowledge, the selenium rectifier has been highly satisfactory in field performance wherever properly applied, and service conditions taken into account.

Selenium-rectifier equipment manufactured by our company, incorporating hundreds of thousands of selenium plates, has established field service records which substantiate the performance and life claims made for this rectifier.

I did not attend the meeting at which the paper of Mr. Yarmack was presented, so I am not familiar with any comments which may have been made from the floor regarding the selenium rectifier. I can only say that those who are interested in investigating the true properties and characteristics of the selenium rectifier, will find it to be a very useful development.

E. A. Harty (nonmember; General Electric Company, West Lynn, Mass.): The method used by the author to obtain the constants of the rectifier circuit, as well as those of the rectifier unit, appears very elaborate and less direct than the following procedure:

Inasmuch as the voltage impressed per element is quite definite and cannot be exceeded without danger of breaking down the blocking layer, there is a definite maximum average d-c voltage that can be obtained for each type of circuit at the maximum rated current.

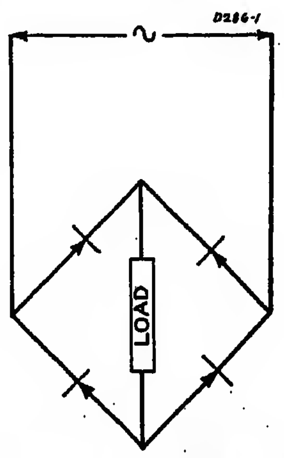

Figure 1. Full-wave single-phase bridge-type circuit

For example, for a single-phase full-wave bridge circuit such as shown in Figure 1 of this discussion, the d-c voltage at full load is 12 volts. Therefore, for every 12 volts required, one cell per leg would be needed.

A family of curves as shown on Figure 2 of this discussion permits estimating the a-c voltage required for each cell per leg, used in the proposed rectifier circuit. Values are shown at different current densities. All that is required is to multiply the readings obtained by the number of series cells used.

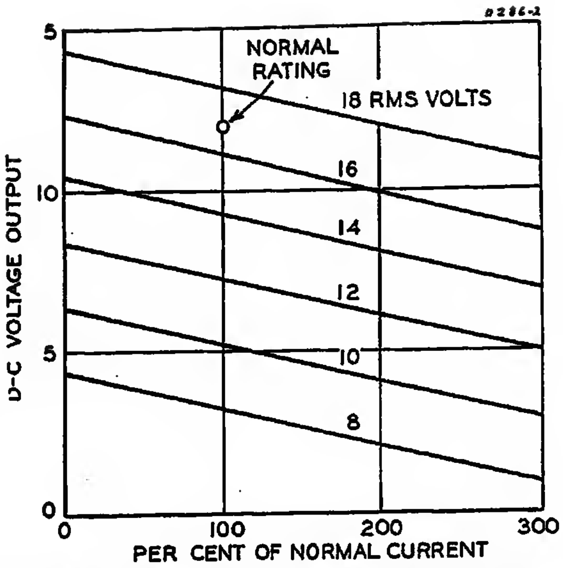

Figure 2. A-c–d-c voltage of unit bridge selenium full-wave rectifier (resistance load)

The author frankly admits that the selenium rectifier ages and that both the output and efficiency decreases with time. However, according to my records based on ten years' experience, the author's "dv" term increases more than 50 per cent. Aging data accumulated from foreign and domestic tests, by the writer, seem to indicate that all selenium rectifiers which were manufactured in Europe previous to 1938 aged very badly if operated at full voltage and that their resistance more than doubled. Typical aging curves are shown in Figure 3. Aging data on units manufactured since 1938 appear to show promise of better aging. Domestic cells are relatively new, and aging data do not exceed two years' duration, and only time will tell how they will age.

Inasmuch as not more than 18 volts rms can be safely applied to selenium elements a family of curves should be given similar to Figure 2, except using cells that have aged fully. To prevent overloading cells, this latter curve should be used for design purposes and not the curves for new elements, as recommended by the author.

Aging in rectifier circuits where the rectifier resistance changes with time can be minimized by making the rectifier resistance a small percentage of the total circuit resistance. Figure 4 shows this graphically. The use of fins, wider spacing, and fans results in making the rectifier resistance a larger portion of the circuit resistance. Assuming that the author's "dv" term, which is a function of the rectifier resistance, changes only 50 per cent by reference to Figure 4, the amount of aging can be anywhere from 5 to 22 per cent depending on whether the rectifier resistance is 10 or 50 per cent of the circuit resistance.

Hence, overrating of selenium rectifiers

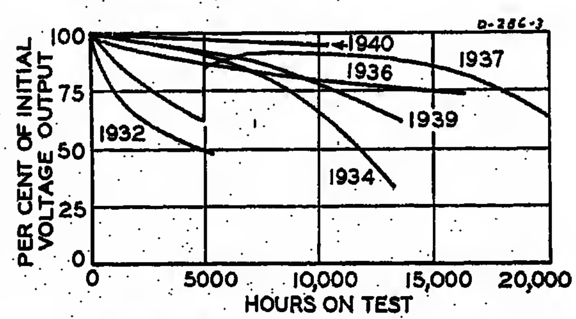

Figure 3. Aging of selenium rectifiers

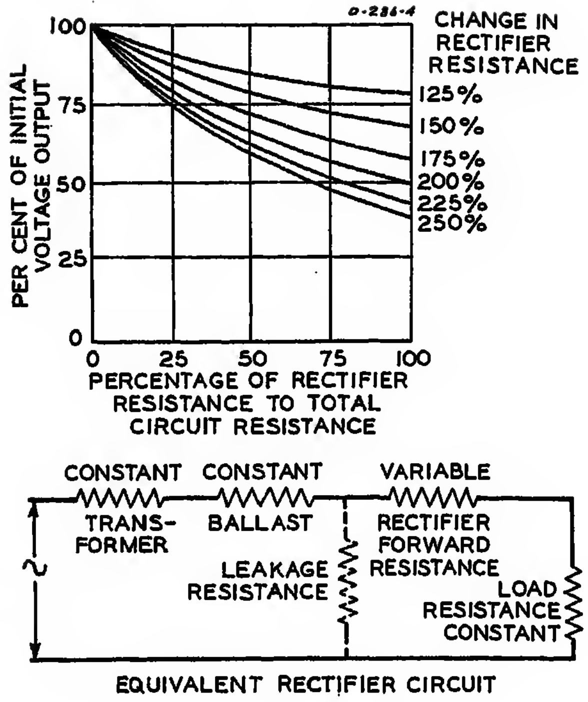

Figure 4

should be watched carefully. D-c voltages should always be derated, to prevent increasing the a-c voltage beyond the safe limits as specified by the manufacturers, which may result in rectifier failures.

John E. Yarmack: Although Mr. Harty's suggested simplified method of design of selenium rectifiers would be useful in some cases, it would not, in the author's opinion, serve the purpose when one deals with a large variety of plates of different assemblies and sizes, and for all possible circuits, kinds of loading and types of service.

As to the aging of selenium rectifiers, the discusser illustrates a marked progress made in the technique of manufacture of selenium rectifiers. The illustrations and comments, however, lack information as to the extent of these tests and the conditions under which they were performed. It is worth reiterating, however, that not voltage per plate, but the current and the ultimate temperature of the plates created by current flowing, is the real factor causing higher or lesser degree of aging of selenium rectifiers.

Reactance and Skin Effect of Concentric Tubular Conductors

Discussion and author's closure of paper 42-78 by H. B. Dwight, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section pages 513–18.

H. W. Bousman (General Electric Company, Schenectady, N. Y.): Those of us who use concentric conductors will welcome this latest contribution to the design of such conductors. Some years ago Professor Dwight taught us to express the resistance ratio of an isolated tube in terms of the square root of the ratio of frequency to resistance per unit length. This parameter has proved to be a great timesaver for the designer who may have to deal with a variety of conductor materials. Even

when copper is used, the parameter is convenient and useful, because it minimizes the computation required to show the effect of temperature on the resistance ratio. Would it be possible to put the resistance ratio of an outer return conductor in terms of this parameter?

Incidentally, there is a relation between the resistance ratio of an outer tube and that of the same tube used as an isolated conductor. The symbols are those of the paper.

$$\left(\frac{R_{ac}}{R_{dc}}\right)_{\substack{\text{as outer}\\ \text{conductor}}}-1=\left[\left(\frac{R_{ac}}{R_{dc}}\right)_{\substack{\text{isolated}\\ \text{tube}}}-1\right]\frac{r}{q}$$

This is a simple slide-rule procedure for design use in determining the resistance of outer tubular conductors from the author's previously published curves for isolated conductors.

H. B. Dwight: In reference to Mr. Bousman's discussion, the curves of Figure 2 may be plotted on mt where

$$m=\sqrt{\left(\frac{8\pi^2 f}{\rho}\right)}$$

as shown in equation 11. The quantity m is a constant, for Figure 2. One may write

$$mt=t\sqrt{\left\{\frac{8\pi f}{R(r^2-q^2)}\right\}} \qquad (1)$$

where R, which equals

$$\frac{\rho}{\pi(r^2-q^2)}$$

is in abohms per centimeter. By multiplying the horizontal readings for each curve in Figure 2 by $\sqrt{r^2-q^2}/t$ times a constant, one can plot the curves on $\sqrt{(f/R)}$, as was done in AIEE TRANSACTIONS, volume 41, 1922, page 189. If desired, curves plotted on mt may be accompanied by the equation

$$mt=0.0277\sqrt{\left\{\frac{tf}{R(d-t)}\right\}} \qquad (2)$$

as was done in the *General Electric Review*, April 1930, page 250, R being in ohms per 1,000 feet. Where the tubular conductors are stranded, it is undoubtedly preferable to use R, the resistance of the conductor for some assigned length, rather than ρ the resistivity.

All of the curve sheets based on R require a slide-rule operation before reading from the curves, but Figure 2 requires no slide-rule work, for solid copper tubes, unless one is using a different frequency or resistivity.

For a frequency f, multiply the tube thickness by $\sqrt{f/60}$ before reading from the curves, as stated after equation 29 in the paper.

For resistivity ρ_1, multiply the tube thickness by $\sqrt{\rho/\rho_1}$ before reading from the curves, where ρ is the resistivity of standard annealed copper at 75 degrees centigrade, in the same units as ρ_1. In this way, changes in resistivity caused by the metal used or the temperature, may be allowed for.

The stranding of tubular conductors has often been a source of misunderstanding. Such conductors are really a mixture of metal and air, and ρ_1 for a stranded conductor should be obtained by dividing R, the resistance of the conductor per unit length (one centimeter or one inch), by $\pi(r^2-q^2)$, the gross area of cross section (square centimeters or square inches).

The equation given in Mr. Bousman's discussion should be useful at low frequencies, for the range of Figure 2, that is, for the resistance ratio of the outer tube less than about 3. It can be derived by omitting the later terms of the low-frequency solution, and it can be checked by readings from Figure 2. For instance, for $t=0.9$ inch and $t/d=0.20$,

$$\frac{R_{ac}-R_{dc}}{R_{dc}}\text{ (outer)}\div\frac{R_{ac}-R_{dc}}{R_{dc}}\text{ (isolated)}$$
$$=\frac{1.80}{1.10}=1.64\text{, from Figure 2}$$

or

$$=\frac{r}{q}=\frac{1}{0.6}=1.67$$

by Mr. Bousman's equation.

For frequencies high enough for the later terms of equations 36 and 37 to be discarded, a different result is obtained, namely,

$$\frac{R_{ac}(\text{outer})}{R_{ac}(\text{isolated})}=\frac{r}{q}$$

However, this has no apparent application, for the natural procedure would be to use the high-frequency formulas directly.

Temperature-Aging Tests on Class-A-Insulated Fractional-Horsepower Motor Stators

Discussion of paper 42-82 by J. A. Scott and B. H. Thompson, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section, pages 499–501.

Jerome J. Taylor (Detroit Edison Company, Detroit, Mich.): The paper is a useful addition to the knowledge of class A materials, which (latter) are a large proportion of all insulation now in use. With wartime conditions exerting pressure toward increased loading of equipment, such knowledge is of very great value. Nevertheless, it is to be hoped that eventually a low-cost insulating material can be developed that will operate indefinitely at high temperatures without deteriorating. The temperature-sensitivity of most present insulations, compared to copper and steel, has for years past forced many designs and ratings to be based on this one factor alone. There is now reason to think that the severity of the restriction will soon be eased. When this is accomplished, ratings can be based on other factors such as efficiency, voltage drop, torque, and so forth, which have a more logical relation to performance, and the field will then be open to new and interesting designs.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): The authors are to be congratulated on the practical method of making tests on small motors. As pointed out in the paper, their findings of degrees' increase to half the life is in fair agreement with what has been found for class A insulation used in transformers. If it were practical to make similar tests on transformers, we might find that the results would not check the 8-degree rule, which I have used for several years, as well as Scott and Thompson found, namely, a 10.5-degree, 11-degree rule and, in one case, a 15-degree rule. The reason for wide variations found in the length of life is given in the following statement which appeared in a paper entitled "Emergency Overloading of Air-Cooled Oil-Immersed Power Transformers by Hot-Spot Temperatures" presented at the summer convention:[1]

"The estimated life of a transformer is at best only a rough approximation. The dielectric strength of insulation does not deteriorate until it has become embrittled and cracked. It is possible therefore for a transformer to continue to operate long after the mechanical life of its insulation is well used up unless subjected to excessive mechanical stresses (short circuit, handling, or other mechanical shocks), since its normal stresses are quite low. It does not follow therefore that a transformer will fail when its insulation is embrittled; on the contrary, if severely strained it might fail before the mechanical strength is completely used up."

While no one can claim to predict the exact life of apparatus by any rule, we are making progress. I feel that the authors of this paper have made a very worth-while contribution to this complex problem.

REFERENCE

1. EMERGENCY OVERLOADING OF AIR-COOLED OIL-IMMERSED POWER TRANSFORMERS BY HOT-SPOT TEMPERATURES, V. M. Montsinger, P. M. Ketchum. AIEE TRANSACTIONS, volume 61, 1942, pages 907–16.

High-Voltage Fusing of Transformer Banks

Discussion and authors' closure of paper 42-80 by H. H. Marsh, Jr., and G. B. Dodds, presented at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942, and published in AIEE TRANSACTIONS, 1942, July section, pages 533–5.

Bruce O. Watkins (nonmember, Rural Electrification Administration, St. Louis, Mo.): It is gratifying to see that the authors give consideration to the setting and the type of the protective device on the load side of the transformer bank before deciding on a fuse for the supply side. On Rural Electrification Administration systems it usually is necessary to install as high a rating of device as possible, consistent with short-circuit protection of the transformers on the load side, in order to obtain a sufficient number of co-ordinated overcurrent devices in series for sectionaliz-

ing the rather lengthy lines. Often severe limitations in sectionalizing the system have been imposed by the supplying utilities' requirements for the supply side fuse.

Some operators also do not seem to realize that the time-current characteristics of fuse links of the same rating, but made by different manufacturers, are totally different. It is entirely insufficient to specify the fuse rating, and probably the better method is to define the required time-current characteristic.

It is to be hoped that other utilities will follow this lead, and that the practice of fusing for a specified time full-load transformer rating will soon become obsolete.

H. L. Rawlins (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper is a very welcome one in that it recites the experience and practices with high-voltage fuses. There has been a dearth of information dealing with high-voltage fuses from the operators' viewpoint, and it is hoped that this paper will open the field for further discussions.

The direct comparison between fused stations and unfused stations is very enlightening, and vividly reveals the ability of high-voltage fuses to rapidly clear a fault before serious damage can occur or the fault spread to adjacent apparatus.

The authors have stressed the use of 34.5-kv fuses on a 22-kv system. This practice may have been desirable at one time and no doubt was adopted before the advent of laboratory tested fuses of high interrupting ability. The requirement of the company with which I am associated is that high-voltage fuses must satisfactorily interrupt all values of current from the minimum current that will melt the link to currents in excess of the interrupting rating, with rated voltage across one unit, on circuits having a rapid rise of transient recovery voltage. Many years of satisfactory operating experience with high-voltage fuses meeting this requirement indicate that overvoltage fusing is not justified. Furthermore, certain types of fuses, when of higher-voltage rating than required, may, during interruption, produce voltage surges in excess of the insulation strength of the system.

Of particular interest are the authors' remarks concerning proper maintenance of high-voltage fuses. Such fuses, protecting transformer banks, when properly applied with respect to secondary protective devices, will never blow unless there is a fault within or immediately adjacent to the transformer. It is conceivable that such a fuse could be in service 20 years or more before being called upon to interrupt a fault. It is apparent, therefore, that a definite program for the inspection and maintenance of high-voltage fuses is required, and it would be interesting to know the requirements set up by the Duquesne Light Company.

H. H. Marsh, Jr., and G. B. Dodds: In Mr. Rawlins' comments of this paper he has brought up two points that make further explanation by the authors desirable. The first of these is his question as to our reasons for using $34^1/_2$-kv fuses on a 22-kv system. As Mr. Rawlins surmised, this practice was adopted in the early days when original spacings and construction of fuses and mountings were found to be inadequate, As pointed out in the paper it was found that the higher-voltage rating fuses cured some of the early difficulties.

Since that time the manufacturers have developed and tested their fuses to the point where reliable and satisfactory operation of fuses at their nominal rated voltage is satisfactory. In the meantime, however, we had installed a considerable number of the fuses of a higher-voltage rating, and we have continued that practice in the Schweitzer and Conrad type *D* and *C* fuses, in order to simplify the replacement and the storeroom stock of fuses. In the use of fuses on other voltages and in the use of fuses of other types, where the usage commenced after satisfactory fuses of nominal system voltage rating were available, we have not continued the practice of using overvoltage fuses.

In the second point brought up by Mr. Rawlins in which he called attention to the fact that fuses may be in service for long periods of time and not be called upon to interrupt a fault, he recognizes that it is difficult to test the condition of such fuses and invites information as to what practice is followed on the Duquesne Light Company system.

As the Schweitzer and Conrad liquid-type fuse is the only fuse we have had in use for a sufficiently long period of time to obtain worth-while experience, our comments will be restricted to this type of fuse. Defects that have been located by observations are low liquid, cracks in the glass tube, and discoloration of the liquid. In the event of the first two of these items, the fuse should obviously be replaced. In connection with the discoloration of the liquid, experience must indicate whether this is a normal or abnormal discoloration. Normal discoloration consists of the liquid assuming a slightly brownish tinge but remaining clear, while abnormal discoloration may cause a milky appearance or a precipitate. In some cases of improper sealing, water may have gained access to the liquid.

In regard to other types of fuses, our experience has been limited either to too few a number or too short a period to be of any value in determining whether the fuses are in good operating condition or not. We would welcome advice from the manufacturers of the Schweitzer and Conrad type *SM* and the Westinghouse *BA* fuses as to how we could determine whether such fuses are in satisfactory operating condition.

Sleet Problems on Electrified Railroads

Discussion and author's closure of paper 42-121 by H. F. Brown, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, August section, pages 589–93.

F. E. Snell (Cleveland Railway Company, Cleveland, Ohio): The problem of sleet prevention in the light traction industry came into existence simultaneously with installation of the first trolley wires strung in localities subjected to freezing weather. Because of geographical location, some cities are naturally more liable to sleet storm damage than others which are situated in the more temperate zones. For this reason the methods used in combating sleet may differ greatly in different sections of the country.

During the last 50 years many devices have been used with varying degrees of success for effective removal of sleet from trolley wires. Some of these devices were soon discarded, because the trolley wire was greatly damaged by their use.

The trolley wheel, used extensively on street cars, has an average life of approximately 12,000 miles. In spite of this average life, a single bad sleet storm may wear out many wheels which are almost new. Carbon shoes, used on modern street cars and trackless trolley coaches as current collectors, are critically affected by sleet, and much trouble is experienced under such circumstances.

In addition to trolley wheel and shoe damage, trolley wires may also be damaged to such an extent that several wire failures occur during a prolonged severe storm. Sleet, accompanied by high winds, may cause considerable damage to overhead plant as well as costly service interruptions.

Without doubt, preparedness is the most important ally of a traction company in combating sleet. Some sections of the country are very susceptible to sudden drops in temperature. Should this occur during a rain storm and at a temperature slightly above the freezing point, formation of ice on trolley wires is a logical result. Any operating difficulties which may develop, however, depend not only upon the severity of the storm but also upon the preparedness of a company promptly to remove ice as it forms. Experience proves that street-car or trackless-trolley overhead can be kept operative as long as vehicles can move in the street.

Contrary to popular belief, neither expensive equipment nor an abnormal organization are necessary to keep overhead plant relatively free from ice during a freezing storm. The one important fact is to know what is coming and be prepared for it. When weather changes may be expected, a short-wave radio tuned to pick up aviation weather reports at stated intervals of time is of great assistance. This, accompanied by a check with the local weather bureau, will permit an operator to foresee the possibility of sleet by several hours. If it is raining when the temperature is slightly above 32 degrees, frequent thermometer readings will indicate any change toward the freezing point.

Co-ordination of all available weather information is of great importance. This work is often one of the duties of a trouble dispatcher, or it may be assigned to some other authorized employee who is capable of determining the probable condition of the weather. When ice threatens to damage property and disrupt service, it is his responsibility to notify the proper officials as far in advance as possible.

At such a time service on overhead plant should be increased as much as possible, because the frequent passage of trolley wheels or shoes will prevent minor ice formation. If conditions become worse, carbon shoes should be removed from the vehicle and replaced with old steel shoes which have grooves worn into their faces. The rela-

tively soft carbon has very little cutting effect and is conducive to severe arcing, whereas the action of the steel shoes is much more pronounced. Frequent service on all wire, accompanied by the use of steel shoes on those vehicles normally equipped for shoe operation, will permit satisfactory operation during average storms.

In extremely severe cases "sleet cutters" should be used. Such a cutter may be attached to the standard trolley wheel for street-car operation, but in the case of trolley coaches the sleet shoes should be substituted for steel shoes. A minimum number of coaches should be provided with sleet shoes at first and the number increased, if necessary, dependent upon the severity of the storm.

A severe storm can also be combated by the use of a line truck. The truck should be equipped with two old trolley bases and two trolley poles having rigid harps and sleet-cutting wheels should be available for instant use. When in service the base spring tension should be set to approximately 40 pounds. This excessive force of the wheels against the wires will effectively remove a heavy coating of ice. As soon as a storm subsides or ice ceases to form, all cutting shoes or wheels should be removed immediately, because they are liable to score the wire if used excessively.

Necessary investment in special equipment is surprisingly low and does not require an increased maintenance personnel.

In closing, two facts are of prime importance and they must never be forgotten or overlooked. Know what is coming and be prepared when it arrives. Experience has often proved that it is easier and cheaper to *keep* out of trouble than it is to *get* out of trouble.

D. R. MacLeod (General Electric Company, Erie, Pa.): Sleet storms can cause serious interruptions in service on electrified railroads. Fortunately, the type of sleet storm which causes interference with electric operation is not of frequent occurrence, but, since it is the aim of the railroads and rapid transit systems to maintain their schedules under all conditions, the operators make provision for this type of emergency also.

One of the difficult problems is that of cars and locomotives lying in yards over night with their pantographs down. Ice may form to such a thickness as to prevent the raising of the pantographs. It would be interesting to know what methods are used to insure getting them in service promptly during sleet storms. When the pantograph has been raised, electric methods of heating provide the best-known means of keeping the pantographs free from ice. The equipment required on an a-c locomotive or car is relatively inexpensive and can be installed in the space available at the base of the pantograph. The equipment must be designed to withstand normal and transient voltages on the trolley and should be protected against faults to ground at the pantograph.

Various methods of using load currents to keep trolley wires free from ice are available. Usually these methods are at the expense of regulation, so that low voltages must be tolerated during the emergency. In this paper mention is made of three schemes one of which has been used for some years. The water-box scheme is an emergency method which can be justified on the basis that it requires an inexpensive equipment. The scheme shown in Figure 3 (scheme 1) of the paper is subject to the disadvantage that care must be taken to prevent disastrous overvoltages in case a ground occurs on one of the trolleys to which the 1,000-volt secondary winding of the heating transformer is connected. A ground on the trolleys is equivalent to a short circuit on the heating transformer. A circuit breaker should be provided on the 1,000-volt side and interlocked with the 11,000-volt breaker so that the latter can not open before the 1,000-volt side is cleared. The 1,000-volt winding must be designed to stand 11,000 volts. Another disadvantage of scheme 1 is that it maintains 1,000 volts between trolleys which could not be permitted where there are crossovers between the tracks.

W. J. Clardy (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): It is mentioned in Mr. Brown's paper that the "dancing" of conductors has been observed when no sleet or wind are present. In some instances, such movement occurs during rapid intensity changes in the magnetic fields surrounding the conductors. These sudden alterations set up repulsions and attractions between cables which cause the oscillations. Any quick current build-up or fade-out produced by circuit interruptions incident to sleet on the contact wire or due to other rapid variations in power demand may lead to the phenomena.

The suggested scheme of using 11,000-volt energy passing through a trolley or feeder circuit and a water rheostat to ground, for heating the wire, appears wasteful of power. A current flow of 800 amperes is 8,800 kw at 11,000 volts and unity power factor. This is 8,800 kilowatt-hours per hour. Thus, at one cent per kilowatt-hour, the operating expense is 88 dollars per hour for each trolley or feeder circuit and some 95 per cent of this amount is wasted in resistor losses.

No mention is made of the measures which may be undertaken to avoid difficulties because of sleet or third rails. This is a problem which requires attention on suburban electrifications and urban rapid transit systems. The Chicago, Aurora and Elgin Railroad has a unique device for freeing the third rail of sleet. It consists of a special six-inch shoe which is moved down in contact with the third rail in advance of the collector shoe. Actuation is by means of a four-inch cylinder supplied with air at 100 pounds pressure. The shoe has seven blunt nose teeth which act as cutters. The teeth are set at a 45-degree angle so as to be self-freeing.

Dwight L. Smith (Chicago Rapid Transit Company, Chicago, Ill.): Mr. Brown's excellent paper deals with the prevention and removal of sleet on overhead trolley only and does not cover the subject so far as lines operating on third rail. The Chicago Rapid Transit Company operates almost entirely on top-contact unprotected third rail and faces a potentially serious sleet problem because of this type of construction. It would be desirable to either convert to under contact rail or to protect the present top contact rail, but both structural and equipment clearances are such that the cost of either of these plans would be prohibitive. Most of the third rail on the elevated lines is 80 pounds with a conductivity equivalent to approximately 1,000,000 centimeters of copper and the third rail to be used in the subway is 144 pounds, special section low carbon with a conductivity equivalent to over 2,000,000 centimeters. With such conductivities, it is manifestly impossible to handle the sleet problem by resistance heating as may be done with overhead systems.

The Chicago Rapid Transit Company has solved the problem by the use of mechanical sleet crushers and scrapers on motor cars. These devices are installed on the beam supporting the trolley shoe collector and are normally held from contact with third rail by cams. When their use is necessary, they are lowered to make contact with the top surface of the rail and are forced down by spring pressure of about 150 pounds. The crusher is a cylinder approximately three inches in diameter with helical ridges which rolls and breaks up and crushes the sleet coating. The scraper consists of two hardened steel blades arranged at an angle of about 30 degrees with the line of the trolley rail, which follow the crushers and scrape off the crushed ice. Formerly these devices were used only for sleet removal and the ordinary shoe collector relied on for current collection; later the scraper was connected in parallel with the collecting shoe and thus itself acts as a current collector.

Naturally, considerable arcing occurs because of imperfect contact, but this has been prevented from jumping to grounded portions of the truck by the use of flashboards and cup washers on the bolt ends. When the type of construction makes it possible, the wooden shoe beam is constructed with its top face at about a 45-degree angle in order to prevent sleet and moisture from collecting on a horizontal surface.

With this device it is possible to remove sleet which has accumulated on the third rail, and the operation of a fairly frequent service prevents further accumulation.

At certain critical locations such as on inclines where the sleet tends to flow downgrade and results in a very heavy coating near the bottom of the grade and in yards where cars have been stored during a sleet storm without any movement on the track, special means are used to remove and prevent further accumulation of sleet. The company has developed a sleet paste which consists of a mixture of powdered graphite, an antifreeze vehicle and a small amount of light oil mixed to the consistency of a thin paste. This paste is applied by hand by means of a long-handled brush and disintegrates heavy sleet coatings rapidly and prevents further sleet from adhering to the rail for an appreciable time. No successful means have been found for applying it other than by hand, and the cost of the paste itself and its application has resulted in confining its use only to such critical locations.

By the two means described above, delays due to sleet accumulation on the third rail have been almost entirely eliminated.

H. F. Brown: Mr. Smith's comments relative to sleet removal from third rail are

interesting and timely, in connection with this general subject. This particular phase of the sleet problem was not touched upon in my paper as being outside its immediate scope. The New Haven Railroad does not operate or maintain any third rail, although their locomotives operate into the Grand Central Station over the New York Central tracks, from under running third rail.

Mr. MacLeod touches upon some design difficulties of scheme 1, outlined in the paper. These were recognized but not detailed in the paper, as this scheme was not used.

Mr. Clardy points out the economic disadvantage of the water-box scheme. Such costs as he mentions must be weighed against the possibility of operation by other forms of motive power and against the cost of delays to important passenger trains. His comments regarding conductor movements (dancing) due to sudden alterations in their surrounding field are important in connection with this subject, since this phenomenon has been often noticed on the feeders mentioned in this paper.

Electric Control for Steam Boilers on Diesel-Electric and Straight Electric Locomotives

Discussion and author's closure of paper 42-127 by E. H. Burgess, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942 and published in AIEE TRANSACTIONS, 1942, August section, pages 604–06.

Arthur Bessey Smith (Associated Electric Laboratories, Inc., Chicago, Ill.): This paper is a welcome addition to the literature of electric control, whether for boilers, machines, or other devices.

The necessary brevity of the paper left numerous points open to question, some of which I believe should be added to complete the picture.

1. It seems to be assumed that the heat generated by the burner varies with the speed of the burner motor.

2. As the boiler pressure rises, it seems that the pressure switch *opens* the contacts in the sequence 5-4-3-2-1.

3. It is not clear how the coils of the pilot relay and the solenoid valve are connected to the heavy duty contacts. If wired exactly as shown, when high pressure has opened all of the contacts, current will be cut off both pilot relay and solenoid; thus both will release.

4. Does the pilot-relay contact close at the operation or at the release of the pilot relay? This is involved in the pilot relay interlock during the off period, when the time-delay relay is said to be kept energized, page 604, column 3 of the paper.

5. How is the water level in the drum or equivalent maintained?

6. What is the function of the coil marked "pressure switch?"

7. On page 604, column 2, "boiler is ready to run"—does this mean "ready to raise steam from cold?"

E. H. Burgess: 1. Heat generated by the burner varies with the speed of the burner motor inasmuch as the amount of fuel forced through the burner is proportionate to the burner motor speed.

2. When the pressure switch coil is energized, the contact fingers close in sequence 1-2-3-4-5, which actually provides step starting for the motor. When the steam pressure rises to a predetermined point number 5 finger opens, thereby inserting a definite amount of resistance in series with the motor through the number 5 load relay. As the pressure continues to rise, the balance of contacts open in sequence 4-3-2-1, and after number 1 opens, the motor stops entirely.

3–4. The pilot relay coil and solenoid valve coil are connected to the armature of the number 1 and number 2 load relays and are only energized when either of these load relay contacts are closed, when high pressure causes all the heavy duty relay contacts to open, then both the solenoid valve and pilot relay became de-energized. The contacts of the pilot relay make only when the coil is de-energized, which, as can be seen from the circuit, complete the circuit to the coil of the outfire relay.

5. During the normal operation of the boiler an excessive amount of water is pumped into the coils, which does not turn into steam. This excess water is removed from the steam line in the separator, and the height of water in the separator is controlled by a ball float. The excess water then returns to the storage tank through a heat exchanger.

6. The multifinger pressure switch is of the normally open contact type which, when the coil is energized, slowly closes the contacts in sequence 1-2-3-4-5. Steam pressure exerts pressure against the contacts only and in no way interferes with the operating coil.

7. "When boiler is ready to run," means that all operating and safety devices are set in normal position, such as main line switch closed, all safety switches closed, and ignition switch in the "on" position. The preceding conditions must be met before the boiler will generate steam, regardless of whether it is from a cold start or from a hot boiler that has just been shut down.

Electric Facilities and Operating Plan for the First Chicago Subway

Discussion of paper 42-137 by C. E. De Leuw, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, November section, pages 780–7.

W. J. Clardy (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. De Leuw's interesting paper gives a comprehensive outline of progress in the betterment of urban travel facilities in Chicago. Rapid transit is essential to the prosperity and growth of every large city. Subway and elevated lines serve as means of low-cost and convenient access to shopping and delivery districts. The territory available for residential purposes is increased, and the concentration of workers in homes near offices is avoided.

The expansion of New York, Chicago, Philadelphia, Boston, and Cleveland demonstrates this dependence on quick travel between various sections of cities. During recent years many additions have been made to the subway lines which serve New York. An interesting phase of the development is the replacement of elevated lines in a number of locations. After new subways were completed and operation initiated, the old elevated routes were abandoned and the structures demolished. Thus, street appearance is improved, and property values bettered. The New York system has introduced some novel types of subway streamlined rolling stock. A multisection car, composed of five bodies on six trucks, is in operation which seats 108 passengers and has a total capacity of 712. The weight of this unit is 182,600 pounds. Another articulated car used consists of three bodies on four trucks. There are 84 seats, the total capacity is 318, and the weight 75,540.

Rapid transit in Chicago dates back to 1892. The present elevated lines are functioning remarkably well within their limitations, but the city requires additional facilities to provide for growth and expansion. The new subway will contribute materially in meeting these needs. War conditions are preventing the immediate purchase of new rolling stock for the subway, but reasonably satisfactory operation can be expected from existing steel cars of the Chicago Rapid Transit Company. The delay in the procurement will prove beneficial because of the increase in production capacity of lightweight materials suitable for car construction after the war.

Relative Expense for Service Restoration With Different Types of Overcurrent Protection for Distribution Circuits

Discussion and authors' closure of paper 42-129 by G. F. Lincks and C. R. Craig, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, November section, pages 813–21.

E. L. Bayles (Northwestern Public Service Company, Huron, S. D.): The Huron-Iroquois line of the Northwestern Public Service Company is a three-phase 11-kv line approximately 48$^1/_2$ miles long with solidly grounded neutral, using number 6 hard-drawn conductor. Thirty-foot poles are used with triangular construction having a 4$^1/_2$-foot crossarm, a forged steel pole-top pin, and 28-inch strap braces. Steel pins are used in the arms, and insulators are nominally 15 kv. A one-quarter-inch Siemens-Martin steel neutral wire is carried the entire length of the circuit on the poles at approximately one foot below the lower attachment point of the braces.

The neutral wire is grounded at each

ınsformer ınstallation, at each overhead y and each pole. Grounding conditions : poor to fair. Driven ground rods on ınsformer installations and down guys : connected to the neutral test from eight ms on up, while pole grounds run from a nimum of 100 ohms on up to an unreadle value.

The terrain is quite flat with maximum posure of line to lightning, wind, and sleet. ıere are practically no trees or other ob:ts which might shield the line, and by : same token faults are not caused by oximity to trees.

Transformers fed from the line are pro:ted by expulsion gap arresters or by ındard valve-type arresters. There are, wever, a number of older types of transmers which have a very low impulse ength and which flash over internally in ne instances at a lower voltage than the :tings of the arresters of either type. ıese transformers are being weeded out as ne goes on but are the probable source of ne few kickouts on this line apart from : trouble experienced on the line itself. asmuch as the transformer fusing is :erposed between the line and transmer troubles, this is largely a matter of ·ordination which in most cases was such to relieve the line by blowing the transmer fuse.

This line normally serves five small wns and a good-sized packing house load ıich taps off at a point a few miles from : source. A 15-kv reclosing oil circuit :aker with time-over current relays pro:ts the entire line while *three* F.P. 119 oil :losers are in the line to the small towns the point just beyond the packing-plant) and thus protect this important load m trouble on the 40 odd miles of line. ıe oil circuit breaker is set at 48 amperes th a time of one second at 300 per cent trip current. The F.P. 119 oil reclosers : the 25-ampere size.

The oil reclosers were installed May 15, 41, and replaced a three-shot reclosing se installation. For the 12-month period ding May 15, 1942, the number of operans recorded by the reclosers were as lows:

ase *A*	149
ase *B*	36
ase *C*	172
tal number of lockouts	4
manent line faults	2
:kouts on repeated transient faults	2
ılts cleared successfully	over 168

In explanation of the unusual number of erations it should be said that the period :luded a rather severe sleet or glaze storm th high winds which resulted in dancing ıductors and numerous transient faults. ı a similar installation near Watertown der sleet storm conditions we have ex:ienced 27 recloser operations over night thout a lockout.

It could not be said in fairness that : installation of these reclosers saved the olacing of over 350 fuses, as no doubt the ne during which the fuse was out would :lude a number of potential cases of uble. Unfortunately, we do not have an :urate record of fuse replacements prior the installation of reclosers. We do ow, however, that during one 24-hour :iod in a sleet storm we replaced 100 links a three-shot fuse at the same point.

From the economic viewpoint we feel that time, material, car mileage, and outages saved by this installation more than justify the installation of this set of oil reclosers.

Bruce O. Watkins (nonmember; Rural Electrification Administration, St. Louis, Mo.): In the paper Mr. Lincks and Mr. Craig assume that there is a substation attendant. Usually on Rural Electrification Administration systems there is no such attendant. As is pointed out, this will result in greater relative benefits for automatic resetting reclosers. Also, it is assumed that in all cases there is a substation breaker. In very few cases are there such breakers on REA systems. A great many resetting reclosers can be purchased for the cost of one substation breaker, and the tendency in REA systems has been to place such reclosers on the line, rather than investing in a substation breaker. Also, since most REA substations are of relatively low capacity, the interrupting rating required of the substation devices has not usually necessitated such a breaker.

The experience with resetting reclosers on REA systems has been very favorable. Managers who have used them report greatly reduced outage time and maintenance costs over the originally fused system. Unfortunately, the exact reduction in such costs is not available. We are now attempting to compare maintenance costs on recloser-equipped systems with fused systems similar in size, consumer density, revenue, and so forth. Such figures may assist in sectionalizing comparisons.

Table I shows a three months' summary of a report on single-pole 15-kv resetting reclosers on REA systems which reported the same number of reclosers for three consecutive months (July, August, and September) in 1941.

There are features of the presently available resetting reclosers which could be improved. The ideal recloser would possess characteristics such that:

1. Internal distribution transformer fuses beyond the recloser would blow before recloser lockout on transformer failure.

2. A larger number could be co-ordinated in series than with present reclosers.

3. Opening time would be sufficiently fast to prevent excess conductor or gap burning.

4. Opening time would be short enough to protect adequately small substation transformers with the larger sizes of reclosers.

5. The installation and co-ordination of less expensive devices beyond the recloser could be made.

Of course some of these objectives conflict, and some compromise will be necessary. We feel, however, that the automatic resetting recloser offers great possibilities in rural distribution sectionalizing and that, as developments continue, they will offer even greater benefits.

Table I. Quarterly Summary

Number of systems reporting	39
Number of reclosers	450
Miles behind reclosers	11,441
Miles per recloser	25.4
Total operations	8,094
Operations per recloser	18
Lockouts	208
Lockouts per recloser	0.462
Per cent lockouts per operation	2.57
Operations per mile	0.706

R. F. Quinn (General Electric Company, Schenectady, N. Y.): The authors have presented a means of placing the problem of whether to sectionalize and with what to sectionalize on a sound economic basis. This study and the conclusions should be of real value to distribution engineers in studying their particular systems with a view to getting the maximum in continuity of service for every dollar invested.

The paper covers all combinations of sectionalizing and branch-protection schemes now available or in common use. However, manual sectionalizing is covered only in general terms. Actual data showing the effect on restoration time and automotive mileage for a line equipped with manual sectionalizing are not included in the curves.

Manual sectionalizing, as commonly employed, splits the main line up into several sections. In locating a fault the trouble crew travels at a high rate of speed to the mid-sectionalizing point, opens it, and then has the station operator close the circuit. If the line remains energized, the fault is obviously beyond the section point and vice versa. They then split the faulted half of the line into smaller sections until they locate the one on which the trouble is located. After locating the faulted section, the crew travels at a slower rate of speed to actually find and repair the fault.

An additional study has been made to arrive at comparable data on manual sectionalizing of a line without branches as in Figure 2 of the paper. Three locations of disconnecting cutouts having solid blades permitted dividing the line into four equal sections. The same general assumptions were used as in the study described in the paper, and it was assumed that the trouble crew:

(*a*). Traveled 30 miles per hour average speed to mid-point, opened cutout, phoned, and had breaker closed, and then either traveled back to the sectionalizing cutout closer to the substation if service was *not* restored, or to the cutout beyond the midpoint if service *was* restored (average speed 30 miles per hour). Climbed pole, opened cutout, and checked to see if service was restored. Then searched faulted section at 15 miles per hour

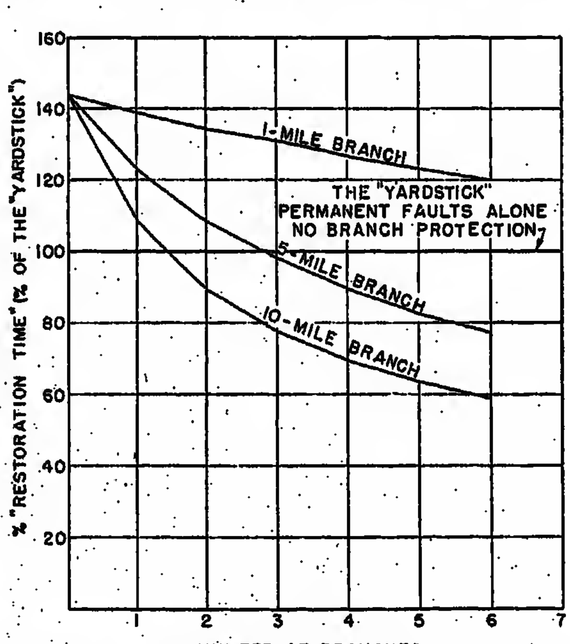

Figure 1. Restoration time for 1-, 5-, and 10-mile branches using manual feeder sectionalizing

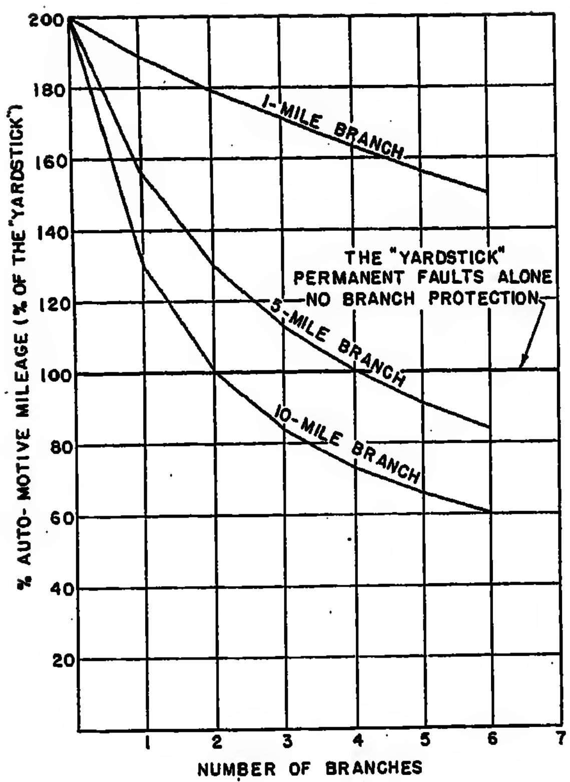

Figure 2. Automotive mileage for 1-, 5-, and 10-mile branches using manual feeder sectionalizing

traveling to mid-point. After repairing faults, traveled back 30 miles per hour to close sectionalizing cutout.

(*b*). With branches added to the feeder studied as in (*a*), search for the fault was confined to one-fourth the total mileage in all the branches. The crew traveled at 15 miles per hour.

(*c*). Five minutes were allowed for climbing the pole and 30 minutes for repairing permanent faults, which are the same values used in the study made by the authors.

The data obtained are plotted in Figures 1 and 2 of this discussion. It should be noted that the values are the same for all percentages of temporary faults. Thus, to make a comparison with the data presented by the authors, the curves on manual sectionalizing Figures 1 and 2 can be plotted directly on the respective curves Figures 5 to 12 of the authors' paper.

These data support the authors' conclusions on manual sectionalizing. They indicate that:

1. Manual sectionalizing of a feeder having no branches increases "restoration time" and automotive mileage in providing an improvement in service continuity over that for an unsectionalized line.

2. The restoration time and automotive mileage is the same for all percentages of temporary faults, and thus manual sectionalizing is most effective at the higher percentages of temporary faults (above 75 per cent).

3. Manually sectionalizing a feeder without any branches is much less beneficial than on a feeder with branches. Traveling out and back on a number of branches in search of the fault can be eliminated thereby.

4. The longer the branches, the greater the reduction of "restoration time" and automotive mileage effected by manually sectionalizing a feeder.

5. Manually sectionalizing a feeder having branches generally provides less reduction of "restoration time" and automotive mileage than automatic protection of the branches except with a number of branches at 85 per cent of temporary faults or higher.

M. C. Westrate (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper is primarily an economical consideration of the fusing problems on distribution circuits and as such makes a logical engineering presentation of the problem. In the conclusions much emphasis is placed on the value of "overlapping the substation reclosing protection with all line protective devices," but this is not always possible, because, in many cases where long feeders are involved, a far end fault may produce less current than the full load current on the feeder at the substation. Also, if such a scheme is to be used, it would seem desirable to have the breaker clearing time below the damaging time for the various line fuses.

The conclusion that "single-element fusing of branches five miles and longer" is economically justified appears reasonable for the general case. However, severe tree exposures often make fusing practical on much shorter branches and possibly the criteria for branch fusing might be based on the number of faults occurring per year rather than length based on an average number of faults per year.

G. F. Lincks and C. R. Craig: The contributions made by those discussing the paper are greatly appreciated by the authors.

E. M. Bayles gives some interesting data on a line where the percentage of temporary faults are much higher than the 85 per cent maximum of the study and there are more faults. (4+ instead of 1 per mile.) These faults apparently occur largely during periods of severe lightning and sleet storms with a majority resulting from a very few storms. All of these special conditions would enhance the economic justification for using automatic resetting reclosers of the type mentioned.

In calling attention to the inability to always set substation breaker relays so as to clear ground faults at the end of the line, W. C. Westrate places emphasis on a limitation to the more widespread use of relaying so the substation reclosing protection overlaps all line protective devices. This limitation is more pronounced on ungrounded circuits than on grounded circuits where the ground relay can be set below the load current of the phase wires. Recognizing this condition, the study presented in the paper pointed out that where such overlapping protection reaches only part way out on the line, the decrease in "restoration time" and automotive mileage over a nonreclosing or reclosing breaker is only approximately one-quarter of the decrease provided by overlapping the whole line. A very fine presentation of the problems involved in this type of overlapping protection will be found in the engineering report 47 Edison Electric Institute publication *J*-1, "Positive Disconnection of Distribution Circuits During Faults to Ground."

In concluding that "single-element fusing of branches five miles and longer is the most effective in saving sufficient restoration expense to liquidate the initial cost," it was not intended to imply that this would never be true on shorter branches. As Mr. Westrate points out, conditions on specific circuits or branches of a circuit may require a different criterion than the length of the branch. In some instances a large number of faults per year or a higher percentage of temporary faults on a very short branch might justify the initial expense of single-element fuses or even reclosers by the savings in restoration expense as well as the improvement in service continuity thus provided.

The emphasis placed on the use of relays and substation breakers which overlap the line protective equipment may have misled Mr. Watkins into the interpretation that the study presented was based primarily on the use of breakers at the substation. Actually, with an attended substation, it makes no difference in the conclusions reached in the paper whether a relay and breaker, a recloser, or a fuse is employed. With an unattended station a reclosing device that reset automatically very likely would be justified by the saving in restoration expense. As Mr. Watkins indicates, the decision as to whether this device is a recloser or a relay and breaker depends on the economies of each circuit.

The operating records with reclosers which REA are compiling should prove of value to the industry. It has been suggested that the value of such records would be enhanced greatly if there were some standards set up for compiling the records. For example, in the three months operating data presented by Mr. Watkins, there is no segregation as to whether valve-type arresters, expulsion protector tubes, or plain rod gaps were employed. If the expulsion protector tubes are not properly co-ordinated with the reclosers, they may cause it to operate unnecessarily. Plain rod gaps always require the recloser to interrupt the short circuit caused when they flash over. With both types, service would be restored on the first reclosure, thus showing a higher percentage of operations without lockout than where valve-type arresters are used. However, most of these momentary circuit interruptions would be avoided with the valve-type arresters. It was suggested that another point of dissimilarity in records is the "yardstick" used for comparison of the improvement provided. Possibly, in lieu of a standard, comparison of actual operating results with the results of the mathematical studies might provide the needed uniformity.

The actual data and curves for manual sectionalizing presented by R. F. Quinn are a valuable addition to the studies presented in the paper. The curves in his Figures 1 and 2 should prove useful, as they can be plotted directly on the curves in the paper.

Modern Cathode-Ray Oscillograph for Testing Lightning Arresters

Discussion and authors' closure of paper 42-108 by E. J. Wade, T. J. Carpenter, and D. D. MacCarthy, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, August section, pages 549–53

O. Ackermann (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors of this paper have by necessity concentrated on explaining the details which make their equipment operate so successfully. This gives an opportunity

to discuss the significance of their work in the field of cathode-ray oscillography in general.

As indicated in the bibliography to their paper, Dufour of France is the father of the high-voltage cold-cathode oscillograph. He used a mechanical sequence switch to apply high voltage to the cathode for a short time and to initiate the electrical phenomenon he wanted to study during this period. In this form, the instrument was introduced in the United States. The system soon proved too clumsy for the graphic recording of surges, to the study of which the instrument was applied. Harrington and Opsahl developed purely electrical high-speed switching by means of three-electrode gaps for the initiation of discharges in circuits serving cathode-ray oscillograph and surge generator. This resulted in a precision and rapidity of timing hitherto unknown. The circuits were published in the *Electric Journal* of August 1927 and have laid the foundation to a

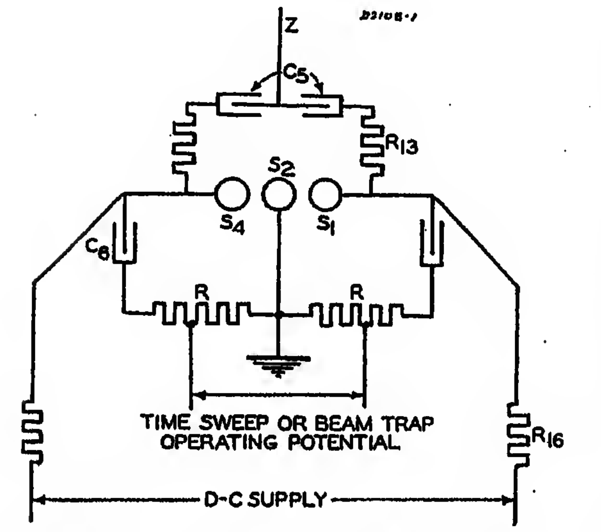

Figure 1. Completely balanced oscillograph trip circuit responding to impulses of either polarity at Z

Notations correspond to those of Figure 6 of the paper

large number of systems of timing circuits interconnected by tripping spark gaps. The cathode-ray oscillograph with "impulse beam" was thus successfully established in the United States.

In the meantime, many workers in Europe had concentrated on the design of oscillographs with continuously energized cathode and with systems of "beam traps" which kept the beam off the photographic film while it was not needed for recording. One such system, that of Doctor Norinder, was introduced in the United States by the Westinghouse Electric and Manufacturing Company in 1928 and was developed by the writer into a system of three or four cross-connected and balanced pairs of plates which, while "untrapping" or releasing the beam, do not produce a deflection of the latter in the recording part of the instrument. This has been disclosed in a paper of the writer in AIEE TRANSACTIONS, volume 49, 1930, page 467.[1] It should not have been necessary for the authors to suggest by their reference to a 1932 British paper that the method had originated outside of this country.

Interest was now focused almost exclusively on the oscillographs designed for continuous beam output. They attained considerable importance in the industry, and as is quite natural with an instrument finding wide application, they had to meet ever rising demands on their performance, particularly on writing speed. Increased writing speed is most directly obtained by raising the cathode voltage and the beam current which, in instruments designed for continuous output, meant complications such as artificial cooling of the discharge tube, higher insulation strength, and larger dimensions.

At this point, the system of the impulse beam, abandoned by most workers, but quietly fostered by the authors and their associates, bears new fruit, as it is, of course, entirely feasible to force a much higher discharge energy through a tube for a short time than the latter could handle continuously. This, however, is not the only thing which accounts for the extremely sharp and clean-cut pictures of 100,000,000-cycle transients obtained by the authors with their new "impulse-beam" oscillograph. In order to achieve this, the timing and beam release circuits must be very carefully laid out physically, shielded, and balanced. In this the authors have done a very good job, as every worker with oscillographs will acknowledge.

Regarding one feature of their circuit, namely, the four-electrode gap, it appears to the writer that a three-electrode gap should function in exactly the same manner. For the four-electrode gap of the authors to operate, *S*-3 must spark to *S*-4 first, and, once this spark is established, *S*-3 and *S*-4 act as one body, as they would if they were connected permanently.

We do not hesitate to give credit to the authors for the direct grounding of the center sphere *S*-2 but believe that the circuit could be simplified and modified as indicated in Figure 1 of this discussion, so as to respond even to surges of either polarity. A portion of the tripping impulse as divided by the resistors *R* and *R*-13 is impressed on spheres *S*-1 and *S*-4, adding to the potential to ground of one and subtracting from that of the other. Whichever potential exceeds the breakdown of the gap to *S*-2 will cause that particular half to flash over. Practically the full potential of *C*-5 now is applied across the other half of the gap which will then break down immediately. This, incidentally, also is the major function of *C*-5 in the authors' original circuit, although this is not mentioned in their paper.

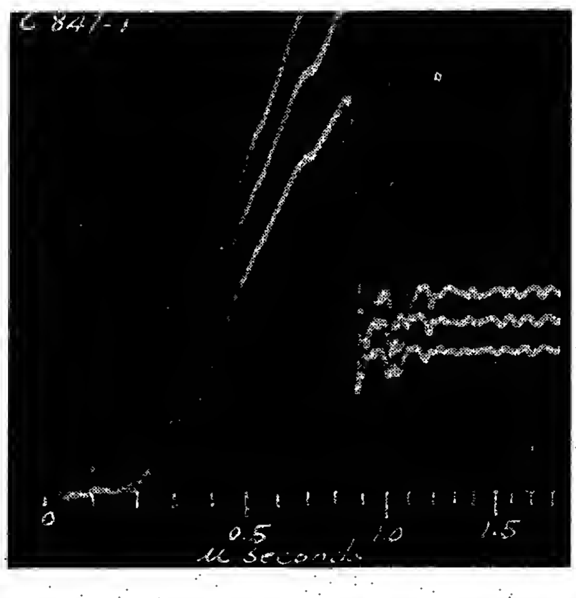

Figure 2. Typical high speed record obtained with continuously excited 50-kv oscillograph

A feature on which more information would be desirable is that of the cathode voltage regulator. One point in particular should have been mentioned in order to make the operation of the whole system clear, namely, that the left-hand terminal of the regulator must become grounded if a voltage of 80 kv is to be obtained at *G*-1.

That there are distinct possibilities in the method of impulse excitation is quite evident, as it has also been demonstrated by the work of Doctor Slack and his associates with impulse-excited high-voltage X Ray tubes. However, the continuously excited oscillograph is simpler in its operation and timing. It is, therefore, more desirable for general work. That it is entirely adequate for all practical purposes, which means to fractions of one microsecond, is demonstrated by hundreds of records such as that shown on Figure 2 of this discussion.

REFERENCE

1. A CATHODE-RAY OSCILLOGRAPH WITH NORINDER RELAY, ITS DESIGN AND APPLICATION, O. Ackermann. AIEE TRANSACTIONS, volume 49, 1930, pages 467–75.

J. M. Bryant and M. Newman (University of Minnesota, Minneapolis, Minn.): The authors are to be congratulated on making improvements in the cold-cathode cathode-ray oscillograph described in their paper. This type of oscillograph offers a better opportunity over the hot-cathode type for obtaining strong traces at ultrahigh frequencies and sweeps. A similar development is shown in technical paper 27, "Developments in High-Speed Oscillography," by J. M. Bryant and M. Newman, published March 1942 by the engineering experiment station of the University of Minnesota. In that paper new design features are given in sufficient detail to allow application to older slower-speed cathode-ray oscillographs. It is interesting that so many design features were solved in a similar manner and at about the same time but through independent work. The trace shown in Figure 8 of the paper under discussion compares in speed of sweep and writing speed with one published by ourselves in "Measurement of Very Short Time Lags," AIEE TRANSACTIONS, volume 59, 1940,[1] which we believe has usefully served as a goal to approach. Attention is called to the fact that "writing speed" is not necessarily limited by the velocity of light.

REFERENCE

1. MEASUREMENT OF VERY SHORT TIME LAGS, J. M. Bryant, M. Newman. AIEE TRANSACTIONS, volume 59, 1940, pages 812–16.

E. J. Wade, T. J. Carpenter, and D. D. MacCarthy: The authors are pleased to have received Mr. Ackermann's thorough discussion of our paper. We are familiar with the cathode-beam relay developed by Norinder and improved by Ackermann. We referred to the work of Burch and Whelpton since we preferred their type of beam trap, because it seemed simpler to build than the Norinder relay, and with it the beam is released by removal of the voltage from the plates. The plates of the Norinder relay must be perfectly balanced in order to avoid a deflection proportional to the voltage that is applied to release the cathode beam.

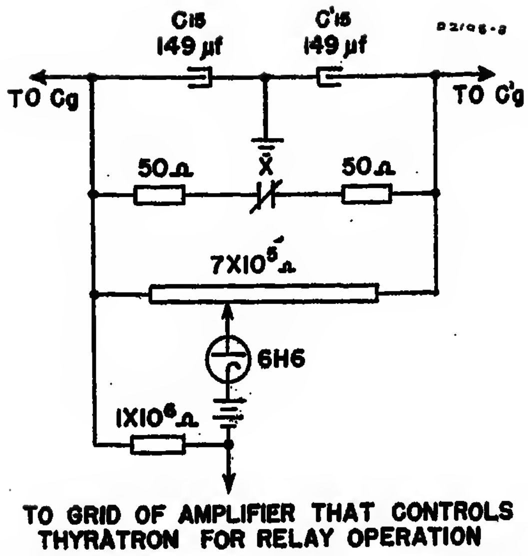

Figure 3. Schematic circuit diagram for cathode voltage regulator

In Figure 1 of his discussion Mr. Ackermann gives a circuit for a three-electrode gap to replace the four-electrode gap shown in Figure 6 of our paper. In our opinion the four-electrode gap is advantageous, since it permits the sweep circuits to be started by an initiating impulse, lower in energy than would be necessary with the three-electrode gap. In order to initiate the complete breakdown of the three-electrode gap, the initiating impulse must change the voltage on one of the end gaps (see Figure 1 in Mr. Ackermann's discussion). This change in potential will cause current to flow through R_{16} to other portions of the high-voltage circuit and through the relatively low-impedance path through C_6 and R. The charges corresponding to these currents must be supplied from the cathode generator and tends to reduce the cathode voltage which should be constant. To start the operation of four-electrode gap, the initiating impulse has only to change the potential of the electrode S_3 which has a low capacity to other parts of the circuit. The time and charge necessary to do this is relatively small. Since the four-electrode gap is always initiated by an impulse from the cathode supply that is negative, there is no advantage in using a gap that will respond to surges of both polarities.

Mr. Ackermann has requested more information on the cathode voltage regulator. A schematic diagram of the regulator is shown in Figure 3 of this discussion. When the cathode generator is put on charge, relay X opens, and one of the capacitors, C_{15} and C_{15}', charges in series with each of the balanced banks C_g and C_g' of the Marx circuit shown in Figure 6 of the paper. The voltage across C_{15} and C_{15}' is proportional to the sum of the voltages on C_g and C_g'. The rectifier tube conducts when the drop on the potentiometer exceeds the bias voltage. This results in the operation of relays that initiate the sequence of operations described in the paper. When the capacitors C_g and C_g' are charged to 20 kv, the voltage on each of the capacitors C_{15} and C_{15}' is 67 volts. During the discharge of the cathode generator, the ground terminal of the capacitor C_g is 67 volts negative with respect to ground which is entirely negligible in comparison with the 80 kv supplied by the generator.

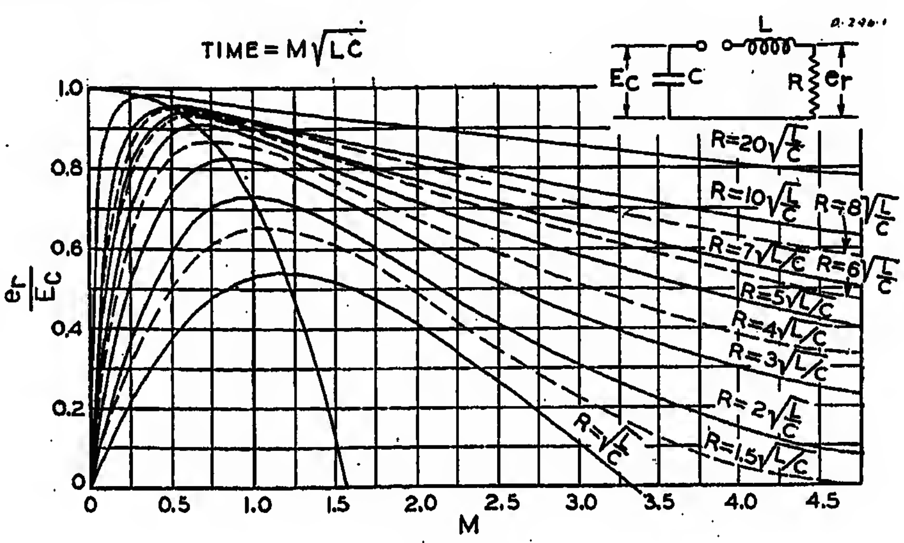
It is of interest to learn that Bryant and Newman have applied many of the same design features to a cold-cathode oscillograph that they have built.

Modern Impulse Generators for Testing Lightning Arresters

Discussion and author's closure of paper 42-96 by Theodore Brownlee, presented at the AIEE summer convention, Chicago, Ill., June 22-26, 1942, and published at AIEE TRANSACTIONS, 1942, August section, pages 539-44.

A. M. Opsahl (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. In an impulse generator for lightning-arrester testing, the primary requirement is that it deliver an impulse test current of specified shape and magnitude through the test piece. The variation in voltage, electrostatic capacity, inductance, resistance, and discharge voltage characteristic of the test piece is so great as to make detailed calculations on each test circuit too laborious. For a number of years the curves in Figure 1 of this discussion have been found very helpful in determining the test circuit to deliver a specified test current.

Figure 1



2. As shown in the sketch, the capacitor discharges through the inductance L and load resistance R. The capacitor discharge formulas were used to obtain general curves applicable to any impulse current generator. The curves show the per cent of capacitor voltage that appears across load resistors. The load resistors are multiples of the impedance characteristic of the circuit $\sqrt{L/C}$. The time scale is plotted in multiples of the time characteristic of the circuit $\sqrt{LC}$.

3. The shape of the desired current wave determines the per cent of capacitor voltage available across the load resistor. The required current then determines the load-resistor magnitude. From this, a numerical value is obtained for the factor $\sqrt{L/C}$. From the required time to crest current in microseconds, a numerical value is obtained for the time factor $\sqrt{LC}$ in microhenries and microfarads. From a solution of these equations, the required capacity and inductance can be obtained.

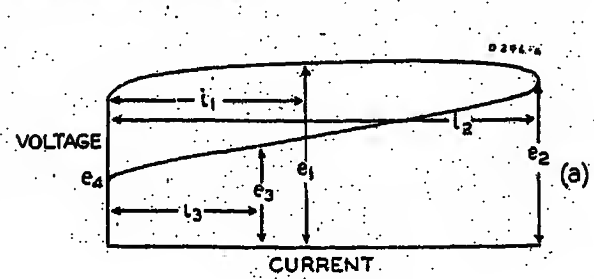


Figure 2

4. As stated by Mr. Brownlee, an arrester valve element is not a linear resistor, so the simple calculation above is not adequate unless the arrester is only a small part of the load resistor. As a matter of economy, to obtain the maximum test from the available equipment, the arrester is as large a part of the load resistance as possible. Mr. Brownlee's Figure 1B shows the arrester substituted for part of the load resistor. In Figure 2 of this discussion is a sketch of a typical volt-ampere curve of a valve arrester. On the rise in current, e_1 is substantially constant, and a better figure is obtained for the required circuit inductance by assuming the arrester is a constant voltage instead of a resistance element. The time to crest current does not vary rapidly with changes in circuit resistance. In the region from e_2 to e_4 there is substantially a straight line. For calculation of crest current, the arrester element can be regarded as a resistance $(e_2-e_4)/i_2$ plus a voltage e_4 which is subtracted from the capacitor voltage.

5. Equal impulse generator elements in series proportionately increase the voltage rating of the arrester element that can be tested, but do not change magnitude or shape of current wave. Equal impulse generator elements in parallel increase the available current without changing the current wave shape.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): Mr. Brownlee has shown in his paper that the wave shape of the output currents of impulse generators can be calculated with very good accuracy, even though part of the discharge circuit contains an impedance which varies with the current. While experience certainly helps, a thorough understanding of the problem on the theoretical basis as shown in the paper certainly is required. For many years the tests on lightning arresters were further unnecessarily complicated by requirements of obtaining a definite voltage wave shape before arrester gap breakdown, followed by a definite current wave shape, so that impulse testing of arresters was really one of the most difficult of the impulse tests. It is therefore very gratifying that the author makes public the results of his experiences.

Of particular interest is the arrangement of generator 1 in a steel housing. Such a housing should go a long way toward eliminating many of the spurious oscillations which are liable to occur with the open type of generator. Here the stray capacitance

formed between capacitors and ground in connection with the circuit inductance produce current flow through the ground circuit, thereby upsetting the balance between testpiece ground and oscillograph ground. The oscillograms presented show that this aim of confining stray capacitance currents has been completely accomplished.

The paper shows the growing importance of impulse tests in the design and research of lightning protective equipment. It is perhaps of interest to note that in the Pittsfield works of the General Electric Company alone, a total of 12 impulse generators is in more or less constant use for the determination of impulse properties of parts as well as of the completed products.

Tests on completed transformers are at times equally complex, not only on account of the complexity of the impulse discharge circuit because of the inductance to ground of the winding tested, but also because of the presence of the other windings on the same core. The voltages at the bushings of the other windings under conditions of test tend to rise up to and above the bushing sparkover, unless suitable impedance to ground is connected to them. While calculations can be made to analyze these voltages for a given transformer, the labor involved would be prohibitive. The electric transient analyzer is used for this purpose. Frequently such an impedance is obtained with Thyrite Since the transient analyzer operates at relatively low voltage (order of 1,000 volts), the amount of Thyrite, when checking with the analyzer, must be of necessity very much smaller than for the actual high-voltage test. It has been possible to match the Thyrite for the two tests effectively, so that for any voltage applied to the transformer, the wave shapes match perfectly. Such a match is of course important to obtain the necessary assurance that failure in the transformer winding did not occur. If the same amount of Thyrite is used for the 70 per cent check wave as for the 100 per cent full wave, the wave tail of the applied wave is liable to be considerably shorter on the 100 per cent wave. Thus, a failure in the winding producing a similar change in wave shape may be obscured.

Calculations such as shown in the paper are always desirable and necessary to obtain checks on the performance of equipment under impulse conditions imposing high stresses on the test specimen.

J. M. Bryant (University of Minnesota, Minneapolis, Minn.): The requirements for tests of all types of lightning arresters to meet standard specifications necessitate an impulse generator (or generators) providing a wide range of currents and voltages. We agree with Mr. Brownlee that under certain conditions a rapid way of determining the resulting current test waves would be from previously established curves for given conditions for a similar type arrester. As an example Figure 3 shows a group of current discharge waves through an arrester, all of which have practically the same specification. In addition to the impulse generator, it is necessary to have an accurate linear shunt for current, an accurate voltage divider for potentials, an oscillograph rapid enough to be capable of recording the events, such as described by Wade, Carpenter, and MacCarthy, and connections from the shunt and voltage divider which eliminate harmonics due to stray magnetic and electrostatic fields without the use of series resistances or other makeshifts which alter the actual values for the current or voltage curves. These specifications make it necessary to use infinite pains in making accurate tests. The author is to be congratulated in the clearness with which he has presented in so short a paper the results of what must have taken years of research and planning.

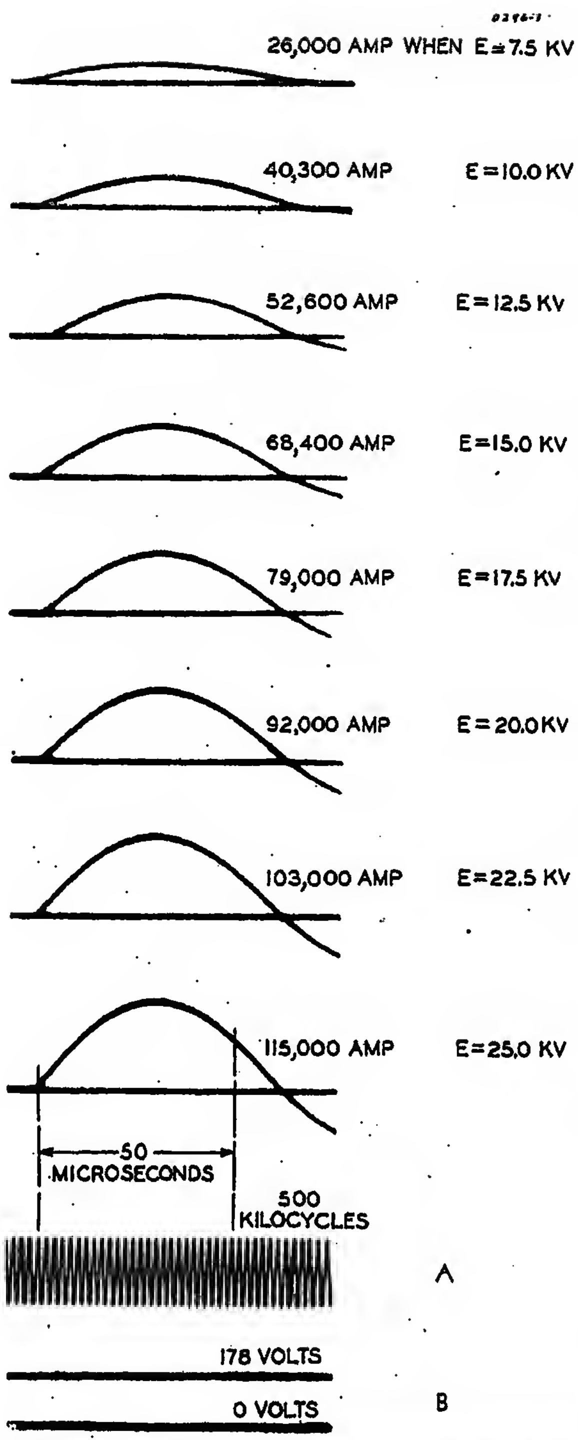

Figure 3. A group of current discharge waves through an arrester

A. Time scale calibrating frequency 500 kilocycles per second two microseconds per cycle

B. Current scale calibration. Shunt resistance 0.00278-ohm. Deflection equals 64,000 amperes

Theodore Brownlee: The discussions by Bryant, Hagenguth, and Opsahl agree well with the text of the paper. Mr. Opsahl's Figure 1 is equivalent to part of Figure 2 in the paper, and, over the range it covers, it permits wave calculations with about the same facility. His simplifications of the volt-ampere characteristic of a lightning arrester shown in Figure 2 are reasonable. Similar results will be obtained using his method or the curves in Figure 5 of the paper.

Regulated Rectifiers in Telephone Offices

Discussion and author's closure of paper 42-95 by D. E. Trucksess, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, August section, pages 613–17.

Clarence E. Lomax (Associated Electric Laboratories, Inc., Chicago, Ill.): This paper by Mr. Trucksess is very timely and is full of interest for all who have to do with the central-office power plant. It suggests to me a number of questions which I believe will be of interest to others.

1. Is supervision provided to indicate burnt-out tubes? If supervision is provided, is it equally effective on full load, light load, and no load?

2. Is there a means provided for extinguishing flashing when flashing occurs, and is it equally effective on full load, light load, and no load?

3. Does a charger which is rated at 30 amperes capacitance hold a constant voltage up to a 30-ampere load, or does the voltage start dropping before the full load is delivered?

4. When two chargers are required to operate in parallel, must any special action be taken to divide the load equally?

5. Is it necessary, when two chargers are used in parallel, to use chargers of equal capacity, equal age, and equal service usage?

Frederick L. Kahn (Automatic Electric Company, Chicago, Ill.): There have been a number of telephone-type regulated rectifiers on the same market which we are in the habit of referring to as "constant voltage rectifiers." These rectifiers use dry-plate rectifying elements (copper oxide or selenium) so that we have almost come to think of regulated chargers being synonymous with nontube-type chargers. We are very much interested to hear that equally close regulation of batteries in telephone exchanges can be obtained by 3-, 10-, and 30-ampere tube chargers, especially as the price of dry-plate units has made their use in chargers of higher capacitance almost prohibitive. The design of the tube-type regulated chargers at this time justifies the assumption that they have a lower first cost than constant voltage charging equipment of various types now available.

The following questions concern only the 48-volt rectifiers of 3-, 10-, and 30-ampere capacity:

1. As these chargers appear to operate continuously when used in regulated charging circuits, how often do tubes have to be replaced?

2. What is the electrical efficiency of these chargers? At what per cent of full load do they have maximum efficiency?

3. Are the 30-ampere chargers cheaper in first cost and operating cost than 25-ampere diverter pole motor generators?

4. What is lowest possible output of 10- and 30-ampere chargers when used in self-regulating service? (trickle charge rate)

5. What overload protection is provided if chargers are connected across a battery discharged during power failure?

6. How are variations of a-c voltage compensated for?

7. Do these rectifiers need any special adjustment for equalizing charge, or does the cutting in of additional countercells automatically raise the output voltage of the chargers?

D. E. Trucksess: The questions of C. E. Lomax and F. L. Kahn pertain to details in the design of the regulated rectifiers listed in Table I. These details and many more were not included in the original paper in order to keep it within the prescribed length.

In answer to Mr. Lomax:

1. In all cases some means are provided to indicate when a rectifier tube has failed. In most cases a voltage relay continually measures the regulated voltage, and, as soon as it goes out of the floating limits, it rings an alarm. In a few cases, a current transformer and relay are used with each individual bulb. The disadvantage of this type of alarm is that the alarm circuits cannot distinguish a tube failure from the condition of zero current produced by the regulating circuit as a result of no office load. Therefore, with regulated tube rectifiers the best alarm is a float voltage alarm.

2. In regard to flashover of the rectifier tubes, the thyratron tube, when used in 24-, 48-, or 130-volt rectifiers, does not flash over. The two-element-tube rectifier tubes flash over with voltage surges from the power line, and flashover relays are provided. These relays automatically disconnect the rectifier from the a-c line and battery during flashover and automatically reclose after the flashover is completed.

3. The 30-ampere regulated rectifiers hold a constant voltage up to full load, and at full load the circuit automatically transfers from a constant voltage-regulating circuit to a constant current-regulating circuit, holding the load at 30 amperes during any further charges in line or increase in load.

4, 5. When two or more regulated rectifiers are operated in parallel with regulation of better than two per cent, it is not practical for rectifiers to be operated under voltage control as the load will not divide equally, and it is impractical to attempt to automatically balance the load between them. When rectifiers, listed in Table I, are required to operate in parallel, means are provided for the constant voltage regulation to be transferred to constant current regulation. Therefore, rectifiers of unequal capacity, age, or service usage may be operated in parallel.

In answer to Mr. Kahn's questions:

1. In general, the tubes used in the regulated rectifiers shown in Table I will operate approximately one year at full load and from $1^1/_2$ to 2 years with the typical telephone type load of full load during the day and light load at night.

2. The electrical efficiency of regulated tube rectifiers is affected by the d-c battery voltage and the rectifier size; therefore, one figure will not cover the wide range of rectifiers listed in Table I. The maximum efficiency occurs at full load, which varies from 60 to 70 per cent for 50-volt rectifiers and 40 to 50 per cent for 24-volt rectifiers.

3. The 30 rectifiers listed in Table I have a cheaper first cost and operating cost than a corresponding size motor-generator set.

4. The 3-, 10-, and 30-ampere regulated tube rectifiers will operate and maintain their regulated voltage down to the trickle charge of the battery, which in most cases is one to five per cent of the full load rating of the rectifier.

5. Overload protection for regulated rectifiers is required in case the rectifier comes back after a power failure and attempts to float a discharged battery. In all cases the rectifiers shown in Table I have automatic overload protection. In the small rectifiers a ballast lamp causes the voltage to droop with overloads. In larger sizes the control is changed automatically from voltage to current regulation at full load.

6. The normal voltage regulation of the phase shift and booster types of control is sufficiently accurate to compensate for variations in the a-c line voltage. With the magnitude type of control, the normal regulations would not be sufficient, and it is supplemented by the line compensating circuit described as part of the combined rectifier and inverter.

7. In regard to equalizing, charging, or overcharging, the larger rectifiers have built into the control circuit a separate voltage control to increase the floating voltage from 2.15 to 2.3 volts per cell. With the smaller rectifiers, the regulating leads are connected to the load side of the countercells so that for overcharging the countercell switch is opened, and the rectifier automatically increases the battery voltage by an amount equal to the drop over the countercells.

Theoretical Possibilities in an Internally Heated Bimetal Type of Thermal Watt-Demand Meter

Discussion and author's closure of paper 42-110 by Edward Lynch, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, October section, pages 764–70.

P. M. Lincoln (Therm-Electric Meters Company, Inc., Ithaca, N. Y.): This paper is a very interesting one and shows a high ability for mathematical analysis. However, there are at least two points in the author's final conclusion that I would question. One has to do with his statement concerning the accuracy of the block-interval demand meter and the other has to do with his conclusion concerning the thermal demand meter.

First, regarding the block-interval type where, to quote his own words, "great accuracy is desirable." The block-interval type of demand meter measures the arithmetic average of the load under measurement. Any arithmetic average is necessarily a discontinuous function of time. As such, it is subject to a possible error of 50 per cent. To make matters worse, this error can be caused to appear at the option of the service user. The block-interval demand meter is perfectly accurate when we consider the particular time interval which it happens to select for measurement, but this time interval is only one out of an infinite number that might be selected. If Mr. Lynch will reread his reference 3, he will note that a series of tests made in Ithaca on block-interval demand meters extending over a period of 18 months showed a maximum error of 27.3 per cent and an average error of 10.1 per cent. In only ten per cent of the cases under measurement in Ithaca was there found no apparent error, and even in these cases there might have been errors if some intermediate time intervals had been chosen. Mr. Lynch's reference 3[1] also points out that maximum demand can be accurately measured only by a "continuous function of time." The logarithmic average is a continuous function of time while the arithmetic average is not and cannot be made a "continuous function of time." The block-interval demand meter is not only not accurate—Mr. Lynch to the contrary notwithstanding—but also cannot be made to be accurate.

Now, coming to Mr. Lynch's analysis of the thermal demand wattmeter, I question whether he carried his analysis far enough to arrive at an accurate result. The thermal wattmeter depends for its indication on the difference in temperature arrived at between two masses of matter which are heated by electric currents. This difference in temperature depends, in turn, not only in the difference in rate of heat application to the two masses of matter but also on the *rate of heat escape*. Final indication of the thermal demand meter is attained only when these two rates have become equal. If the rate of heat escape were always directly proportional to temperature elevation, Mr. Lynch's analysis would be perfectly correct and constitutes a beautiful piece of mathematical analysis. However, as pointed out in my paper, "An Improved Electrothermic Instrument,"[2] the rate of heat escape when such heat escape takes place by any method other than thermal conduction does not follow a first power law against temperature elevation. In the thermal wattmeter, where the actuating element is of bimetal strip as described by Mr. Lynch, most of the heat escapes by thermal convection. As proved by Chester W. Rice in his AIEE paper entitled "Free Convection of Heat in Gases and Liquids—II"[3], thermal convection varies as the 1.25 power of the temperature elevation—*not* the first power. Mr. Lynch does not take account of this in his analysis. I would, therefore, question the accuracy of the conclusions he arrives at in his paper.

I fully agree with Mr. Lynch that the "simple exponential is ideal." Due to the time taken for heat diffusion, the simple exponential cannot be entirely realized, but it can be closely approached. Why does not Mr. Lynch go still further and point out that the use of the thermal demand meter is the only known way in which maximum demand can be accurately measured?

3. Free Convection of Heat in Gases and Liquids—II, Chester W. Rice. AIEE Transactions, volume 43, 1924, pages 131–43.

Edward Lynch: It was with much interest that I read P. M. Lincoln's remarks and studied his discussion. His first point can, perhaps, be more clearly understood without an opportunity for misunderstanding if we say, as he has, that "the block-interval demand meter is perfectly accurate" in indicating continual arithmetic average demand and add, as I have, that the thermal demand meter indicates a slightly different quantity which has been designated as continuous logarithmic average demand. The accuracy and precision of both types of meters as measuring devices is of such a high order that each can be built to measure the quantity for which it is intended and with accuracies well beyond requirements of normal use.

The second point in question illustrates an important "design principle." Heat escape from the actuating elements of thermal meters should be by controlled conduction rather than by radiation or convection. In the mathematical analysis this means that heat escape is proportional to the first power of temperature rise.

Doctor Lincoln stated that in the thermal wattmeter where the actuating element is a bimetal strip most of the heat escape is by

thermal convection. This was not the case in the internally heated bimetal meter designed to check the analysis made in the main paper. In fact, the internally heated bimetal meter inherently fosters heat escape by conduction. This is easily realized when one recognizes the close correlation between electrical and thermal conductivity. Since we must have good electrical conductivity into and out of and between the actuating elements we readily have available good thermal conductivity as well. This was taken advantage of in the design of the meter on which tests were made, and the results of these tests substantiated the analytical conclusions reached.

A New Jewel for Indicating Instruments

Discussion and authors' closure of paper 42-134 by F. K. McCune and J. H. Goss, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, September section, pages 673–6.

John H. Miller (Weston Electrical Instrument Corporation, Newark, N. J.): The description of the test methods used on the new glass jewel for indicating instruments by McCune and Goss and the tabulation of the results are currently of importance to those using electric indicating instruments, because it indicates the dynamic character of the art and is assurance that functional quality is being maintained in such instruments, even in spite of important material difficulties.

The Weston Electrical Instrument Corporation is manufacturing glass instrument jewels in large quantities, and these jewels are being used with eminently satisfactory results in many fields. Aircraft instruments, incorporating electric mechanisms, are being almost wholly supplied with this type of bearing.

About ten years ago the Weston Electrical Instrument Corporation started an investigation of substitutes for sapphire jewels to obtain a more perfect contour and surface than was possible in sapphire, as was required for highly sensitive instruments. Glass jewels were known and used at that time; in fact, a patent was issued as far back as 1899, covering glass *V* jewels, but none was found of satisfactory quality for use in Weston instruments.

Preliminary work was therefore done on the development of a satisfactory glass jewel in the Weston laboratories, and by 1934 and 1935 extensive field tests on a new form of glass jewel showed it to be equal to and in many respects superior to sapphire, particularly where vibration was encountered.

In view of the evident usefulness of this type of bearing, as well as a matter of protection against the possibility of cessation of sapphire-bearing imports, a small pilot plant was installed about 1938 to establish a satisfactory production technique. When the war broke out in Europe, and shipments of sapphire bearings were cut off, a very large number of these glass jewels were supplied to Sangamo-Weston, Ltd., England, whose tests confirmed their usefulness in aircraft instruments. It is understood that today practically all electrical instruments used by the Royal Air Force, which were manufactured in England, carry jewels of this type, now manufactured in that country.

This extensive manufacturing experience enabled the Weston Company to expand the pilot plant to a full-fledged production basis as sapphire bearings became more difficult to obtain in the United States and that expansion has been continuous and is still going on.

The Weston glass jewel, known as the Weston *V* bearing, has been developed with perhaps greater stress on the matter of surface finish and resistance to vibration than to the factor of shock, although shock tests of the order of 250*G* appear to be required in any direction before pitting takes place with a moving system having less than one gram weight. As is indicated by McCune and Goss, vibration tests have been surprisingly satisfactory, and it seems apparent from such tests conducted in the Weston laboratories, at the Bureau of Standards, and elsewhere, that actual jewel wear is materially less under conditions of severe vibration with the *V* bearing as compared to the sapphire. The perfection of the surface finish is probably responsible, as well as the fact that the bearing more nearly approaches the hardness of the pivot, thus reducing the tendency of the pivot to wear.

While it is admittedly difficult to cut a perfect pit in a sapphire, it is hardly believed that variation in lineal cutting speed from center to periphery, as referred to by McCune and Goss, is responsible for the difficulty, since the cutting tool traverses any point in the sapphire once every revolution, and will take off as great a thickness of material near the center as near the edge. Wear on the cutting tool is perhaps a function of cutting speed, but it is believed that cutting speed is not a factor with regard to the relative depth of material removed per revolution.

It is interesting to note that the coefficient of friction varies so little between materials, and it seems evident that the criterion in the bearing is not so much the friction coefficient, but rather its ability to maintain its original shape and surface under conditions of severe vibration, shock, and use. It seems quite probable that these new special glass bearings, as developed in the several laboratories, will find fields of usefulness in future years in small instruments with light elements, where high sensitivity is required, even though sapphire bearings again become as plentiful as in years gone by.

F. K. McCune and J. H. Goss: Mr. Miller has presented an interesting history of the Weston Electric Instrument Corporation's experience with glass jewels. His findings are in general agreement with ours and are especially interesting on vibration. Work not complete at the time of writing the paper has shown the following curve to be typical of instrument performance after severe vibration.

Mr. Miller has stated "shock tests of the order of 250*G* appear to be required in any direction before pitting takes place" for a moving system of one gram weight.

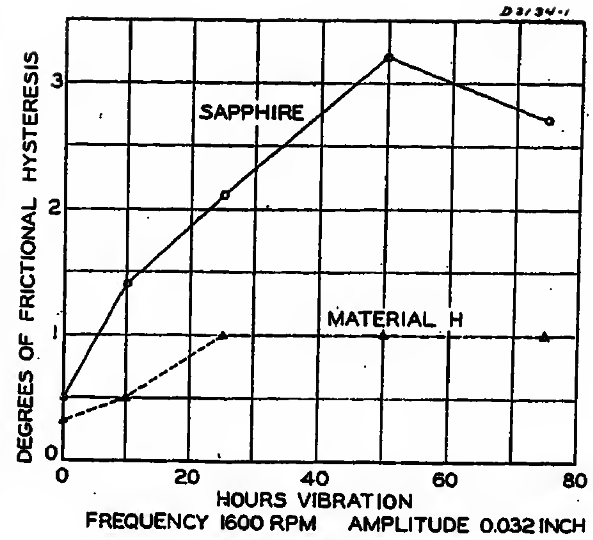

Figure 1

Our experience has indicated that such a value may depend materially on the speed with which the acceleration reaches its maximum and varies with the rigidity of the moving system in question. Work done on a device in which the motion was of the form of a damped sine wave with a time of 1.5×10^{-3} seconds from initiation to completion of a half-cycle gave very different values from those obtained with a slow rate of loading the jewel surface. However, the value at which the pivot was mushroomed in the case of the sapphire was approximately that at which a blemish would be produced in the jewels of material *H*.

In conclusion, the authors are both continuing work on the *V* jewels and progressing the development of ring jewels from the same material. Many hundreds of thousands of the *V* jewels have already been produced with characteristics as represented in this paper.

A New Moving-Magnet Instrument for Direct Current

Discussion and authors' closure of paper 42-123 by H. T. Faus and J. R. Macintyre, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, August section, pages 586–8.

John H. Miller (Weston Electrical Instrument Corporation, Newark, N. J.): A comparison of the energy for full-scale deflection taken by the new moving magnet instrument mechanism of Faus and Macintyre, with that required for conventional mechanisms may be of interest.

It is stated in the paper that with a moving element weight of 0.205 gram and an effective torque for a full scale of 0.35 millimeter-gram, giving a torque-to-weight ratio of 1.7, the coil energy was 0.05 watt for full scale.

Conventional small a-c iron-vane instruments, with somewhat heavier moving elements, on the basis of springs to give the same torque-to-weight ratio, would require 0.5 watt. In other words, the new instrument discussed has an energy sensitivity something like ten times that of conventional soft-iron instruments, which have been used for many years.

Making the comparison with permanent-magnet moving-coil instruments, and using a moving system of practically the same weight, we find that for one of the simpler structures with moderate damping, there would be required about 0.00036 watt, or something like $^1/_{150}$ of the energy needed for the new instrument.

However, this is on the basis of a design of nearly three decades ago, and more recent instruments compared on the same basis of equal torque-to-weight ratio, and with about the same moving element weight, are regularly being produced with high coercive force magnets to give full-scale deflection on 0.000025 watt, $^1/_{2,000}$ of the energy taken by the new instrument.

It is believed that this comparison with equal torque-to-weight ratios is quite valid, since, obviously, both old and new types of mechanisms can be supplied with bearings of any one of the several types currently used, and, with similar bearings and similar moving system weights, similar torque-to-weight ratio should be the determining criteria.

While it is admitted that iron-vane instruments of conventional design have a considerable d-c error, this, of course, can be reduced, if important, by the use of suitable material in the iron vanes.

In the relatively wide energy span separating the conventional iron-vane instruments and the best of the permanent-magnet moving-coil instruments, a span from 500,000 down to 25 microwatts, or a factor of 20,000 to 1, this new design, on a comparable torque-to-weight ratio basis, has only progressed one decimal place from the conventional iron-vane type.

Since the only advantage of the new mechanism is low cost, one wonders if it is sufficiently less costly to justify the relatively high energy taken from a circuit which effectively limits its broad applications.

J. R. Macintyre and **H. T. Faus:** A comparison of the moving magnet instrument with the iron-vane a-c instrument is not relevant, since reasonably accurate and well-damped instruments of this type are as expensive as moving coil instruments. Our comparison was with the lower-cost polarized vane instrument which has the additional disadvantages of poor scale distribution, short scale, and poor damping.

The comparison of the microwatt sensitivity of the moving magnet instrument with that of the moving-coil instrument does not give an accurate picture of the relative merits of the two designs. For example, Mr. Miller gives a figure of 0.000025 watt for full-scale deflection on a sensitive moving-coil instrument. Using this figure, one not familiar with instruments might assume that a ten-ampere ammeter could be built with a resistance of $\frac{0.000025}{100} = 0.00000025$ ohm. This is not the case, because springs of the required low torque cannot be built to carry ten amperes, much less to have a resistance as low as the above value. The general practice in a moving-coil instrument of this rating is to use a shunt with a 50-millivolt drop and to connect the instrument winding, in series with a suitable resistor, across this shunt. The net result is an instrument with an over-all loss of 0.5 watt. An instrument of the same rating in the moving magnet design would have a winding consisting of a single turn of heavy copper wire occupying the entire winding space. The total watts loss of the instrument would be about 0.05 watt. The addition of a shunt to give ambient temperature compensation equivalent to that of the moving-coil instrument would not increase this to more than 0.1 watt, or one-fifth the power required by the complete moving-coil instrument.

The general practice is to build voltmeters with a full-scale current of ten milliamperes except for particular applications where low current consumption is required. Using a full-scale current of ten milliamperes, a moving magnet voltmeter with jeweled bearings can be built in full-scale ranges from ten volts up with a torque-to-weight ratio adequate to insure a sustained accuracy of two per cent of full-scale reading. This is equivalent to that usually guaranteed for minature moving-coil instruments. It refers to the exact construction shown in the paper and by no means represents the ultimate sensitivity obtainable in moving magnet instruments. Since the over-all power consumed by both types of instruments is the same, the moving magnet design is at no disadvantage because of the greater power consumed by its element.

From the foregoing it is apparent that there is a wide range of instrument ratings in which no use can be made of the maximum sensitivity of the moving-coil instrument and in which the moving magnet instrument is at no disadvantage due to its lower sensitivity.

The authors felt that the implied advantages of the instrument would be apparent to those familiar with instruments. However, in view of Mr. Miller's comments, "Since the only advantage of the new mechanism is low cost," it may be well to bring some of these advantages into greater prominence.

The maximum change in reading of the moving magnet instrument in a ten-gauss field is one half of one per cent of full-scale reading. The corresponding change for a moving-coil instrument is of the order of three per cent. The stray field produced by the permanent magnet of a moving-coil instrument will cause a considerable error in the reading of another moving-coil instrument when mounted close to it and is sufficient to cause an appreciable error in a magnetic compass at a distance of several feet. Mounting on a steel panel will change its calibration because of the shunting effect of the panel on the instrument magnet. Effective shielding to overcome these deficiencies is difficult, because a shield close to the magnet will shunt a large part of its flux, and one far from it will increase the outside dimension of the instrument. In either case the calibration difficulties will be increased, as the instrument must be calibrated with the shield in place, and the shield interferes with the stabilizing a-c knockdown treatment which should be given to the instrument magnet. None of these difficulties are experienced with the moving magnet instrument. These instrument elements may be mounted as closely together as their physical dimensions permit. Since their dimensions are so much smaller than those of moving-coil instruments, it is possible to mount more of these instruments in a given space. This is a very valuable feature in many applications.

Another valuable feature of the moving-magnet construction is the readiness with which it may be adapted for measuring current ratios by substitution of another fixed coil for the control magnets. The instrument then becomes a ratio meter and the scale distribution may be predicted by the same vectorial construction shown in Figure 4.

Emergency Overloads for Oil-Insulated Transformers

Discussion and authors' closure of paper 42-101 by F. J. Vogel and T. K. Sloat, presented at the AIEE summer convention, Chicago, Ill., June 22–26, 1942, and published in AIEE TRANSACTIONS, 1942, September section, pages 669–73.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): This paper adds some further data on the aging of insulation and gives some proposals on how to use the data. I cannot agree with some of the claims set forth in the paper, for example, the statement that at 120 degrees centigrade the tensile strength drops to approximately 50 per cent and levels off. Further, it states that it would appear that this 50 per cent strength would be maintained for long periods of time. This is an important point, because, if true, it would permit long-time operation at 120 degrees centigrade without any further sacrifice in the life of a transformer. As a matter of fact, the data in Figure 5 on Fuller board aged in oil protected by nitrogen show a continued decrease in tensile strength.

I agree that the way in which the curves are plotted in Figure 1 might lead one to assume that the tensile strength had leveled off. All aging data that I have ever obtained fell on a straight line when plotted on semilogarithmic paper, with time on the logarithmic scale and temperature on the uniform scale and temperature on the uniform scale. In fact, all of the aging data shown in Mr. Clark's paper fall on a straight line indicating in some cases and actually showing in other cases that the tensile strength continues to deteriorate at the same semilogarithmic rate until zero life is reached. This is one nature's laws discovered many years ago by Sir Isaac Newton and known as the "die away curve."

I have taken the liberty of replotting the data shown in Figure 1 of the authors' paper on semilogarithmic paper. Figure 1 indicates that the tensile strength does not level off but apparently continues to deteriorate at the same rate. When replotted on semilogarithmic paper, and extrapolation of the data shown in their Figures 5 and 11 indicates the 135 degrees centigrade life is longer than the 120 degrees centigrade life. Furthermore, there appears to be no consistent rule in degrees increase to double the rate of aging as shown by these curves.

In a discussion of Figure 5 it is stated that the markedly lower strengths obtained with pressboard and varnished cambric, as compared to Manila paper alone, are due to higher acidity. However, these tests were made with oxygen-free oil, protected by a nitrogen atmosphere. These results are therefore inconsistent with the claim that the panacea is to provide an inert gas cushion above the oil.

The assumption that the hot-spot rise over top oil varies as the loss 0.8 can be used

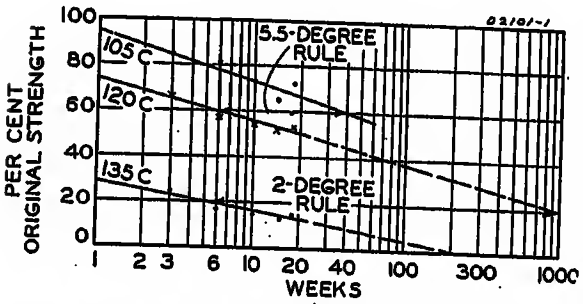

Figure 1. Tensile strength of Manila paper in oxygen-free oil protected by a nitrogen atmosphere from Figure 1 of paper by Vogel and Sloat

for all classes of transformers, particularly small distribution-type coils, does not agree with our findings. For instance, we have found that under the condition where the 0.8 power holds for horizontal coils, for vertical coils the exponential power ranges from approximately 0.9 to 1.0, depending on the thickness of the winding. For thick windings having high internal gradients and small surface drop, the power is close to unity as would be expected. In general, for thin single-layer vertical coils, the power is approximately 0.1 higher than for horizontal coils. This is, of course, due to the greater effect of the viscosity of the oil for horizontal than for vertical coils at the lower temperatures, whereas for the higher temperatures the difference in the effect of viscosity tends to disappear. This effect on the temperature rise of the horizontal and vertical coils is very well illustrated in Figures 3 and 4 of reference 1.

Jerome J. Taylor (Detroit Edison Company, Detroit, Mich.): The paper is very fine in showing effects of thermochemical factors on the mechanical strength of transformer insulation. This is a valuable but somewhat more specialized study than indicated by its title. From an operating standpoint, a correlation between mechanical strength and electrical failure still has to be made; this subject is barely touched. Destructive testing of small motor stators has been recently reported.[1] It appears that similar tests of (small) transformers are practical and that the results would add interpretative value to the more difficult studies already accomplished.

F. Von Voigtlander (The Commonwealth and Southern Corporation, Jackson, Mich.): The authors have shown that transformers of the usual design can probably be considerably overloaded without serious effect on their life, and there appears to be unanimity of opinion on this point throughout the industry. The writer would like to call attention to the fact that overloading transformers also proportionally increases the transformer regulation. Furthermore, much of the load growth which is requiring the overloading of transformers is industrial load, usually of lower power factor than the system average. This may result in a considerable increase in the system requirements of reactive power, which would also increase the regulation of the transformers. Superimposed on this is the increase of reactive losses in the transmission system caused by the increased line loadings at lower power factors. If sufficient reactive capacity is not available near the load centers, the system voltages may sag considerably, thereby further adding to the reactive power demands.

It therefore follows that, unless the system is unusually well supplied with reactive capacitance, considerable attention should be paid to this matter of adequate voltage, as otherwise it is possible that the overload ability of transformers cannot be fully realized because of distribution voltage limitations, and no substitute for volts at the customer's service has yet been found.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The results shown in Figure 1 of the paper are very surprising in that they indicate practically no deterioration in the aging tests between 6 and 18 weeks. According to these data,

Table I

Test Temperature Degrees Centigrade	Mechanical Strength After 100 Days—Per Cent of Original Value: Chicago Tests Average	Chicago Tests Minimum	Tests by Vogel and Sloat Figure 3
100	99	91	78
125	67	54	32

insulation kept indefinitely at 105 degrees centigrade would remain at 70 per cent of its original strength, and 120 degrees could not produce more than 50 per cent deterioration at any time. In the oven-aging tests in Chicago on sealed oxygen-free samples of various makes of impregnated-paper insulated cables, which were described in my paper on "Load Rating of Cable—II,"[1] a sharp decrease in tearing strength occurred in tests at 125 degrees centigrade between two and five months. This decrease was found for each of the several samples tested. The studies made years ago at the Massachusetts Institute of Technology, on the effect of heat on paper insulation, corroborate the continuously decreasing trend of mechanical strength with time of aging, found in the recent Chicago tests. Possibly, tests on a large number of samples for durations beyond 18 weeks would modify the slope of the curves in Figure 1 of the paper.

Also, the slopes of the curves in Figure 3 of the paper, which are obtained by cross-plotting from Figure 1, are subject to question. The 20, 40, and 50 per cent curves are based on only one measured point, and the 60, 65, and 70 per cent curves are based on two points. The uncertainty of the slope of the curves is illustrated by the fact that, according to Figure 1, the strength remains at 54 per cent in the 120-degree test between 8 and 18 weeks while, according to Figure 3, the strength decreases at 120 degrees from 54 per cent after eight weeks to 49 per cent after 14 weeks.

Table I of this discussion is a comparison of the results obtained in the oven-aging tests in Chicago, Figure 1 of my paper on "Load Rating of Cable—II," with values taken from Figure 3 of the paper by Vogel and Sloat.

Do the authors have an explanation for these large discrepancies?

F. M. Clark (General Electric Company, Pittsfield, Mass.): My interest in this paper concerns primarily the following statement which is made in the general summary:

"Acids are formed in service by contact between oxygen and transformer oil. Excluding this contact by blanketing the transformer with inert gas results in a high mechanical strength of the insulation at a given temperature and time or conversely permits a higher operating temperature."

On the basis of the data submitted in the paper this statement can be true only within definite limits. It cannot be true at 135 degrees centigrade, for, if one compares the data for Manila paper of Figure 1 and Figure 11, one finds no real advantage from the use of the nitrogen gas. I have reproduced in Figure 2 of this discussion the

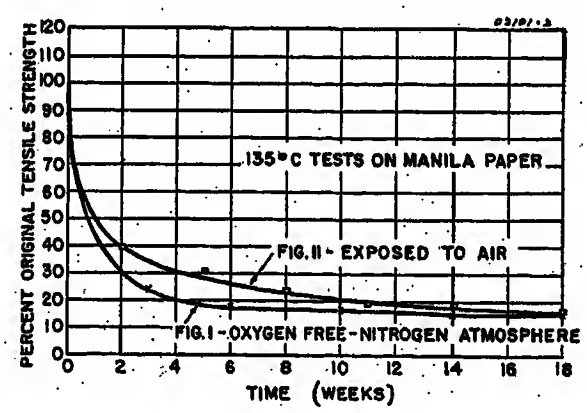

Figure 2

pertinent data presented by the authors. A relation such as this indicates that at 135 degrees centigrade heat alone causes paper deterioration at a rate which is not dependent on the oxidation effects referred to by the authors.

Although the authors do not illustrate the behavior of oil-treated Fuller board aged in the presence of oxygen the remarkable stability of the Fuller board in the absence of oxygen (Figure 9 of the paper) might possibly be taken as support for the author's contention that oxidized oil is responsible for the mechanical deterioration of the cellulose. The Fuller board of Figure 9 is characterized by substantially no de-

crease in mechanical strength during a period of 18 weeks at 120 degrees centigrade. This apparent mechanical stability is contrary to the data accumulated in our own laboratory and does not agree with the authors' data of Figure 1 for Manila paper, where a loss of 50 per cent in tensile strength is shown for the same oxygen-free test conditions. Neither do the data agree with the previously published work of C. F. Hill to which the authors refer. Mr. Hill states that cellulose is "subject to both temperature and oxidation effects, the temperature effect of course taking place above 105 degrees centigrade."

In Figure 3 of this discussion I have compared the data on Fuller board presented by Mr. Hill with that presented by the authors, converting Mr. Hill's data to percentage of original tensile strength in order to make the comparison clear. Although both investigators are in fair agreement at 135–140 degrees centigrade aging, there is a marked divergence in the data presented for the temperature range from 105–120 degrees centigrade. In our own laboratory we obtain, as does Mr. Hill, a decrease in strength as the aging progresses, but, unlike Mr. Hill, we find no stabilization in mechanical strength after about 50 per cent of the initial strength has been lost. The mechanical deterioration in the studies which we have

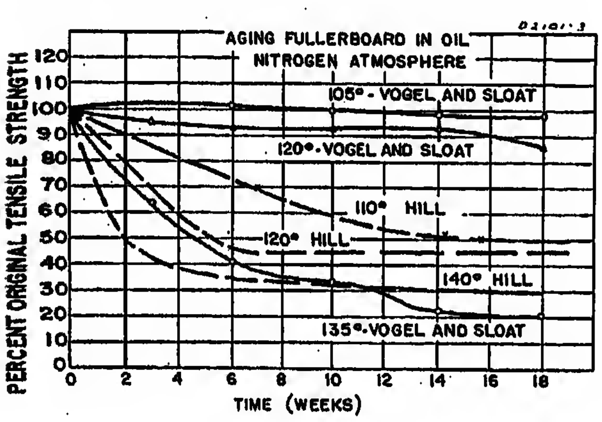

Figure 3

carried out proceeds continuously in a semilogarithmic relation to the time factor of heating.

Our own explanation of the fundamental cause of mechanical deterioration in cellulose differs greatly from that offered by the authors who attribute it to acid formation in the oil. I am not especially concerned with the data presented which test the combined effect of Fuller board and varnished cloth. Obviously acids derived from sources foreign to the cellulose or the oil may or may not affect the mechanical strength of the cellulose, depending upon their chemical natures Their presence, as described by the author. in Figure 6, is not dependent on the presence of oxygen. No data are presented by the authors correlating the behavior of such combinations of materials with the thesis advanced. Furthermore, the effect of acids derived from varnished films appears to be of but academic interest, for, as the authors state, acid formation from this source has been practically eliminated by the use of synthetic materials. I am, however, concerned with the suggestion that acid formation in the oil through oxidation is responsible for the mechanical deterioration. I call attention to the fact that the 50 per cent deterioration in the mechanical strength of Manila paper in Figure 1 was obtained with substantially no change in the oil acidity.

Elimination of acid formation as the result of oxidation in mineral oil can be brought about by a variety of methods. Only one of these methods, the elimination of oxygen, produces any substantial effect on the mechanical aging of cellulose. I suggest that the presence of oxygen affects the mechanical life of oil-immersed cellulose because of its direct oxidation action on the cellulose. As such, as suggested by Mr. Hill the effect of oxygen is most important for the lower temperatures applied. As the temperature is raised, the mechanical deterioration because of heat alone becomes of increasing importance. This type of deterioration involves the formation of acids derived from the cellulose and occurs whether or not oxygen is present. The use of nitrogen to eliminate oil acidity is not of fundamental importance. Although the elimination of oxygen may be of academic value in promoting the mechanical stability of cellulose insulation if a transformer is operated at temperatures of 75–95 degrees centigrade, it must be remembered that the oxidation reaction itself proceeds so slowly at these temperatures that it is demonstrated only with great difficulty. Higher temperatures of operation in the range of 100–120 degrees centigrade, or higher in the case of overload conditions, bring into play the thermal type of cellulose deterioration. This type of deterioration becomes of greater importance as the temperature and the duration of its application are increased. In a general sense, we have found that the insulation will age at a rate not materially affected by the presence or absence of mineral oil. Acids derived from mineral transformer oil of the American type have not been found to be a dominating factor in determining the mechanical life of the insulation.

T. K. Sloat and F. J. Vogel: We desire to acknowledge Mr. Von Voigtlander's discussion, and it is true that regulation must be considered in any application.

With reference to Mr. Taylor's discussion, tests on small transformers have been made and indicate that they are still operative, even after thousands of overloads and high temperature cycles. The results of these tests and others will undoubtedly furnish the material for papers which will be presented at a later time.

We are rather surprised at the small amount of deterioration shown in Mr. Halperin's discussion. Neither Mr. Clark's nor our tests indicate such high values after 100 days at 100 or 125 degrees centigrade. Mr. Halperin has criticized the construction of Figure 3. For purposes of analysis, data in the form of Figure 3 were more valuable than Figure 1, which was the original data. When curves are drawn with different parameters, unless the data are extremely accurate, some variations are to be expected. In this particular case, the very nature of the materials led to variations which could not be eliminated except by an extremely large number of tests and samples.
